  > For development environments where the server configuration handles secure redirection instead of HTTPS Redirection Middleware, we recommend using temporary redirects (302) rather than permanent redirects (301). Link caching can cause unstable behavior in development environments.

- Adding a `Strict-Transport-Security` (HSTS) header ensures all subsequent requests made by the client are over HTTPS. For guidance on setting the `Strict-Transport-Security` header, see Enforce HTTPS in ASP.NET Core.
- If HTTPS will be disabled in the future, use one of the following approaches:
  - Don't add the HSTS header.
  - Choose a short `max-age` value.

Add the */etc/nginx/proxy.conf* configuration file:

nginx

```
proxy_redirect          off;
proxy_set_header        Host $host;
proxy_set_header        X-Real-IP $remote_addr;
proxy_set_header        X-Forwarded-For $proxy_add_x_forwarded_for;
```

```
proxy_set_header        X-Forwarded-Proto $scheme;
client_max_body_size    10m;
client_body_buffer_size 128k;
proxy_connect_timeout   90;
proxy_send_timeout      90;
proxy_read_timeout      90;
proxy_buffers           32 4k;
```

Ubuntu

Replace the contents of the */etc/nginx/nginx.conf* configuration file with the following file. The example contains both `http` and `server` sections in one configuration file.

nginx

```
http {
    include        /etc/nginx/proxy.conf;
    limit_req_zone $binary_remote_addr zone=one:10m rate=5r/s;
    server_tokens  off;

    sendfile on;
    # Adjust keepalive_timeout to the lowest possible value that makes sense
    # for your use case.
    keepalive_timeout   29;
    client_body_timeout 10; client_header_timeout 10; send_timeout 10;

    upstream helloapp{
        server 127.0.0.1:5000;
    }

    server {
        listen                  443 ssl http2;
        listen                  [::]:443 ssl http2;
        server_name             example.com *.example.com;
        ssl_certificate         /etc/ssl/certs/testCert.crt;
        ssl_certificate_key     /etc/ssl/certs/testCert.key;
        ssl_session_timeout     1d;
        ssl_protocols           TLSv1.2 TLSv1.3;
        ssl_prefer_server_ciphers off;
        ssl_ciphers             ECDHE-ECDSA-AES128-GCM-SHA256:ECDHE-RSA-
AES128-GCM-SHA256:ECDHE-ECDSA-AES256-GCM-SHA384:ECDHE-RSA-AES256-GCM-
SHA384:ECDHE-ECDSA-CHACHA20-POLY1305:ECDHE-RSA-CHACHA20-POLY1305:DHE-RSA-
AES128-GCM-SHA256:DHE-RSA-AES256-GCM-SHA384;
        ssl_session_cache       shared:SSL:10m;
        ssl_session_tickets     off;
        ssl_stapling            off;

        add_header X-Frame-Options DENY;
        add_header X-Content-Type-Options nosniff;
```

```
        #Redirects all traffic
        location / {
            proxy_pass http://helloapp;
            limit_req  zone=one burst=10 nodelay;
        }
    }
}
```

> **Note**
>
> Blazor WebAssembly apps require a larger `burst` parameter value to accommodate the larger number of requests made by an app. For more information, see Host and deploy ASP.NET Core Blazor WebAssembly.

> **Note**
>
> The preceding example disables Online Certificate Status Protocol (OCSP) Stapling. If enabled, confirm that the certificate supports the feature. For more information and guidance on enabling OCSP, see the following properties in the Module ngx_http_ssl_module (Nginx documentation) article:
>
> - `ssl_stapling`
> - `ssl_stapling_file`
> - `ssl_stapling_responder`
> - `ssl_stapling_verify`

Secure Nginx from clickjacking

Clickjacking, also known as a *UI redress attack*, is a malicious attack where a website visitor is tricked into clicking a link or button on a different page than they're currently visiting. Use `X-FRAME-OPTIONS` to secure the site.

To mitigate clickjacking attacks:

1. Edit the *nginx.conf* file:

```
Bash

sudo nano /etc/nginx/nginx.conf
```

Within the `http{}` code block, add the line: `add_header X-Frame-Options "SAMEORIGIN";`

2. Save the file.

3. Restart Nginx.

MIME-type sniffing

This header prevents most browsers from MIME-sniffing a response away from the declared content type, as the header instructs the browser not to override the response content type. With the `nosniff` option, if the server says the content is `text/html`, the browser renders it as `text/html`.

1. Edit the *nginx.conf* file:

```
Bash

sudo nano /etc/nginx/nginx.conf
```

Within the `http{}` code block, add the line: `add_header X-Content-Type-Options "nosniff";`

2. Save the file.

3. Restart Nginx.

Additional Nginx suggestions

After upgrading the shared framework on the server, restart the ASP.NET Core apps hosted by the server.

>
> For the current release, see the **.NET 8 version of this article**.

The following articles are available for learning about hosting ASP.NET Core apps in Docker:

Introduction to Containers and Docker

See how containerization is an approach to software development in which an application or service, its dependencies, and its configuration are packaged together as a container image. The image can be tested and then deployed to a host.

What is Docker

Discover how Docker is an open-source project for automating the deployment of apps as portable, self-sufficient containers that can run on the cloud or on-premises.

Docker Terminology

Learn terms and definitions for Docker technology.

Docker containers, images, and registries

Find out how Docker container images are stored in an image registry for consistent deployment across environments.

Run an ASP.NET Core app in Docker containers Learn how to build and dockerize an ASP.NET Core app. Explore Docker images maintained by Microsoft and examine use cases.

.NET Docker samples Samples and guidance that demonstrate how to use .NET and Docker for development, testing and production.

Visual Studio Container Tools

Discover how Visual Studio supports building, debugging, and running ASP.NET Core apps targeting either .NET Framework or .NET Core on Docker for Windows. Both Windows and Linux containers are supported.

Publish to Azure Container Registry
Find out how to use the Visual Studio Container Tools extension to deploy an ASP.NET Core app to a Docker host on Azure using PowerShell.

Configure ASP.NET Core to work with proxy servers and load balancers
Additional configuration might be required for apps hosted behind proxy servers and load balancers. Passing requests through a proxy often obscures information about the original request, such as the scheme and client IP. It might be necessary to forward some information about the request manually to the app.

GC using Docker and small containers Discusses GC selection with small containers.

System.IO.IOException: The configured user limit (128) on the number of inotify instances has been reached

Disabling `reloadOnChange` can significantly reduce the number of opened files. To disable reloading configuration files, set the environment variable `DOTNET_HOSTBUILDER__RELOADCONFIGONCHANGE=false`

For alternative approaches or to leave feedback on this problem, see this GitHub issue.

Run an ASP.NET Core app in Docker containers

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article shows how to run an ASP.NET Core app in Docker containers.

Windows Home Edition doesn't support Hyper-V, and Hyper-V is needed for Docker.

See Containerize a .NET app with dotnet publish for information on containerized a .NET app with `dotnet publish`.

ASP.NET Core Docker images

For this tutorial, you download an ASP.NET Core sample app and run it in Docker containers. The sample works with both Linux and Windows containers.

The sample Dockerfile uses the Docker multi-stage build feature to build and run in different containers. The build and run containers are created from images that are provided in Docker Hub by Microsoft:

- `dotnet/sdk`

  The sample uses this image for building the app. The image contains the .NET SDK, which includes the Command Line Tools (CLI). The image is optimized for local development, debugging, and unit testing. The tools installed for development and compilation make the image relatively large.

- `dotnet/aspnet`

  The sample uses this image for running the app. The image contains the ASP.NET Core runtime and libraries and is optimized for running apps in production. Designed for speed of deployment and app startup, the image is relatively small, so network performance from Docker Registry to Docker host is optimized. Only

the binaries and content needed to run an app are copied to the container. The contents are ready to run, enabling the fastest time from `docker run` to app startup. Dynamic code compilation isn't needed in the Docker model.

Prerequisites

- .NET SDK 8.0
- Docker client 18.03 or later
  - Linux distributions
    - Debian
    - Fedora
    - Ubuntu
  - macOS
  - Windows
- Git

Download the sample app

- Download the sample by cloning the .NET Docker repository:

```
Console
git clone https://github.com/dotnet/dotnet-docker
```

Run the app locally

- Navigate to the project folder at *dotnet-docker/samples/aspnetapp/aspnetapp*.
- Run the following command to build and run the app locally:

```
.NET CLI
dotnet run
```

- Go to `http://localhost:<port>` in a browser to test the app.
- Press Ctrl+C at the command prompt to stop the app.

Run in a Linux container or Windows container

- To run in a Linux container, right-click the System Tray's Docker client icon and select switch to Linux containers.
- To run in a Windows container, right-click the System Tray's Docker client icon and select switch to Windows containers.
- Navigate to the Dockerfile folder at *dotnet-docker/samples/aspnetapp*.
- Run the following commands to build and run the sample in Docker:

  Console

  ```
  docker build -t aspnetapp .
  docker run -it --rm -p <port>:8080 --name aspnetcore_sample aspnetapp
  ```

  The `build` command arguments:
  - Name the image aspnetapp.
  - Look for the Dockerfile in the current folder (the period at the end).

  The run command arguments:
  - Allocate a pseudo-TTY and keep it open even if not attached. (Same effect as `--interactive --tty`.)
  - Automatically remove the container when it exits.
  - Map `<port>` on the local machine to port 8080 in the container.
  - Name the container aspnetcore_sample.
  - Specify the aspnetapp image.
- Go to `http://localhost:<port>` in a browser to test the app.

Build and deploy manually

In some scenarios, you might want to deploy an app to a container by copying its assets that are needed at run time. This section shows how to deploy manually.

- Navigate to the project folder at *dotnet-docker/samples/aspnetapp/aspnetapp*.
- Run the dotnet publish command:

  .NET CLI

  ```
  dotnet publish -c Release -o published
  ```

  The command arguments:

    - Build the app in release mode (the default is debug mode).
    - Create the assets in the *published* folder.

- Run the app.

    - Windows:

```
.NET CLI

dotnet published\aspnetapp.dll
```

    - Linux:

```
.NET CLI

dotnet published/aspnetapp.dll
```

- Browse to `http://localhost:<port>` to see the home page.

To use the manually published app within a Docker container, create a new *Dockerfile* and use the `docker build .` command to build an image.

```
Dockerfile

FROM mcr.microsoft.com/dotnet/aspnet:8.0 AS runtime
WORKDIR /app
COPY published/ ./
ENTRYPOINT ["dotnet", "aspnetapp.dll"]
```

To see the new image use the `docker images` command.

The Dockerfile

Here's the *Dockerfile* used by the `docker build` command you ran earlier. It uses `dotnet publish` the same way you did in this section to build and deploy.

```
Dockerfile

# https://hub.docker.com/_/microsoft-dotnet
FROM mcr.microsoft.com/dotnet/sdk:8.0 AS build
WORKDIR /source

# copy csproj and restore as distinct layers
COPY *.sln .
COPY aspnetapp/*.csproj ./aspnetapp/
RUN dotnet restore
```

```
# copy everything else and build app
COPY aspnetapp/. ./aspnetapp/
WORKDIR /source/aspnetapp
RUN dotnet publish -c release -o /app --no-restore

# final stage/image
FROM mcr.microsoft.com/dotnet/aspnet:8.0
WORKDIR /app
COPY --from=build /app ./
ENTRYPOINT ["dotnet", "aspnetapp.dll"]
```

In the preceding *Dockerfile*, the `*.csproj` files are copied and restored as distinct *layers*. When the `docker build` command builds an image, it uses a built-in cache. If the `*.csproj` files haven't changed since the `docker build` command last ran, the `dotnet restore` command doesn't need to run again. Instead, the built-in cache for the corresponding `dotnet restore` layer is reused. For more information, see Best practices for writing Dockerfiles.

Additional resources

Developing ASP.NET Core Applications with Docker over HTTPS

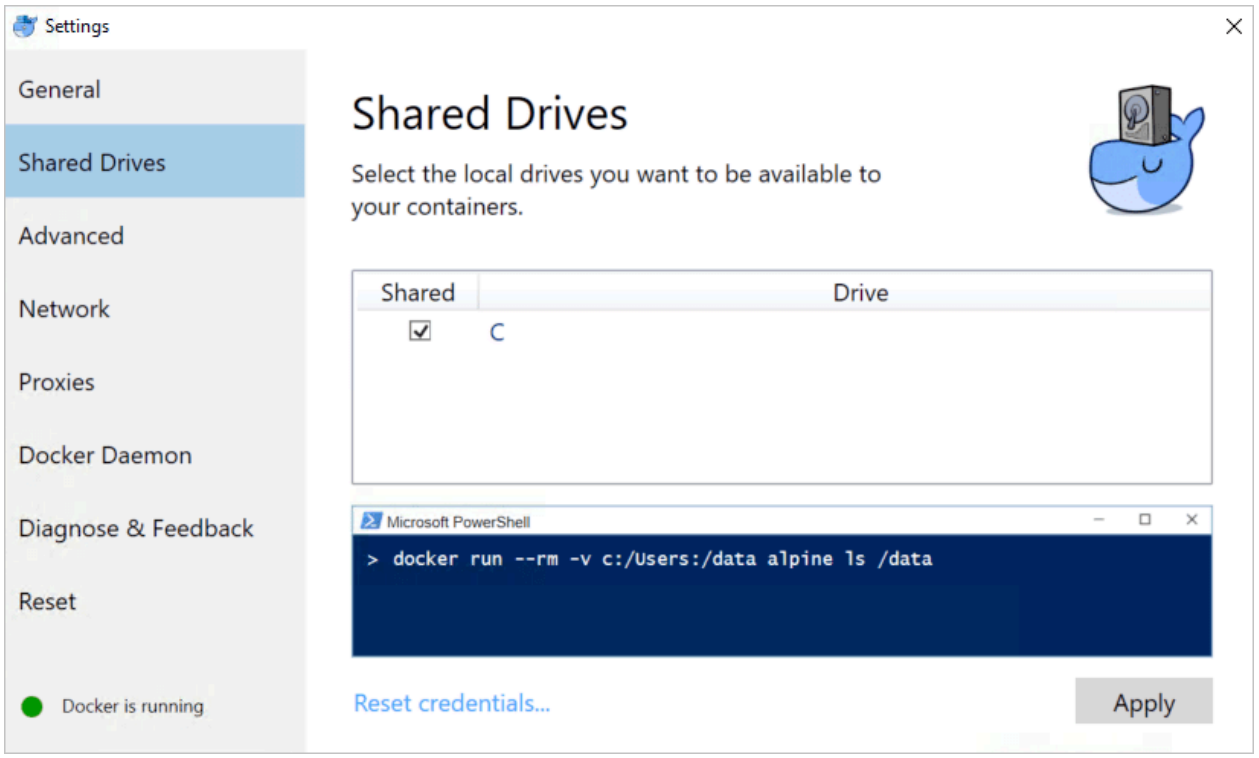
Visual Studio Container Tools with ASP.NET Core

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Visual Studio 2017 and later versions support building, debugging, and running containerized ASP.NET Core apps targeting .NET Core. Both Windows and Linux containers are supported.

View or download sample code (how to download)



Prerequisites

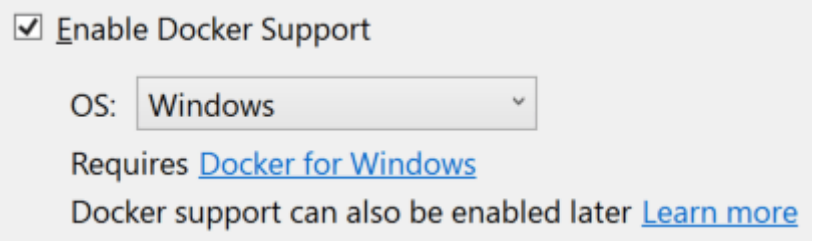
- Docker for Windows
- Visual Studio 2019 with the **.NET Core cross-platform development** workload

Installation and setup

For Docker installation, first review the information at Docker for Windows: What to know before you install. Next, install Docker For Windows.

Shared Drives in Docker for Windows must be configured to support volume mapping and debugging. Right-click the System Tray's Docker icon, select **Settings**, and select **Shared Drives**. Select the drive where Docker stores files. Click **Apply**.

> **Tip**
>
> Visual Studio 2017 versions 15.6 and later prompt when **Shared Drives** aren't configured.



Add a project to a Docker container

To containerize an ASP.NET Core project, the project must target .NET Core. Both Linux and Windows containers are supported.

When adding Docker support to a project, choose either a Windows or a Linux container. The Docker host must be running the same container type. To change the container type in the running Docker instance, right-click the System Tray's Docker icon and choose **Switch to Windows containers...** or **Switch to Linux containers...**.

New app

When creating a new app with the **ASP.NET Core Web Application** project templates, select the **Enable Docker Support** checkbox:

If the target framework is .NET Core, the **OS** drop-down allows for the selection of a container type.

Existing app

For ASP.NET Core projects targeting .NET Core, there are two options for adding Docker support via the tooling. Open the project in Visual Studio, and choose one of the following options:

- Select **Docker Support** from the **Project** menu.
- Right-click the project in **Solution Explorer** and select **Add** > **Docker Support**.

The Visual Studio Container Tools don't support adding Docker to an existing ASP.NET Core project targeting .NET Framework.

Dockerfile overview

A *Dockerfile*, the recipe for creating a final Docker image, is added to the project root. Refer to Dockerfile reference for an understanding of the commands within it. This particular *Dockerfile* uses a multi-stage build with four distinct, named build stages:

Dockerfile

```
FROM mcr.microsoft.com/dotnet/core/aspnet:2.1 AS base
WORKDIR /app
EXPOSE 59518
EXPOSE 44364

FROM mcr.microsoft.com/dotnet/core/sdk:2.1 AS build
WORKDIR /src
COPY HelloDockerTools/HelloDockerTools.csproj HelloDockerTools/
RUN dotnet restore HelloDockerTools/HelloDockerTools.csproj
COPY . .
WORKDIR /src/HelloDockerTools
RUN dotnet build HelloDockerTools.csproj -c Release -o /app

FROM build AS publish
RUN dotnet publish HelloDockerTools.csproj -c Release -o /app

FROM base AS final
```

```
WORKDIR /app
COPY --from=publish /app .
ENTRYPOINT ["dotnet", "HelloDockerTools.dll"]
```

The preceding *Dockerfile* image includes the ASP.NET Core runtime and NuGet packages. The packages are just-in-time (JIT) compiled to improve startup performance.

When the new project dialog's **Configure for HTTPS** checkbox is checked, the *Dockerfile* exposes two ports. One port is used for HTTP traffic; the other port is used for HTTPS. If the checkbox isn't checked, a single port (80) is exposed for HTTP traffic.

Add container orchestrator support to an app

Visual Studio 2017 versions 15.7 or earlier support Docker Compose as the sole container orchestration solution. The Docker Compose artifacts are added via **Add** > **Docker Support**.

Visual Studio 2017 versions 15.8 or later add an orchestration solution only when instructed. Right-click the project in **Solution Explorer** and select **Add** > **Container Orchestrator Support**. The following choices are available:

- Docker Compose
- Service Fabric
- Kubernetes/Helm

Docker Compose

The Visual Studio Container Tools add a *docker-compose* project to the solution with the following files:

- *docker-compose.dcproj*: The file representing the project. Includes a `<DockerTargetOS>` element specifying the OS to be used.
- *.dockerignore*: Lists the file and directory patterns to exclude when generating a build context.
- *docker-compose.yml*: The base Docker Compose file used to define the collection of images built and run with `docker-compose build` and `docker-compose run`, respectively.
- *docker-compose.override.yml*: An optional file, read by Docker Compose, with configuration overrides for services. Visual Studio executes `docker-compose -f "docker-compose.yml" -f "docker-compose.override.yml"` to merge these files.

The *docker-compose.yml* file references the name of the image that's created when the project runs:

```yaml
version: '3.4'

services:
  hellodockertools:
    image: ${DOCKER_REGISTRY}hellodockertools
    build:
      context: .
      dockerfile: HelloDockerTools/Dockerfile
```

In the preceding example, `image: hellodockertools` generates the image `hellodockertools:dev` when the app runs in **Debug** mode. The `hellodockertools:latest` image is generated when the app runs in **Release** mode.

Prefix the image name with the Docker Hub username (for example, `dockerhubusername/hellodockertools`) if the image is pushed to the registry. Alternatively, change the image name to include the private registry URL (for example, `privateregistry.domain.com/hellodockertools`) depending on the configuration.

If you want different behavior based on the build configuration (for example, Debug or Release), add configuration-specific *docker-compose* files. The files should be named according to the build configuration (for example, *docker-compose.vs.debug.yml* and *docker-compose.vs.release.yml*) and placed in the same location as the *docker-compose-override.yml* file.

Using the configuration-specific override files, you can specify different configuration settings (such as environment variables or entry points) for Debug and Release build configurations.

For Docker Compose to display an option to run in Visual Studio, the docker project must be the startup project.

Service Fabric

In addition to the base Prerequisites, the Service Fabric orchestration solution demands the following prerequisites:

- Microsoft Azure Service Fabric SDK version 2.6 or later
- Visual Studio's **Azure Development** workload

Service Fabric doesn't support running Linux containers in the local development cluster on Windows. If the project is already using a Linux container, Visual Studio prompts to switch to Windows containers.

The Visual Studio Container Tools do the following tasks:

- Adds a *<project_name>Application* **Service Fabric Application** project to the solution.
- Adds a *Dockerfile* and a *.dockerignore* file to the ASP.NET Core project. If a *Dockerfile* already exists in the ASP.NET Core project, it's renamed to *Dockerfile.original*. A new *Dockerfile*, similar to the following, is created:

  Dockerfile

  ```
  # See https://aka.ms/containerimagehelp for information on how to use
  Windows Server 1709 containers with Service Fabric.
  # FROM microsoft/aspnetcore:2.0-nanoserver-1709
  FROM microsoft/aspnetcore:2.0-nanoserver-sac2016
  ARG source
  WORKDIR /app
  COPY ${source:-obj/Docker/publish} .
  ENTRYPOINT ["dotnet", "HelloDockerTools.dll"]
  ```

- Adds an `<IsServiceFabricServiceProject>` element to the ASP.NET Core project's `.csproj` file:

  XML

  ```
  <IsServiceFabricServiceProject>True</IsServiceFabricServiceProject>
  ```

- Adds a *PackageRoot* folder to the ASP.NET Core project. The folder includes the service manifest and settings for the new service.

For more information, see Deploy a .NET app in a Windows container to Azure Service Fabric.

Debug

Select **Docker** from the debug drop-down in the toolbar, and start debugging the app. The **Docker** view of the **Output** window shows the following actions taking place:

- The *2.1-aspnetcore-runtime* tag of the *microsoft/dotnet* runtime image is acquired (if not already in the cache). The image installs the ASP.NET Core and .NET Core

runtimes and associated libraries. It's optimized for running ASP.NET Core apps in production.
- The `ASPNETCORE_ENVIRONMENT` environment variable is set to `Development` within the container.
- Two dynamically assigned ports are exposed: one for HTTP and one for HTTPS. The port assigned to localhost can be queried with the `docker ps` command.
- The app is copied to the container.
- The default browser is launched with the debugger attached to the container using the dynamically assigned port.

The resulting Docker image of the app is tagged as *dev*. The image is based on the *2.1-aspnetcore-runtime* tag of the *microsoft/dotnet* base image. Run the `docker images` command in the **Package Manager Console** (PMC) window. The images on the machine are displayed:

Console

```
REPOSITORY        TAG                   IMAGE ID      CREATED         SIZE
hellodockertools  dev                   d72ce0f1dfe7  30 seconds ago
255MB
microsoft/dotnet  2.1-aspnetcore-runtime  fcc3887985bb  6 days ago
255MB
```

> **Note**
>
> The *dev* image lacks the app contents, as **Debug** configurations use volume mounting to provide the iterative experience. To push an image, use the **Release** configuration.

Run the `docker ps` command in PMC. Notice the app is running using the container:

Console

```
CONTAINER ID        IMAGE                  COMMAND                  CREATED
STATUS              PORTS                   NAMES
baf9a678c88d        hellodockertools:dev   "C:\\remote_debugge..."   21
seconds ago      Up 19 seconds       0.0.0.0:37630->80/tcp
dockercompose4642749010770307127_hellodockertools_1
```

Edit and continue

Changes to static files and Razor views are automatically updated without the need for a compilation step. Make the change, save, and refresh the browser to view the update.

Code file modifications require compilation and a restart of Kestrel within the container. After making the change, use `CTRL+F5` to perform the process and start the app within the container. The Docker container isn't rebuilt or stopped. Run the `docker ps` command in PMC. Notice the original container is still running as of 10 minutes ago:

Console

```
CONTAINER ID        IMAGE                  COMMAND                  CREATED
STATUS              PORTS                   NAMES
baf9a678c88d        hellodockertools:dev   "C:\\remote_debugge..."   10
minutes ago      Up 10 minutes       0.0.0.0:37630->80/tcp
dockercompose4642749010770307127_hellodockertools_1
```

Publish Docker images

Once the develop and debug cycle of the app is completed, the Visual Studio Container Tools assist in creating the production image of the app. Change the configuration drop-down to **Release** and build the app. The tooling acquires the compile/publish image from Docker Hub (if not already in the cache). An image is produced with the *latest* tag, which can be pushed to the private registry or Docker Hub.

Run the `docker images` command in PMC to see the list of images. Output similar to the following is displayed:

Console

```
REPOSITORY        TAG                    IMAGE ID      CREATED
SIZE
hellodockertools  latest                 e3984a64230c  About a minute ago
258MB
hellodockertools  dev                    d72ce0f1dfe7  4 minutes ago
255MB
microsoft/dotnet  2.1-sdk                9e243db15f91  6 days ago
1.7GB
microsoft/dotnet  2.1-aspnetcore-runtime  fcc3887985bb  6 days ago
255MB
```

> ⓘ **Note**
>
> The `docker images` command returns intermediary images with repository names and tags identified as <*none*> (not listed above). These unnamed images are

produced by the multi-stage build *Dockerfile*. They improve the efficiency of building the final image—only the necessary layers are rebuilt when changes occur. When the intermediary images are no longer needed, delete them using the docker rmi command.

There may be an expectation for the production or release image to be smaller in size by comparison to the *dev* image. Because of the volume mapping, the debugger and app were running from the local machine and not within the container. The *latest* image has packaged the necessary app code to run the app on a host machine. Therefore, the delta is the size of the app code.

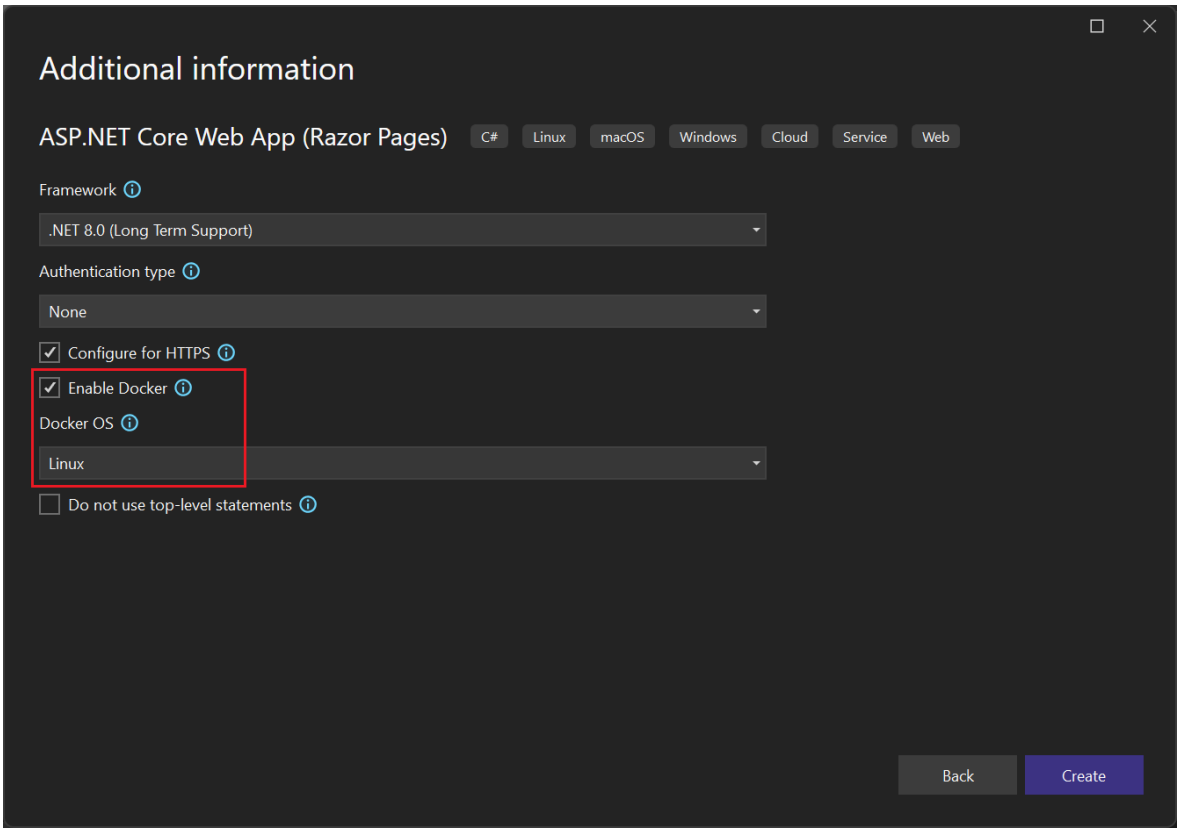
Deploy an ASP.NET container to a container registry using Visual Studio

Article • 08/22/2024

Docker is a lightweight container engine, similar in some ways to a virtual machine, which you can use to host applications and services. This tutorial walks you through using Visual Studio to publish your containerized application to an Azure Container Registry.

If you don't have an Azure subscription, create a free account before you begin.



Prerequisites

- Install the latest version of Visual Studio 2022 with the "ASP.NET and web development" workload.
- Install Docker Desktop for Windows.

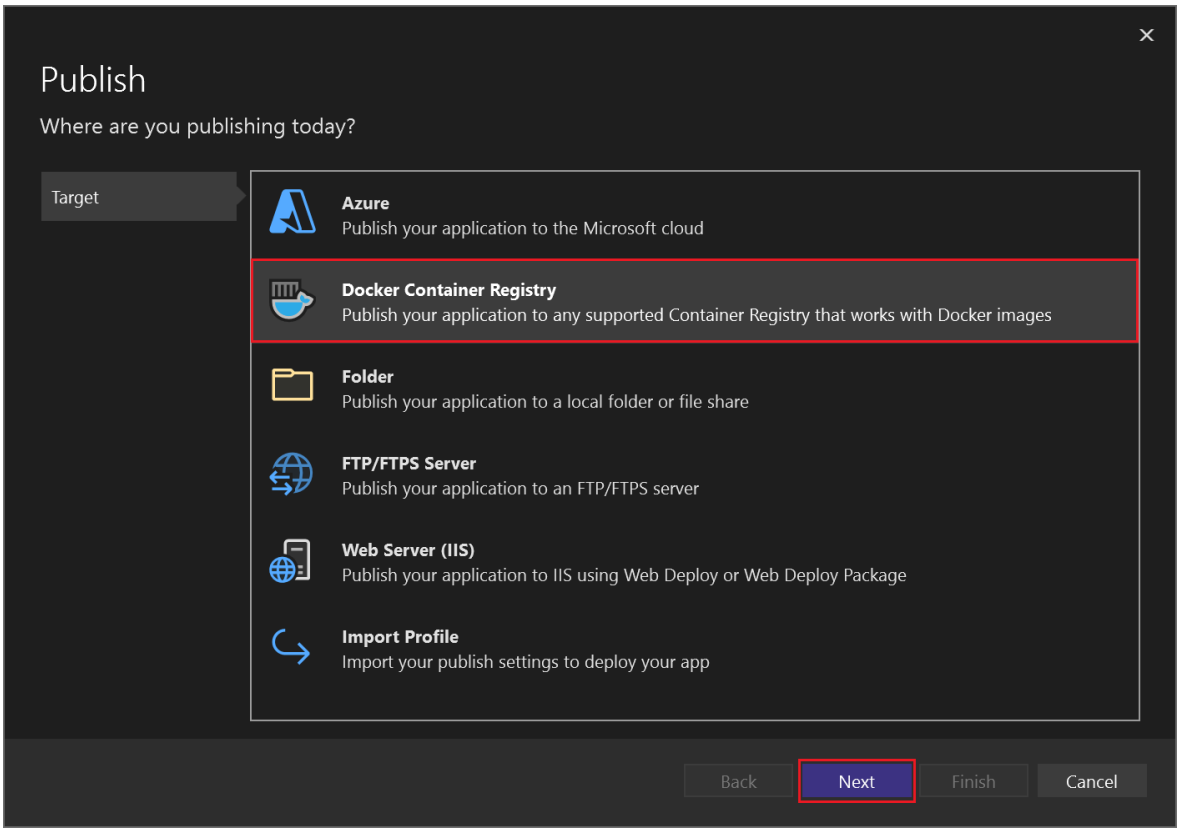
Create an ASP.NET Core web app

The following steps guide you through creating a basic ASP.NET Core app that you use in this tutorial. If you already have a project, you can skip this section.

1. In the Visual Studio start window, select **Create a new project**.
2. Select **ASP.NET Core Web App**, and then select **Next**.
3. Enter a name for your new application (or use the default name), specify the location on disk, and then select **Next**.
4. Select the .NET version you want to target. If you're not sure, choose the LTS (long-term support) release.

5. Choose whether you want SSL support by selecting or clearing the **Configure for HTTPS** checkbox.

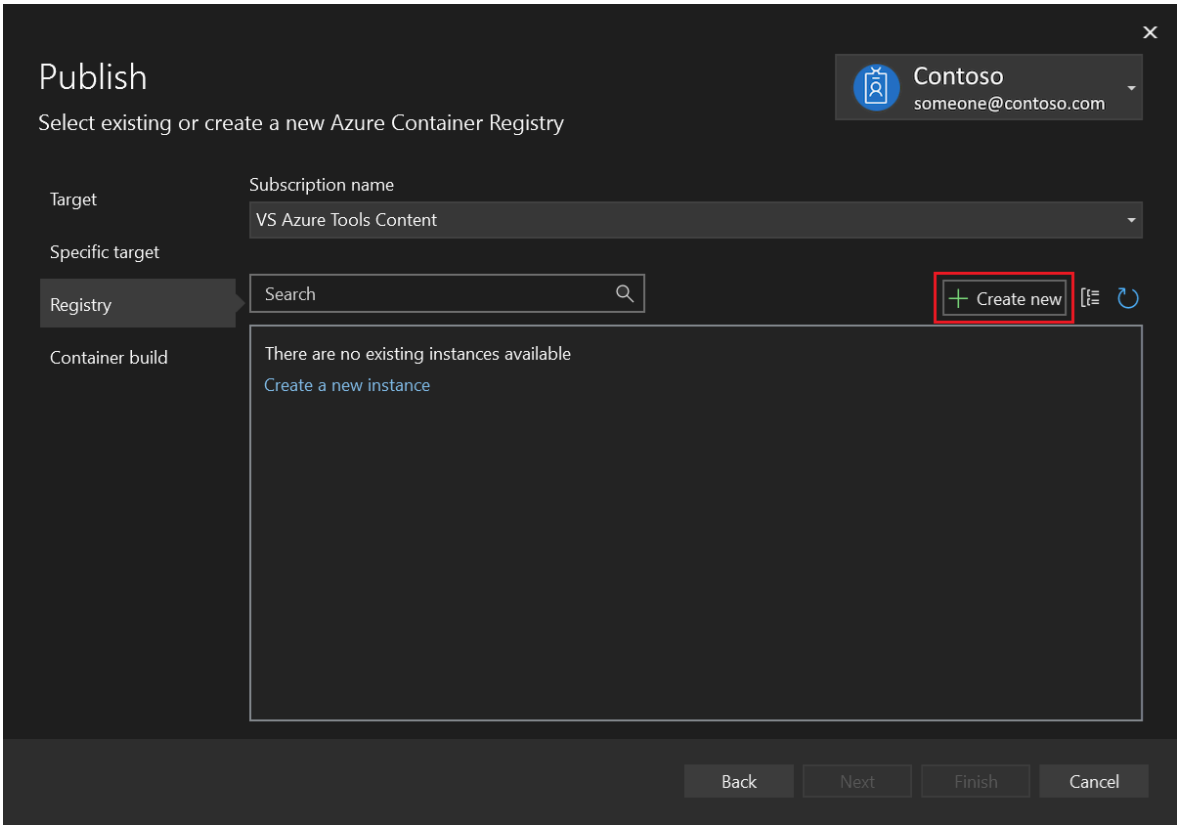
6. Select the **Enable Docker** checkbox.



7. Use the **Docker OS** dropdown list to select the type of container you want: **Windows** or **Linux**.

8. Select **Create** to complete the process.

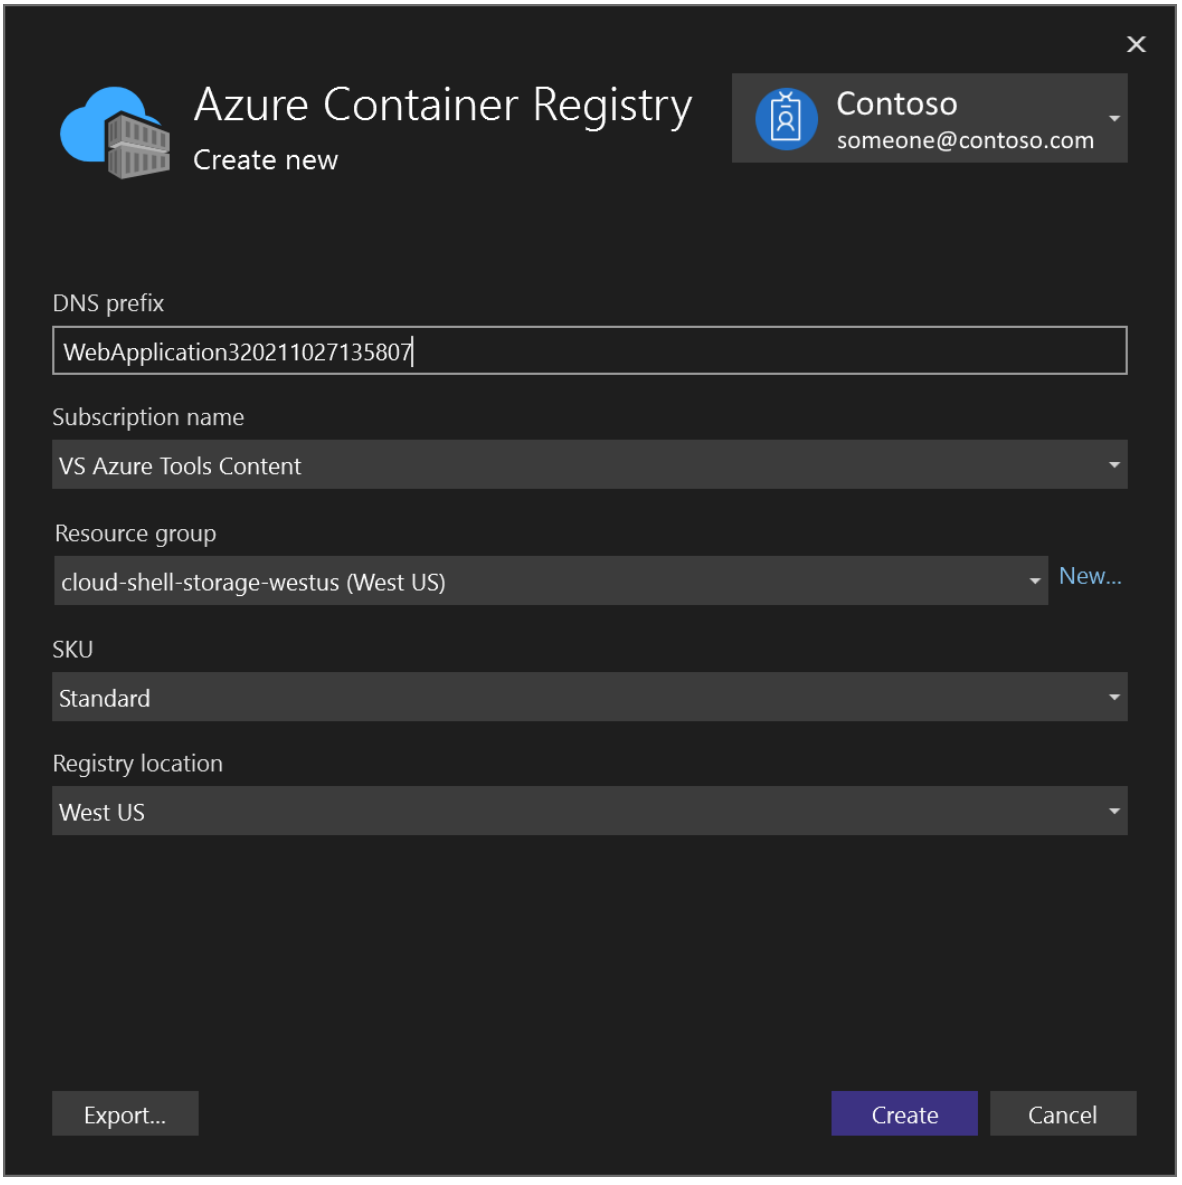
Publish your container to Azure Container Registry



1. Right-click your project in **Solution Explorer** and choose **Publish**. The **Publish** dialog opens.

2. On the **Target** tab, select **Docker Container Registry**, and then select **Next**.

3. On the **Specific target** tab, select **Azure Container Registry**, and then select **Next**.



4. On the **Registry** tab, select the **Create new** (+) option at the right:

5. Fill in your desired values in the **Azure Container Registry** screen.

Expand table

Setting	Suggested value	Description
DNS Prefix	Globally unique name	Name that uniquely identifies your container registry.
Subscription	Your subscription	The Azure subscription to use.
Resource Group	Your resource group	Name of the resource group in which to create your container registry. Select **New** to create a new resource group.
SKU	"Standard"	Select the service tier of the container registry.
Registry Location	A nearby location	Choose a location in a region close to you or close to other services that you expect to use the container registry.

6. After you enter the resource values, select **Create**.

Visual Studio validates the property values and creates the new container resource. When the process completes, Visual Studio returns to the **Publish** dialog and selects the new container in the list.

7. Select **Finish** to publish the new container.

You can now pull the container from the registry to any host capable of running Docker images, such as Azure Container Instances.

Configure ASP.NET Core to work with proxy servers and load balancers

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Chris Ross

In the recommended configuration for ASP.NET Core, the app is hosted using ASP.NET Core Module (ANCM) for IIS, Nginx, or Apache. Proxy servers, load balancers, and other network appliances often obscure information about the request before it reaches the app:

- When HTTPS requests are proxied over HTTP, the original scheme (HTTPS) is lost and must be forwarded in a header.
- Because an app receives a request from the proxy and not its true source on the Internet or corporate network, the originating client IP address must also be forwarded in a header.

This information may be important in request processing, for example in redirects, authentication, link generation, policy evaluation, and client geolocation.

Apps intended to run on web farm should read Host ASP.NET Core in a web farm.

Forwarded headers

By convention, proxies forward information in HTTP headers.

Expand table

Header	Description
X-Forwarded-For (XFF)	Holds information about the client that initiated the request and subsequent proxies in a chain of proxies. This parameter may contain IP addresses and, optionally, port numbers. In a chain of proxy servers, the first parameter indicates

Header	Description
	the client where the request was first made. Subsequent proxy identifiers follow. The last proxy in the chain isn't in the list of parameters. The last proxy's IP address, and optionally a port number, are available as the remote IP address at the transport layer.
X-Forwarded-Proto (XFP)	The value of the originating scheme, HTTP or HTTPS. The value may also be a list of schemes if the request has traversed multiple proxies.
X-Forwarded-Host (XFH)	The original value of the Host header field. Usually, proxies don't modify the Host header. See Microsoft Security Advisory CVE-2018-0787 for information on an elevation-of-privileges vulnerability that affects systems where the proxy doesn't validate or restrict Host headers to known good values.
`X-Forwarded-Prefix`	The original base path requested by the client. This header can be useful for applications to correctly generate URLs, redirects, or links back to the client.

The Forwarded Headers Middleware, ForwardedHeadersMiddleware, reads these headers and fills in the associated fields on HttpContext.

The middleware updates:

- HttpContext.Connection.RemoteIpAddress: Set using the `X-Forwarded-For` header value. Additional settings influence how the middleware sets `RemoteIpAddress`. For details, see the Forwarded Headers Middleware options. The consumed values are removed from `X-Forwarded-For`, and the old value of HttpContext.Connection.RemoteIpAddress is persisted in `X-Original-For`. Note: This process may be repeated several times if there are multiple values in `X-Forwarded-For/Proto/Host/Prefix`, resulting in several values moved to `X-Original-*`, including the original `RemoteIpAddress/Host/Scheme/PathBase`.
- HttpContext.Request.Scheme: Set using the X-Forwarded-Proto header value. The consumed value is removed from `X-Forwarded-Proto`, and the old value of HttpContext.Request.Scheme is persisted in `X-Original-Proto`.
- HttpContext.Request.Host: Set using the `X-Forwarded-Host` header value. The consumed value is removed from `X-Forwarded-Host`, and the old value of HttpContext.Request.Host is persisted in `X-Original-Host`.
- HttpContext.Request.PathBase: Set using the `X-Forwarded-Prefix` header value. The consumed value is removed from `X-Forwarded-Prefix`, and the old value of HttpContext.Request.PathBase is persisted in `X-Original-Prefix`.

For more information on the preceding, see this GitHub issue.

Forwarded Headers Middleware default settings can be configured. For the default settings:

- There is only ***one proxy*** between the app and the source of the requests.
- Only loopback addresses are configured for known proxies and known networks.
- The forwarded headers are named X-Forwarded-For, X-Forwarded-Proto, X-Forwarded-Host and `X-Forwarded-Prefix`.
- The `ForwardedHeaders` value is `ForwardedHeaders.None`, the desired forwarders must be set here to enable the middleware.

Not all network appliances add the `X-Forwarded-For` and `X-Forwarded-Proto` headers without additional configuration. Consult your appliance manufacturer's guidance if proxied requests don't contain these headers when they reach the app. If the appliance uses different header names than `X-Forwarded-For` and `X-Forwarded-Proto`, set the ForwardedForHeaderName and ForwardedProtoHeaderName options to match the header names used by the appliance. For more information, see Forwarded Headers Middleware options and Configuration for a proxy that uses different header names.

IIS/IIS Express and ASP.NET Core Module

Forwarded Headers Middleware is enabled by default by IIS Integration Middleware when the app is hosted out-of-process behind IIS and the ASP.NET Core Module (ANCM) for IIS. Forwarded Headers Middleware is activated to run first in the middleware pipeline with a restricted configuration specific to the ASP.NET Core Module. The restricted configuration is due to trust concerns with forwarded headers, for example, IP spoofing. The middleware is configured to forward the X-Forwarded-For and X-Forwarded-Proto headers and is restricted to a single localhost proxy. If additional configuration is required, see the Forwarded Headers Middleware options.

Other proxy server and load balancer scenarios

Outside of using IIS Integration when hosting out-of-process, Forwarded Headers Middleware isn't enabled by default. Forwarded Headers Middleware must be enabled for an app to process forwarded headers with UseForwardedHeaders. After enabling the middleware if no ForwardedHeadersOptions are specified to the middleware, the default ForwardedHeadersOptions.ForwardedHeaders are ForwardedHeaders.None.

Configure the middleware with ForwardedHeadersOptions to forward the X-Forwarded-For and X-Forwarded-Proto headers.

Forwarded Headers Middleware order

Forwarded Headers Middleware should run before other middleware. This ordering ensures that the middleware relying on forwarded headers information can consume the header values for processing. Forwarded Headers Middleware can run after diagnostics and error handling, but it must be run before calling UseHsts:

C#

```
using Microsoft.AspNetCore.HttpOverrides;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedHeaders =
        ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseForwardedHeaders();
    app.UseHsts();
}
else
{
    app.UseDeveloperExceptionPage();
    app.UseForwardedHeaders();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Alternatively, call `UseForwardedHeaders` before diagnostics:

C#

```
using Microsoft.AspNetCore.HttpOverrides;

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddRazorPages();
builder.Services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedHeaders =
        ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
});

var app = builder.Build();

app.UseForwardedHeaders();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

> **Note**
>
> If no ForwardedHeadersOptions are specified or applied directly to the extension method with UseForwardedHeaders, the default headers to forward are ForwardedHeaders.None. The ForwardedHeaders property must be configured with the headers to forward.

Nginx configuration

To forward the `X-Forwarded-For` and `X-Forwarded-Proto` headers, see Host ASP.NET Core on Linux with Nginx. For more information, see NGINX: Using the Forwarded header.

Apache configuration

`X-Forwarded-For` is added automatically. For more information, see Apache Module mod_proxy: Reverse Proxy Request Headers.

Forwarded Headers Middleware options

ForwardedHeadersOptions control the behavior of the Forwarded Headers Middleware. The following example changes the default values:

- Limits the number of entries in the forwarded headers to `2`.
- Adds a known proxy address of `127.0.10.1`.
- Changes the forwarded header name from the default `X-Forwarded-For` to `X-Forwarded-For-My-Custom-Header-Name`.

C#

```
using System.Net;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardLimit = 2;
    options.KnownProxies.Add(IPAddress.Parse("127.0.10.1"));
    options.ForwardedForHeaderName = "X-Forwarded-For-My-Custom-Header-
Name";
});

var app = builder.Build();

app.UseForwardedHeaders();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Expand table

Option	Description
AllowedHosts	Restricts hosts by the `X-Forwarded-Host` header to the values provided. • Values are compared using ordinal-ignore-case.

Option	Description
	• Port numbers must be excluded. • If the list is empty, all hosts are allowed. • A top-level wildcard `*` allows all non-empty hosts. • Subdomain wildcards are permitted but don't match the root domain. For example, `*.contoso.com` matches the subdomain `foo.contoso.com` but not the root domain `contoso.com`. • Unicode host names are allowed but are converted to Punycode for matching. • IPv6 addresses must include bounding brackets and be in conventional form (for example, `[ABCD:EF01:2345:6789:ABCD:EF01:2345:6789]`). IPv6 addresses aren't special-cased to check for logical equality between different formats, and no canonicalization is performed. • Failure to restrict the allowed hosts may allow a cyberattacker to spoof links generated by the service. The default value is an empty `IList<string>`.
ForwardedForHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XForwardedForHeaderName. This option is used when the proxy/forwarder doesn't use the `X-Forwarded-For` header but uses some other header to forward the information. The default is `X-Forwarded-For`.
ForwardedHeaders	Identifies which forwarders should be processed. See the ForwardedHeaders Enum for the list of fields that apply. Typical values assigned to this property are `ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto`. The default value is ForwardedHeaders.None.
ForwardedHostHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XForwardedHostHeaderName. This option is used when the proxy/forwarder doesn't use the `X-Forwarded-Host` header but uses some other header to forward the information. The default is `X-Forwarded-Host`.
ForwardedProtoHeaderName	Use the header specified by this property instead of the one specified by

Option	Description
	ForwardedHeadersDefaults.XForwardedProtoHeaderName. This option is used when the proxy/forwarder doesn't use the `X-Forwarded-Proto` header but uses some other header to forward the information. The default is `X-Forwarded-Proto`.
ForwardLimit	Limits the number of entries in the headers that are processed. Set to `null` to disable the limit, but this should only be done if `KnownProxies` or `KnownNetworks` are configured. Setting a non-`null` value is a precaution (but not a guarantee) to protect against misconfigured proxies and malicious requests arriving from side-channels on the network. Forwarded Headers Middleware processes headers in reverse order from right to left. If the default value (`1`) is used, only the rightmost value from the headers is processed unless the value of `ForwardLimit` is increased. The default is `1`.
KnownNetworks	Address ranges of known networks to accept forwarded headers from. Provide IP ranges using Classless Interdomain Routing (CIDR) notation. If the server is using dual-mode sockets, IPv4 addresses are supplied in an IPv6 format (for example, `10.0.0.1` in IPv4 represented in IPv6 as `::ffff:10.0.0.1`). See IPAddress.MapToIPv6. Determine if this format is required by looking at the HttpContext.Connection.RemoteIpAddress. The default is an `IList`<IPNetwork> containing a single entry for `new IPNetwork(IPAddress.Loopback, 8)`.
KnownProxies	Addresses of known proxies to accept forwarded headers from. Use `KnownProxies` to specify exact IP address matches. If the server is using dual-mode sockets, IPv4 addresses are supplied in an IPv6 format (for example, `10.0.0.1` in IPv4 represented in IPv6 as `::ffff:10.0.0.1`). See IPAddress.MapToIPv6. Determine if this format is required by looking at the HttpContext.Connection.RemoteIpAddress. The default is an `IList`<IPAddress> containing a single entry for `IPAddress.IPv6Loopback`.
OriginalForHeaderName	Use the header specified by this property instead of the one specified by

Option	Description
	ForwardedHeadersDefaults.XOriginalForHeaderName. The default is `X-Original-For`.
OriginalHostHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XOriginalHostHeaderName. The default is `X-Original-Host`.
OriginalProtoHeaderName	Use the header specified by this property instead of the one specified by ForwardedHeadersDefaults.XOriginalProtoHeaderName. The default is `X-Original-Proto`.
RequireHeaderSymmetry	Require the number of header values to be in sync between the ForwardedHeadersOptions.ForwardedHeaders being processed. The default in ASP.NET Core 1.x is `true`. The default in ASP.NET Core 2.0 or later is `false`.

Scenarios and use cases

When it isn't possible to add forwarded headers and all requests are secure

In some cases, it might not be possible to add forwarded headers to the requests proxied to the app. If the proxy is enforcing that all public external requests are HTTPS, the scheme can be manually set before using any type of middleware:

C#

```
using Microsoft.AspNetCore.HttpOverrides;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedHeaders =
        ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
});

var app = builder.Build();
```

```
app.Use((context, next) =>
{
    context.Request.Scheme = "https";
    return next(context);
});

app.UseForwardedHeaders();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

This code can be disabled with an environment variable or other configuration setting in a development or staging environment:

C#

```
using Microsoft.AspNetCore.HttpOverrides;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedHeaders =
        ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
});

var app = builder.Build();

if (!app.Environment.IsProduction())
{
    app.Use((context, next) =>
    {
        context.Request.Scheme = "https";
        return next(context);
    });
}

app.UseForwardedHeaders();

if (!app.Environment.IsDevelopment())
```

```
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Work with path base and proxies that change the request path

Some proxies pass the path intact but with an app base path that should be removed so that routing works properly. UsePathBaseExtensions.UsePathBase middleware splits the path into HttpRequest.Path and the app base path into HttpRequest.PathBase.

If `/foo` is the app base path for a proxy path passed as `/foo/api/1`, the middleware sets `Request.PathBase` to `/foo` and `Request.Path` to `/api/1` with the following command:

C#

```
app.UsePathBase("/foo");
// ...
app.UseRouting();
```

> **Note**
>
> When using WebApplication (see Migrate from ASP.NET Core 5.0 to 6.0), app.UseRouting must be called after `UsePathBase` so that the routing middleware can observe the modified path before matching routes. Otherwise, routes are matched before the path is rewritten by `UsePathBase` as described in the Middleware Ordering and Routing articles.

The original path and path base are reapplied when the middleware is called again in reverse. For more information on middleware order processing, see ASP.NET Core Middleware.

If the proxy trims the path (for example, forwarding `/foo/api/1` to `/api/1`), fix redirects and links by setting the request's PathBase property:

C#

```
app.Use((context, next) =>
{
    context.Request.PathBase = new PathString("/foo");
    return next(context);
});
```

If the proxy is adding path data, discard part of the path to fix redirects and links by using StartsWithSegments and assigning to the Path property:

C#

```
app.Use((context, next) =>
{
    if (context.Request.Path.StartsWithSegments("/foo", out var remainder))
    {
        context.Request.Path = remainder;
    }

    return next(context);
});
```

Configuration for a proxy that uses different header names

If the proxy doesn't use headers named `X-Forwarded-For` and `X-Forwarded-Proto` to forward the proxy address/port and originating scheme information, set the ForwardedForHeaderName and ForwardedProtoHeaderName options to match the header names used by the proxy:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedForHeaderName = "HeaderNamUsedByProxy_X-Forwarded-
For_Header";
    options.ForwardedProtoHeaderName = "HeaderNamUsedByProxy_X-Forwarded-
Proto_Header";
});

var app = builder.Build();

app.UseForwardedHeaders();
```

```
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Forward the scheme for Linux and non-IIS reverse proxies

Apps that call UseHttpsRedirection and UseHsts put a site into an infinite loop if deployed to an Azure Linux App Service, Azure Linux virtual machine (VM), or behind any other reverse proxy besides IIS. TLS is terminated by the reverse proxy, and Kestrel isn't made aware of the correct request scheme. OAuth and OIDC also fail in this configuration because they generate incorrect redirects. UseIISIntegration adds and configures Forwarded Headers Middleware when running behind IIS, but there's no matching automatic configuration for Linux (Apache or Nginx integration).

To forward the scheme from the proxy in non-IIS scenarios, enable the Forwarded Headers Middleware by setting `ASPNETCORE_FORWARDEDHEADERS_ENABLED` to `true`. Warning: This flag uses settings designed for cloud environments and doesn't enable features such as the KnownProxies option to restrict which IPs forwarders are accepted from.

Certificate forwarding

Azure

To configure Azure App Service for certificate forwarding, see Configure TLS mutual authentication for Azure App Service. The following guidance pertains to configuring the ASP.NET Core app.

- Configure Certificate Forwarding Middleware to specify the header name that Azure uses. Add the following code to configure the header from which the middleware builds a certificate.
- Call UseCertificateForwarding before the call to UseAuthentication.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddCertificateForwarding(options =>
    options.CertificateHeader = "X-ARR-ClientCert");

var app = builder.Build();

app.UseCertificateForwarding();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();
app.UseAuthentication();

app.MapRazorPages();

app.Run();
```

Other web proxies

If a proxy is used that isn't IIS or Azure App Service's Application Request Routing (ARR), configure the proxy to forward the certificate that it received in an HTTP header.

- Configure Certificate Forwarding Middleware to specify the header name. Add the following code to configure the header from which the middleware builds a certificate.
- Call UseCertificateForwarding before the call to UseAuthentication.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddCertificateForwarding(options =>
    options.CertificateHeader = "YOUR_CERTIFICATE_HEADER_NAME");

var app = builder.Build();

app.UseCertificateForwarding();
```

```
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();
app.UseAuthentication();

app.MapRazorPages();

app.Run();
```

If the proxy isn't base64-encoding the certificate, as is the case with Nginx, set the `HeaderConverter` option. Consider the following example:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddCertificateForwarding(options =>
{
    options.CertificateHeader = "YOUR_CUSTOM_HEADER_NAME";
    options.HeaderConverter = (headerValue) =>
    {
        // Conversion logic to create an X509Certificate2.
        var clientCertificate = ConversionLogic.CreateAnX509Certificate2();
        return clientCertificate;
    };
});

var app = builder.Build();

app.UseCertificateForwarding();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();
app.UseAuthentication();

app.MapRazorPages();
```

```
app.Run();
```

Troubleshoot

When headers aren't forwarded as expected, enable `debug` level logging and HTTP request logging. UseHttpLogging must be called after UseForwardedHeaders:

C#

```
using Microsoft.AspNetCore.HttpLogging;
using Microsoft.AspNetCore.HttpOverrides;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddHttpLogging(options =>
{
    options.LoggingFields = HttpLoggingFields.RequestPropertiesAndHeaders;
});

builder.Services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedHeaders =
        ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
});

var app = builder.Build();

app.UseForwardedHeaders();
app.UseHttpLogging();

app.Use(async (context, next) =>
{
    // Connection: RemoteIp
    app.Logger.LogInformation("Request RemoteIp: {RemoteIpAddress}",
        context.Connection.RemoteIpAddress);

    await next(context);
});

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
```

```
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

If there are multiple values in a given header, Forwarded Headers Middleware processes headers in reverse order from right to left. The default `ForwardLimit` is `1` (one), so only the rightmost value from the headers is processed unless the value of `ForwardLimit` is increased.

The request's original remote IP must match an entry in the KnownProxies or KnownNetworks lists before forwarded headers are processed. This limits header spoofing by not accepting forwarders from untrusted proxies. When an unknown proxy is detected, logging indicates the address of the proxy:

Console

```
September 20th 2018, 15:49:44.168 Unknown proxy: 10.0.0.100:54321
```

In the preceding example, 10.0.0.100 is a proxy server. If the server is a trusted proxy, add the server's IP address to `KnownProxies`, or add a trusted network to `KnownNetworks`. For more information, see the Forwarded Headers Middleware options section.

C#

```
using Microsoft.AspNetCore.HttpOverrides;
using System.Net;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.Configure<ForwardedHeadersOptions>(options =>
{
    options.ForwardedHeaders =
        ForwardedHeaders.XForwardedFor | ForwardedHeaders.XForwardedProto;
    options.KnownProxies.Add(IPAddress.Parse("10.0.0.100"));
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseForwardedHeaders();
    app.UseHsts();
}
else
```

```
{
    app.UseDeveloperExceptionPage();
    app.UseForwardedHeaders();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

To display the logs, add `"Microsoft.AspNetCore.HttpLogging": "Information"` to the `appsettings.Development.json` file:

JSON

```
{
  "DetailedErrors": true,
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning",
      "Microsoft.AspNetCore.HttpLogging": "Information"
    }
  }
}
```

ⓘ Important

Only allow trusted proxies and networks to forward headers. Otherwise, IP spoofing attacks are possible.

Deploying and scaling an ASP.NET Core app on Azure Container Apps

Article • 09/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Apps deployed to Azure that experience intermittent high demand benefit from scalability to meet demand. Scalable apps can scale out to ensure capacity during workload peaks and then scale down automatically when the peak drops, which can lower costs. Horizontal scaling (scaling out) adds new instances of a resource, such as VMs or database replicas. This article demonstrates how to deploy a horizontally scalable ASP.NET Core app to Azure container apps by completing the following tasks:

1. Set up the sample project
2. Deploy the app to Azure Container Apps
3. Scale and troubleshoot the app
4. Create the Azure Services
5. Connect the Azure services
6. Configure and redeploy the app

This article uses Razor Pages, but most of it applies to other ASP.NET Core apps.

In some cases, basic ASP.NET Core apps are able to scale without special considerations. However, apps that utilize certain framework features or architectural patterns require extra configurations, including the following:

- **Secure form submissions**: Razor Pages, MVC and Web API apps often rely on form submissions. By default these apps use cross site forgery tokens and internal data protection services to secure requests. When deployed to the cloud, these apps must be configured to manage data protection service concerns in a secure, centralized location.
- **SignalR circuits**: Blazor Server apps require the use of a centralized Azure SignalR service in order to securely scale. These services also utilize the data protection

services mentioned previously.

- **Centralized caching or state management services**: Scalable apps may use Azure Cache for Redis to provide distributed caching. Azure storage may be needed to store state for frameworks such as Microsoft Orleans, which can help write apps that manage state across many different app instances.

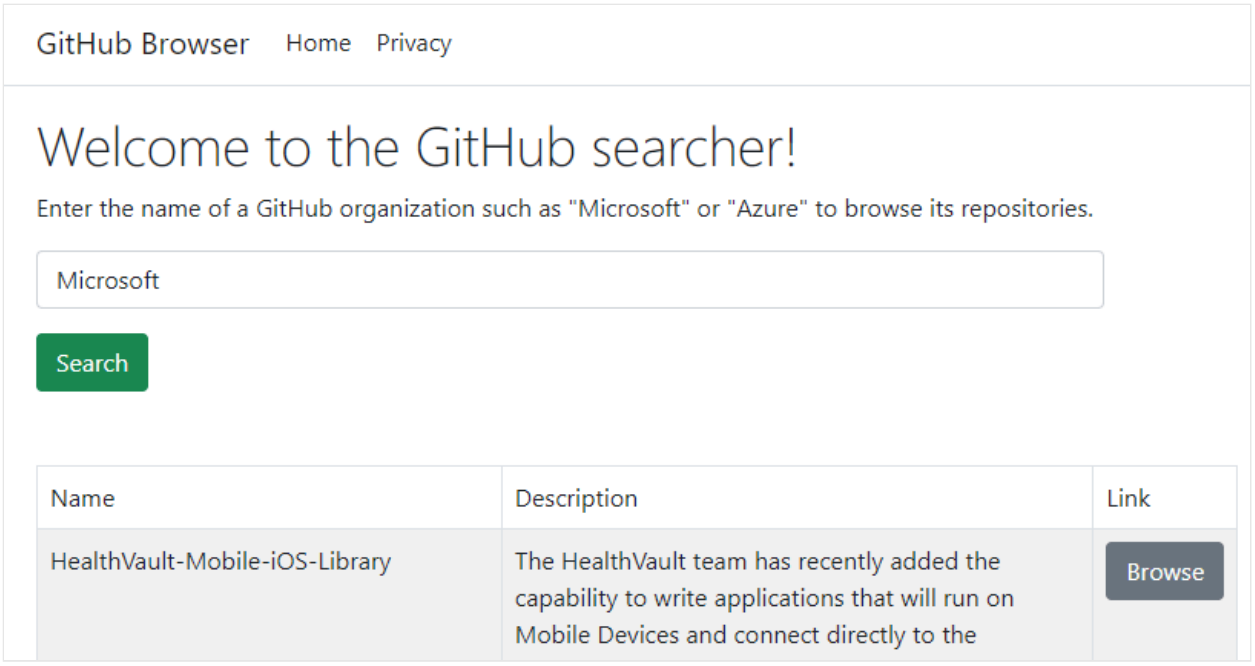
The steps in this article demonstrate how to properly address the preceding concerns by deploying a scalable app to Azure Container Apps. Most of the concepts in this tutorial also apply when scaling Azure App Service instances.

Set up the sample project

Use the GitHub Explorer sample app to follow along with this tutorial. Clone the app from GitHub using the following command:

.NET CLI

```
git clone "https://github.com/dotnet/AspNetCore.Docs.Samples.git"
```



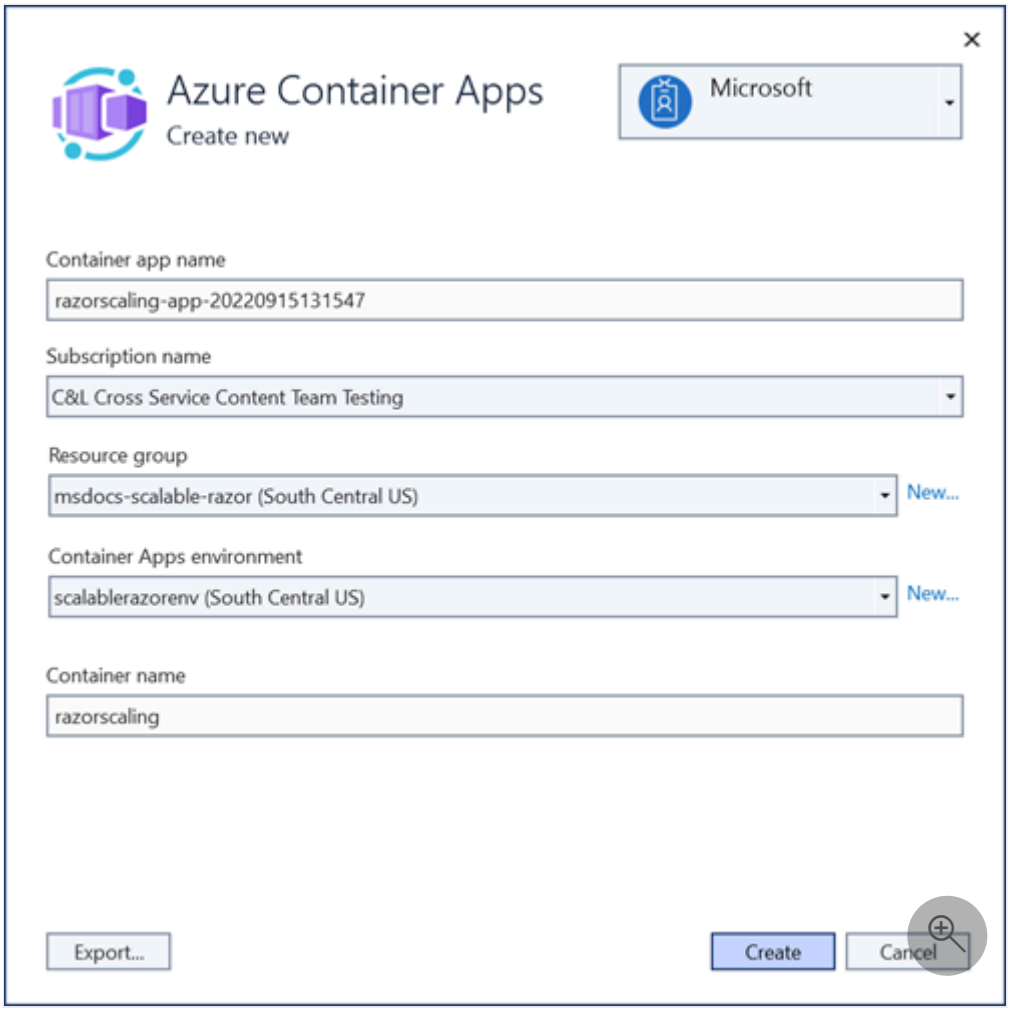
Navigate to the `/tutorials/scalable-razor-apps/start` folder and open the `ScalableRazor.csproj`.

The sample app uses a search form to browse GitHub repositories by name. The form relies on the built-in ASP.NET Core data protection services to handle antiforgery concerns. By default, when the app scales horizontally on Container Apps, the data protection service throws an exception.

Test the app

1. Launch the app in Visual Studio. The project includes a Docker file, which means that the arrow next to the run button can be selected to start the app using either a Docker Desktop setup or the standard ASP.NET Core local web server.

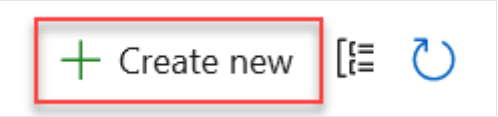
Use the search form to browse for GitHub repositories by name.



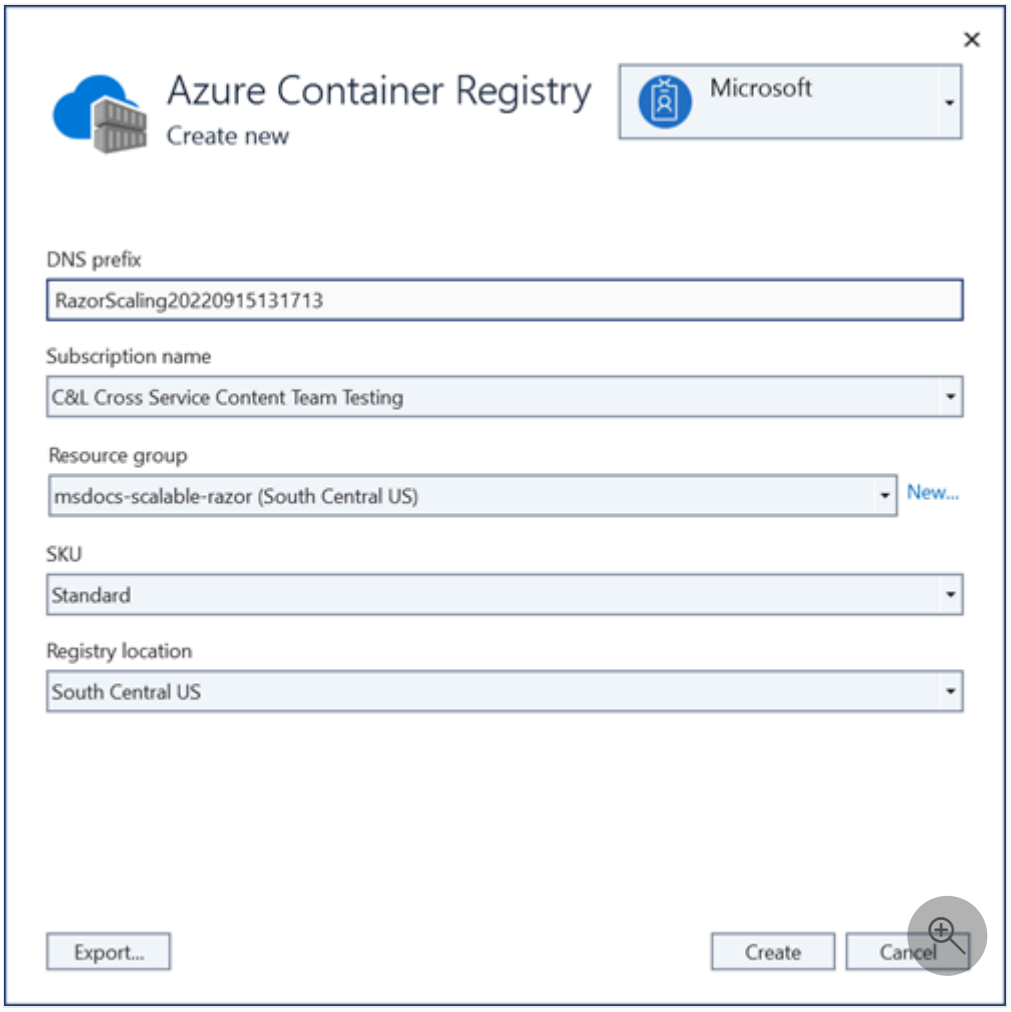
Deploy the app to Azure Container Apps

Visual Studio is used to deploy the app to Azure Container Apps. Container apps provide a managed service designed to simplify hosting containerized apps and microservices.

> ⓘ **Note**
>
> Many of the resources created for the app require a location. For this app, location isn't important. A real app should select a location closest to the clients. You may want to select a location near you.



1. In Visual Studio solution explorer, right click on the top level project node and select **Publish**.
2. In the publishing dialog, select **Azure** as the deployment target, and then select **Next**.
3. For the specific target, select **Azure Container Apps (Linux)**, and then select **Next**.
4. Create a new container app to deploy to. Select the green + icon to open a new dialog and enter the following values:



- **Container app name**: Leave the default value or enter a name.
- **Subscription name**: Select the subscription to deploy to.
- **Resource group**: Select **New** and create a new resource group called *msdocs-scalable-razor*.
- **Container apps environment**: Select **New** to open the container apps environment dialog and enter the following values:
  - **Environment name**: Keep the default value.
  - **Location**: Select a location near you.
  - **Azure Log Analytics Workspace**: Select **New** to open the log analytics workspace dialog.
    - **Name**: Leave the default value.
    - **Location**: Select a location near you and then select **Ok** to close the dialog.
  - Select **Ok** to close the container apps environment dialog.
- Select **Create** to close the original container apps dialog. Visual Studio creates the container app resource in Azure.

5. Once the resource is created, make sure it's selected in the list of container apps, and then select **Next**.

6. You'll need to create an Azure Container Registry to store the published image artifact for your app. Select the green + icon on the container registry screen.

7. Leave the default values, and then select **Create**.

8. After the container registry is created, make sure it's selected, and then select finish to close the dialog workflow and display a summary of the publishing profile.

   If Visual Studio prompts you to enable the Admin user to access the published docker container, select **Yes**.

9. Select **Publish** in the upper right of the publishing profile summary to deploy the app to Azure.

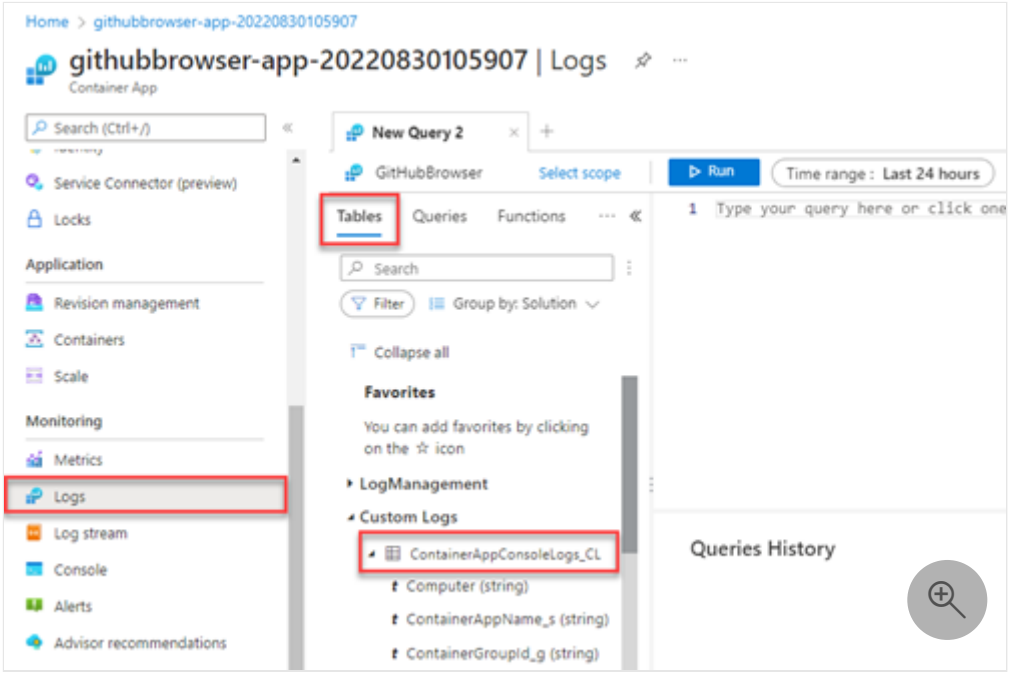
When the deployment finishes, Visual Studio launches the browser to display the hosted app. Search for `Microsoft` in the form field, and a list of repositories is displayed.

Scale and troubleshoot the app

The app is currently working without any issues, but we'd like to scale the app across more instances in anticipation of high traffic volumes.

1. In the Azure portal, search for the `razorscaling-app-****` container app in the top level search bar and select it from the results.
2. On the overview page, select **Scale** from the left navigation, and then select **+ Edit and deploy**.
3. On the revisions page, switch to the **Scale** tab.
4. Set both the min and max instances to **4** and then select **Create**. This configuration change guarantees your app is scaled horizontally across four instances.

Navigate back to the app. When the page loads, at first it appears everything is working correctly. However, when a search term is entered and submitted, an error may occur. If an error is not displayed, submit the form several more times.



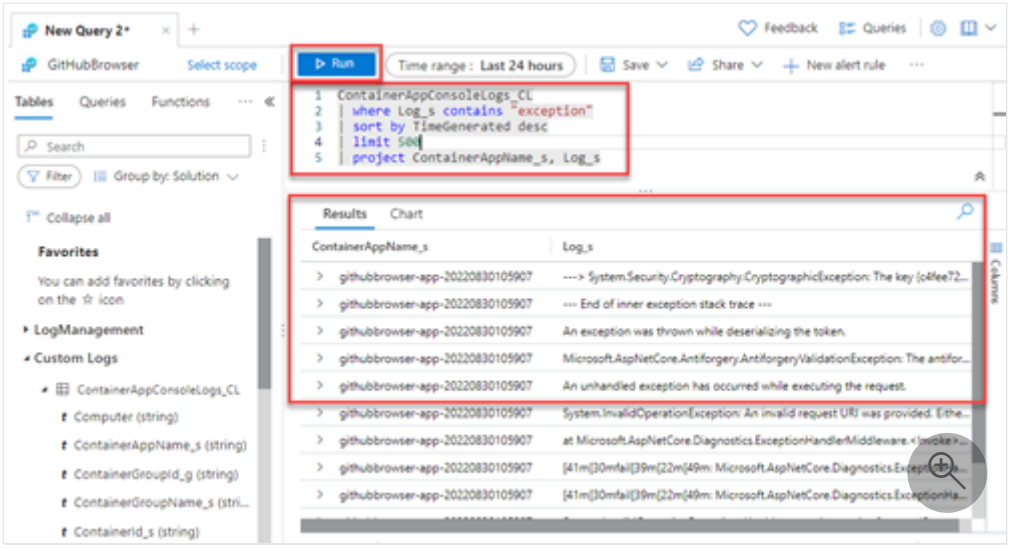
Troubleshooting the error

It's not immediately apparent why the search requests are failing. The browser tools indicate a 400 Bad Request response was sent back. However, you can use the logging features of container apps to diagnose errors occurring in your environment.

1. On the overview page of the container app, select **Logs** from the left navigation.

2. On the **Logs** page, close the pop-up that opens and navigate to the **Tables** tab.

3. Expand the **Custom Logs** item to reveal the **ContainerAppConsoleLogs_CL** node. This table holds various logs for the container app that can be queried to troubleshoot problems.



4. In the query editor, compose a basic query to search the **ContainerAppConsoleLogs_CL Logs** table for recent exceptions, such as the following script:

```KQL
ContainerAppConsoleLogs_CL
| where Log_s contains "exception"
| sort by TimeGenerated desc
| limit 500
| project ContainerAppName_s, Log_s
```

   The preceding query searches the **ContainerAppConsoleLogs_CL** table for any rows that contain the word exception. The results are ordered by the time generated, limited to 500 results, and only include the **ContainerAppName_s** and **Log_s** columns to make the results easier to read.

5. Select **Run**, a list of results is displayed. Read through the logs and note that most of them are related to antiforgery tokens and cryptography.

> **ⓘ Important**
>
> The errors in the app are caused by the .NET data protection services. When multiple instances of the app are running, there is no guarantee that the HTTP POST request to submit the form is routed to the same container that initially loaded the page from the HTTP GET request. If the requests are handled by different instances, the antiforgery tokens aren't handled correctly and an exception occurs.

   In the steps ahead, this issue is resolved by centralizing the data protection keys in an Azure storage service and protecting them with Key Vault.

Create the Azure Services

To resolve the preceding errors, the following services are created and connected to the app:

- Azure Storage Account: Handles storing data for the Data Protection Services. Provides a centralized location to store key data as the app scales. Storage accounts can also be used to hold documents, queue data, file shares, and almost any type of blob data.
- Azure KeyVault: This service stores secrets for an app, and is used to help manage encryption concerns for the Data Protection Services.

Create the storage account service

1. In the Azure portal search bar, enter `Storage accounts` and select the matching result.
2. On the storage accounts listing page, select **+ Create**.
3. On the **Basics** tab, enter the following values:

    - **Subscription**: Select the same subscription that you chose for the container app.
    - **Resource Group**: Select the *msdocs-scalable-razor* resource group you created previously.
    - **Storage account name**: Name the account *scalablerazorstorageXXXX* where the X's are random numbers of your choosing. This name must be unique across all of Azure.
    - **Region**: Select the same region you previously selected.

4. Leave the rest of the values at their default and select **Review**. After Azure validates the inputs, select **Create**.

Azure provisions the new storage account. When the task completes, choose **Go to resource** to view the new service.

Create the storage container

Create a Container to store the app's data protection keys.

1. On the overview page for the new storage account, select **Storage browser** on the left navigation.
2. Select **Blob containers**.
3. Select **+ Add container** to open the **New container** flyout menu.

4. Enter a name of *scalablerazorkeys*, leave the rest of the settings at their defaults, and then select **Create**.

The new containers appear on the page list.

Create the key vault service

Create a key vault to hold the keys that protect the data in the blob storage container.

1. In the Azure portal search bar, enter `Key Vault` and select the matching result.
2. On the key vault listing page, select **+ Create**.
3. On the **Basics** tab, enter the following values:

    - **Subscription**: Select the same subscription that was previously selected.
    - **Resource Group**: Select the *msdocs-scalable-razor* resource group previously created.
    - **Key Vault name**: Enter the name *scalablerazorvaultXXXX*.
    - **Region**: Select a region near your location.

4. Leave the rest of the settings at their default, and then select **Review + create**. Wait for Azure to validate your settings, and then select **Create**.

Azure provisions the new key vault. When the task completes, select **Go to resource** to view the new service.

Create the key

Create a secret key to protect the data in the blob storage account.

1. On the main overview page of the key vault, select **Keys** from the left navigation.
2. On the **Create a key** page, select **+ Generate/Import** to open the **Create a key** flyout menu.
3. Enter *razorkey* in the **Name** field. Leave the rest of the settings at their default values and then select **Create**. A new key appears on the key list page.

Connect the Azure Services

The Container App requires a secure connection to the storage account and the key vault services in order to resolve the data protection errors and scale correctly. The new services are connected together using the following steps:

> **ⓘ Important**

> Security role assignments through Service Connector and other tools typically take a minute or two to propagate, and in some rare cases can take up to eight minutes.

Connect the storage account

1. In the Azure portal, navigate to the Container App overview page.
2. On the left navigation, select **Service connector**
3. On the Service Connector page, choose **+ Create** to open the **Creation Connection** flyout panel and enter the following values:

    - **Container**: Select the Container App created previously.
    - **Service type**: Choose **Storage - blob**.
    - **Subscription**: Select the subscription previously used.
    - **Connection name**: Leave the default value.
    - **Storage account**: Select the storage account created previously.
    - **Client type**: Select **.NET**.

4. Select **Next: Authentication** to progress to the next step.
5. Select **System assigned managed identity** and choose **Next: Networking**.
6. Leave the default networking options selected, and then select **Review + Create**.
7. After Azure validates the settings, select **Create**.

The service connector enables a system-assigned managed identity on the container app. It also assigns a role of **Storage Blob Data Contributor** to the identity so it can perform data operations on the storage containers.

Connect the key vault

1. In the Azure portal, navigate to your Container App overview page.
2. On the left navigation, select **Service connector**.
3. On the Service Connector page, choose **+ Create** to open the **Creation Connection** flyout panel and enter the following values:

    - **Container**: Select the container app created previously.
    - **Service type**: Choose **Key Vault**.
    - **Subscription**: Select the subscription previously used.
    - **Connection name**: Leave the default value.
    - **Key vault**: Select the key vault created previously.
    - **Client type**: Select **.NET**.

4. Select **Next: Authentication** to progress to the next step.
5. Select **System assigned managed identity** and choose **Next: Networking**.

6. Leave the default networking options selected, and then select **Review + Create**.
7. After Azure validates the settings, select **Create**.

The service connector assigns a role to the identity so it can perform data operations on the key vault keys.

Configure and redeploy the app

The necessary Azure resources have been created. In this section the app code is configured to use the new resources.

1. Install the following NuGet packages:

    - **Azure.Identity**: Provides classes to work with the Azure identity and access management services.
    - **Microsoft.Extensions.Azure**: Provides helpful extension methods to perform core Azure configurations.
    - **Azure.Extensions.AspNetCore.DataProtection.Blobs**: Allows storing ASP.NET Core DataProtection keys in Azure Blob Storage so that keys can be shared across several instances of a web app.
    - **Azure.Extensions.AspNetCore.DataProtection.Keys**: Enables protecting keys at rest using the Azure Key Vault Key Encryption/Wrapping feature.

    .NET CLI

    ```
    dotnet add package Azure.Identity
    dotnet add package Microsoft.Extensions.Azure
    dotnet add package Azure.Extensions.AspNetCore.DataProtection.Blobs
    dotnet add package Azure.Extensions.AspNetCore.DataProtection.Keys
    ```

2. Update `Program.cs` with the following highlighted code:

    C#

    ```
    using Azure.Identity;
    using Microsoft.AspNetCore.DataProtection;
    using Microsoft.Extensions.Azure;
    var builder = WebApplication.CreateBuilder(args);
    var BlobStorageUri = builder.Configuration["AzureURIs:BlobStorage"];
    var KeyVaultURI = builder.Configuration["AzureURIs:KeyVault"];

    builder.Services.AddRazorPages();
    builder.Services.AddHttpClient();
    builder.Services.AddServerSideBlazor();
    ```

```
builder.Services.AddAzureClientsCore();

builder.Services.AddDataProtection()
                .PersistKeysToAzureBlobStorage(new Uri(BlobStorageUri),
                                               new
DefaultAzureCredential())
                .ProtectKeysWithAzureKeyVault(new Uri(KeyVaultURI),
                                               new
DefaultAzureCredential());
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The preceding changes allow the app to manage data protection using a centralized, scalable architecture. `DefaultAzureCredential` discovers the managed identity configurations enabled earlier when the app is redeployed.

Update the placeholders in `AzureURIs` section of the `appsettings.json` file to include the following:

1. Replace the `<storage-account-name>` placeholder with the name of the `scalablerazorstorageXXXX` storage account.
2. Replace the `<container-name>` placeholder with the name of the `scalablerazorkeys` storage container.
3. Replace the `<key-vault-name>` placeholder with the name of the `scalablerazorvaultXXXX` key vault.
4. Replace the `<key-name>` placeholder in the key vault URI with the `razorkey` name created previously.

```
C#
```

```
{
  "GitHubURL": "https://api.github.com",
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "AzureURIs": {
    "BlobStorage": "https://<storage-account-
name>.blob.core.windows.net/<container-name>/keys.xml",
    "KeyVault": "https://<key-vault-name>.vault.azure.net/keys/<key-
name>/"
  }
}
```

Redeploy the app

The app is now configured correctly to use the Azure services created previously. Redeploy the app for the code changes to be applied.

1. Right click on the project node in the solution explorer and select **Publish**.
2. On the publishing profile summary view, select the **Publish** button in the upper right corner.

Visual Studio redeploys the app to the container apps environment created previously. When the processes finished, the browser launches to the app home page.

Test the app again by searching for *Microsoft* in the search field. The page should now reload with the correct results every time you submit.

Configure roles for local development

The existing code and configuration of the app can also work while running locally during development. The `DefaultAzureCredential` class configured previously is able to pick up local environment credentials to authenticate to Azure Services. You'll need to assign the same roles to your own account that were assigned to your app's managed identity in order for the authentication to work. This should be the same account you use to log into Visual Studio or the Azure CLI.

Sign-in to your local development environment

You'll need to be signed in to the Azure CLI, Visual Studio, or Azure PowerShell for your credentials to be picked up by `DefaultAzureCredential`.

Azure CLI

Azure CLI

```
az login
```

Assign roles to your developer account

1. In the Azure portal, navigate to the `scalablerazor****` storage account created previously.
2. Select **Access Control (IAM)** from the left navigation.
3. Choose **+ Add** and then **Add role assignment** from the drop-down menu.
4. On the **Add role assignment** page, search for `Storage blob data contributor`, select the matching result, and then select **Next**.
5. Make sure **User, group, or service principal** is selected, and then select **+ Select members**.
6. In the **Select members** flyout, search for your own *user@domain* account and select it from the results.
7. Choose **Next** and then select **Review + assign**. After Azure validates the settings, select **Review + assign** again.

As previously stated, role assignment permissions might take a minute or two to propagate, or in rare cases up to eight minutes.

Repeat the previous steps to assign a role to your account so that it can access the key vault service and secret.

1. In the Azure portal, navigate to the `razorscalingkeys` key vault created previously.
2. Select **Access Control (IAM)** from the left navigation.
3. Choose **+ Add** and then **Add role assignment** from the drop-down menu.
4. On the **Add role assignment** page, search for `Key Vault Crypto Service Encryption User`, select the matching result, and then select **Next**.
5. Make sure **User, group, or service principal** is selected, and then select **+ Select members**.
6. In the **Select members** flyout, search for your own *user@domain* account and select it from the results.

7. Choose **Next** and then select **Review + assign**. After Azure validates your settings, select **Review + assign** again.

You may need to wait again for this role assignment to propagate.

You can then return to Visual Studio and run the app locally. The code should continue to function as expected. `DefaultAzureCredential` uses your existing credentials from Visual Studio or the Azure CLI.

Reliable web app patterns

See *The Reliable Web App Pattern for.NET* YouTube videos and article for guidance on creating a modern, reliable, performant, testable, cost-efficient, and scalable ASP.NET Core app, whether from scratch or refactoring an existing app.

Host ASP.NET Core in a web farm

Article • 09/18/2024

> **Important**

>
> For the current release, see the .NET 8 version of this article.

By Chris Ross

A *web farm* is a group of two or more web servers (or *nodes*) that host multiple instances of an app. When requests from users arrive to a web farm, a *load balancer* distributes the requests to the web farm's nodes. Web farms improve:

- **Reliability/availability**: When one or more nodes fail, the load balancer can route requests to other functioning nodes to continue processing requests.
- **Capacity/performance**: Multiple nodes can process more requests than a single server. The load balancer balances the workload by distributing requests to the nodes.
- **Scalability**: When more or less capacity is required, the number of active nodes can be increased or decreased to match the workload. Web farm platform technologies, such as Azure App Service, can automatically add or remove nodes at the request of the system administrator or automatically without human intervention.
- **Maintainability**: Nodes of a web farm can rely on a set of shared services, which results in easier system management. For example, the nodes of a web farm can rely upon a single database server and a common network location for static resources, such as images and downloadable files.

This topic describes configuration and dependencies for ASP.NET core apps hosted in a web farm that rely upon shared resources.

General configuration

Host and deploy ASP.NET Core

Learn how to set up hosting environments and deploy ASP.NET Core apps. Configure a process manager on each node of the web farm to automate app starts and restarts.

Each node requires the ASP.NET Core runtime. For more information, see the topics in the Host and deploy area of the documentation.

Configure ASP.NET Core to work with proxy servers and load balancers
Learn about configuration for apps hosted behind proxy servers and load balancers, which often obscure important request information.

Deploy ASP.NET Core apps to Azure App Service
Azure App Service is a Microsoft cloud computing platform service for hosting web apps, including ASP.NET Core. App Service is a fully managed platform that provides automatic scaling, load balancing, patching, and continuous deployment.

App data

When an app is scaled to multiple instances, there might be app state that requires sharing across nodes. If the state is transient, consider sharing an IDistributedCache. If the shared state requires persistence, consider storing the shared state in a database.

Required configuration

Data Protection and Caching require configuration for apps deployed to a web farm.

Data Protection

The ASP.NET Core Data Protection system is used by apps to protect data. Data Protection relies upon a set of cryptographic keys stored in a *key ring*. When the Data Protection system is initialized, it applies default settings that store the key ring locally. Under the default configuration, a unique key ring is stored on each node of the web farm. Consequently, each web farm node can't decrypt data that's encrypted by an app on any other node. The default configuration isn't generally appropriate for hosting apps in a web farm. An alternative to implementing a shared key ring is to always route user requests to the same node. For more information on Data Protection system configuration for web farm deployments, see Configure ASP.NET Core Data Protection.

Caching

In a web farm environment, the caching mechanism must share cached items across the web farm's nodes. Caching must either rely upon a common Redis cache, a shared SQL Server database, or a custom caching implementation that shares cached items across the web farm. For more information, see Distributed caching in ASP.NET Core.

Dependent components

The following scenarios don't require additional configuration, but they depend on technologies that require configuration for web farms.

Expand table

Scenario	Depends on ...
Authentication	Data Protection (see Configure ASP.NET Core Data Protection). For more information, see Use cookie authentication without ASP.NET Core Identity and Share authentication cookies among ASP.NET apps.
Identity	Authentication and database configuration. For more information, see Introduction to Identity on ASP.NET Core.
Session	Data Protection (encrypted cookies) (see Configure ASP.NET Core Data Protection) and Caching (see Distributed caching in ASP.NET Core). For more information, see Session and state management: Session state.
TempData	Data Protection (encrypted cookies) (see Configure ASP.NET Core Data Protection) or Session (see Session and state management: Session state). For more information, see Session and state management: TempData.
Antiforgery	Data Protection (see Configure ASP.NET Core Data Protection). For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Troubleshoot

Data Protection and caching

When Data Protection or caching isn't configured for a web farm environment, intermittent errors occur when requests are processed. This occurs because nodes don't share the same resources and user requests aren't always routed back to the same node.

Consider a user who signs into the app using cookie authentication. The user signs into the app on one web farm node. If their next request arrives at the same node where they signed in, the app is able to decrypt the authentication cookie and allows access to the app's resource. If their next request arrives at a different node, the app can't decrypt

the authentication cookie from the node where the user signed in, and authorization for the requested resource fails.

When any of the following symptoms occur **intermittently**, the problem is usually traced to improper Data Protection or caching configuration for a web farm environment:

- Authentication breaks: The authentication cookie is misconfigured or can't be decrypted. OAuth (Facebook, Microsoft, Twitter) or OpenIdConnect logins fail with the error "Correlation failed."
- Authorization breaks: Identity is lost.
- Session state loses data.
- Cached items disappear.
- TempData fails.
- POSTs fail: The antiforgery check fails.

For more information on Data Protection configuration for web farm deployments, see Configure ASP.NET Core Data Protection. For more information on caching configuration for web farm deployments, see Distributed caching in ASP.NET Core.

Obtain data from apps

If the web farm apps are capable of responding to requests, obtain request, connection, and additional data from the apps using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Additional resources

- Custom Script Extension for Windows: Downloads and executes scripts on Azure virtual machines, which is useful for post-deployment configuration and software installation.

Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Sayed Ibrahim Hashimi and Rick Anderson

This document focuses on using Visual Studio 2019 or later to create and use publish profiles. The publish profiles created with Visual Studio can be used with MSBuild and Visual Studio. For instructions on publishing to Azure, see Publish an ASP.NET Core app to Azure with Visual Studio.

The `dotnet new mvc` command produces a project file containing the following root-level <Project> element:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">
    <!-- omitted for brevity -->
</Project>
```

The preceding `<Project>` element's `Sdk` attribute imports the MSBuild properties and targets from *$(MSBuildSDKsPath)\Microsoft.NET.Sdk.Web\Sdk\Sdk.props* and *$(MSBuildSDKsPath)\Microsoft.NET.Sdk.Web\Sdk\Sdk.targets*, respectively. The default location for `$(MSBuildSDKsPath)` (with Visual Studio 2019 Enterprise) is the *%programfiles(x86)%\Microsoft Visual Studio\2019\Enterprise\MSBuild\Sdks* folder.

`Microsoft.NET.Sdk.Web` (Web SDK) depends on other SDKs, including `Microsoft.NET.Sdk` (.NET Core SDK) and `Microsoft.NET.Sdk.Razor` (Razor SDK). The MSBuild properties and targets associated with each dependent SDK are imported. Publish targets import the appropriate set of targets based on the publish method used.

When MSBuild or Visual Studio loads a project, the following high-level actions occur:

- Build project
- Compute files to publish
- Publish files to destination

Compute project items

When the project is loaded, the MSBuild project items (files) are computed. The item type determines how the file is processed. By default, `.cs` files are included in the `Compile` item list. Files in the `Compile` item list are compiled.

The `Content` item list contains files that are published in addition to the build outputs. By default, files matching the patterns `wwwroot\**`, `**\*.config`, and `**\*.json` are included in the `Content` item list. For example, the `wwwroot\**` globbing pattern matches all files in the *wwwroot* folder and its subfolders.

The Web SDK imports the Razor SDK. As a result, files matching the patterns `**\*.cshtml` and `**\*.razor` are also included in the `Content` item list.

To explicitly add a file to the publish list, add the file directly in the `.csproj` file as shown in the Include Files section.

When selecting the **Publish** button in Visual Studio or when publishing from the command line:

- The properties/items are computed (the files that are needed to build).
- **Visual Studio only**: NuGet packages are restored. (Restore needs to be explicit by the user on the CLI.)
- The project builds.
- The publish items are computed (the files that are needed to publish).
- The project is published (the computed files are copied to the publish destination).

When an ASP.NET Core project references `Microsoft.NET.Sdk.Web` in the project file, an `app_offline.htm` file is placed at the root of the web app directory. When the file is present, the ASP.NET Core Module gracefully shuts down the app and serves the `app_offline.htm` file during the deployment. For more information, see the ASP.NET Core Module configuration reference.

Basic command-line publishing

Command-line publishing works on all .NET Core-supported platforms and doesn't require Visual Studio. In the following examples, the .NET CLI's dotnet publish command

is run from the project directory (which contains the `.csproj` file). If the project folder isn't the current working directory, explicitly pass in the project file path. For example:

.NET CLI

```
dotnet publish C:\Webs\Web1
```

Run the following commands to create and publish a web app:

.NET CLI

```
dotnet new mvc
dotnet publish
```

The `dotnet publish` command produces a variation of the following output:

Console

```
C:\Webs\Web1>dotnet publish
Microsoft (R) Build Engine version {VERSION} for .NET Core
Copyright (C) Microsoft Corporation. All rights reserved.

  Restore completed in 36.81 ms for C:\Webs\Web1\Web1.csproj.
  Web1 -> C:\Webs\Web1\bin\Debug\{TARGET FRAMEWORK MONIKER}\Web1.dll
  Web1 -> C:\Webs\Web1\bin\Debug\{TARGET FRAMEWORK MONIKER}\Web1.Views.dll
  Web1 -> C:\Webs\Web1\bin\Debug\{TARGET FRAMEWORK MONIKER}\publish\
```

The default publish folder format is *bin\Debug\{TARGET FRAMEWORK MONIKER}\publish*. For example, *bin\Debug\netcoreapp2.2\publish*.

The following command specifies a `Release` build and the publishing directory:

.NET CLI

```
dotnet publish -c Release -o C:\MyWebs\test
```

The `dotnet publish` command calls MSBuild, which invokes the `Publish` target. Any parameters passed to `dotnet publish` are passed to MSBuild. The `-c` and `-o` parameters map to MSBuild's `Configuration` and `OutputPath` properties, respectively.

MSBuild properties can be passed using either of the following formats:

- `-p:<NAME>=<VALUE>`
- `/p:<NAME>=<VALUE>`

For example, the following command publishes a `Release` build to a network share. The network share is specified with forward slashes (*//r8/*) and works on all .NET Core supported platforms.

.NET CLI

```
dotnet publish -c Release /p:PublishDir=//r8/release/AdminWeb
```

Confirm that the published app for deployment isn't running. Files in the *publish* folder are locked when the app is running. Deployment can't occur because locked files can't be copied.

Publish profiles

This section uses Visual Studio 2019 or later to create a publishing profile. Once the profile is created, publishing from Visual Studio or the command line is available. Publish profiles can simplify the publishing process, and any number of profiles can exist.

Create a publish profile in Visual Studio by choosing one of the following paths:

- Right-click the project in **Solution Explorer** and select **Publish**.
- Select **Publish {PROJECT NAME}** from the **Build** menu.

The **Publish** tab of the app capabilities page is displayed. If the project lacks a publish profile, the **Pick a publish target** page is displayed. You're asked to select one of the following publish targets:

- Azure App Service
- Azure App Service on Linux
- Azure Virtual Machines
- Folder
- IIS, FTP, Web Deploy (for any web server)
- Import Profile

To determine the most appropriate publish target, see What publishing options are right for me.

When the **Folder** publish target is selected, specify a folder path to store the published assets. The default folder path is *bin\{PROJECT CONFIGURATION}\{TARGET FRAMEWORK MONIKER}\publish*. For example, *bin\Release\netcoreapp2.2\publish*. Select the **Create Profile** button to finish.

Once a publish profile is created, the **Publish** tab's content changes. The newly created profile appears in a drop-down list. Below the drop-down list, select **Create new profile** to create another new profile.

Visual Studio's publish tool produces a *Properties/PublishProfiles/{PROFILE NAME}.pubxml* MSBuild file describing the publish profile. The *.pubxml* file:

- Contains publish configuration settings and is consumed by the publishing process.
- Can be modified to customize the build and publish process.

When publishing to an Azure target, the *.pubxml* file contains your Azure subscription identifier. With that target type, adding this file to source control is discouraged. When publishing to a non-Azure target, it's safe to check in the *.pubxml* file.

Sensitive information (like the publish password) is encrypted on a per user/machine level. It's stored in the *Properties/PublishProfiles/{PROFILE NAME}.pubxml.user* file. Because this file can store sensitive information, it shouldn't be checked into source control.

For an overview of how to publish an ASP.NET Core web app, see Host and deploy ASP.NET Core. The MSBuild tasks and targets necessary to publish an ASP.NET Core web app are open-source in the dotnet/websdk repository.

The following commands can use folder, MSDeploy, and Kudu publish profiles. Because MSDeploy lacks cross-platform support, the following MSDeploy options are supported only on Windows.

Folder (works cross-platform):

.NET CLI

```
dotnet publish WebApplication.csproj /p:PublishProfile=<FolderProfileName>
```

.NET CLI

```
dotnet build WebApplication.csproj /p:DeployOnBuild=true /p:PublishProfile=
<FolderProfileName>
```

MSDeploy:

.NET CLI

```
dotnet publish WebApplication.csproj /p:PublishProfile=<MsDeployProfileName>
```

```
/p:Password=<DeploymentPassword>
```

.NET CLI

```
dotnet build WebApplication.csproj /p:DeployOnBuild=true /p:PublishProfile=
<MsDeployProfileName> /p:Password=<DeploymentPassword>
```

MSDeploy package:

.NET CLI

```
dotnet publish WebApplication.csproj /p:PublishProfile=
<MsDeployPackageProfileName>
```

.NET CLI

```
dotnet build WebApplication.csproj /p:DeployOnBuild=true /p:PublishProfile=
<MsDeployPackageProfileName>
```

In the preceding examples:

- `dotnet publish` and `dotnet build` support Kudu APIs to publish to Azure from any platform. Visual Studio publish supports the Kudu APIs, but it's supported by WebSDK for cross-platform publish to Azure.
- Don't pass `DeployOnBuild` to the `dotnet publish` command.

For more information, see Microsoft.NET.Sdk.Publish.

Add a publish profile to the project's *Properties/PublishProfiles* folder with the following content:

XML

```
<Project>
  <PropertyGroup>
    <PublishProtocol>Kudu</PublishProtocol>
    <PublishSiteName>nodewebapp</PublishSiteName>
    <UserName>username</UserName>
    <Password>password</Password>
  </PropertyGroup>
</Project>
```

Folder publish example

When publishing with a profile named *FolderProfile*, use any of the following commands:

.NET CLI

```
dotnet publish /p:Configuration=Release /p:PublishProfile=FolderProfile
```

.NET CLI

```
dotnet build /p:DeployOnBuild=true /p:PublishProfile=FolderProfile
```

Bash

```
msbuild /p:DeployOnBuild=true /p:PublishProfile=FolderProfile
```

The .NET CLI's dotnet build command calls `msbuild` to run the build and publish process. The `dotnet build` and `msbuild` commands are equivalent when passing in a folder profile. When calling `msbuild` directly on Windows, the .NET Framework version of MSBuild is used. Calling `dotnet build` on a non-folder profile:

- Invokes `msbuild`, which uses MSDeploy.
- Results in a failure (even when running on Windows). To publish with a non-folder profile, call `msbuild` directly.

The following folder publish profile was created with Visual Studio and publishes to a network share:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<!--
This file is used by the publish/package process of your Web project.
You can customize the behavior of this process by editing this
MSBuild file.
-->
<Project ToolsVersion="4.0"
xmlns="http://schemas.microsoft.com/developer/msbuild/2003">
  <PropertyGroup>
    <WebPublishMethod>FileSystem</WebPublishMethod>
    <PublishProvider>FileSystem</PublishProvider>
    <LastUsedBuildConfiguration>Release</LastUsedBuildConfiguration>
    <LastUsedPlatform>Any CPU</LastUsedPlatform>
    <SiteUrlToLaunchAfterPublish />
    <LaunchSiteAfterPublish>True</LaunchSiteAfterPublish>
    <ExcludeApp_Data>False</ExcludeApp_Data>
    <PublishFramework>netcoreapp1.1</PublishFramework>
    <ProjectGuid>c30c453c-312e-40c4-aec9-394a145dee0b</ProjectGuid>
    <publishUrl>\\r8\Release\AdminWeb</publishUrl>
```

```
    <DeleteExistingFiles>False</DeleteExistingFiles>
  </PropertyGroup>
</Project>
```

In the preceding example:

- The `<ExcludeApp_Data>` property is present merely to satisfy an XML schema requirement. The `<ExcludeApp_Data>` property has no effect on the publish process, even if there's an *App_Data* folder in the project root. The *App_Data* folder doesn't receive special treatment as it does in ASP.NET 4.x projects.
- The `<LastUsedBuildConfiguration>` property is set to `Release`. When publishing from Visual Studio, the value of `<LastUsedBuildConfiguration>` is set using the value when the publish process is started. `<LastUsedBuildConfiguration>` is special and shouldn't be overridden in an imported MSBuild file. This property can, however, be overridden from the command line using one of the following approaches.
  - Using the .NET CLI:

    .NET CLI

    ```
    dotnet publish /p:Configuration=Release
    /p:PublishProfile=FolderProfile
    ```

    .NET CLI

    ```
    dotnet build -c Release /p:DeployOnBuild=true
    /p:PublishProfile=FolderProfile
    ```

  - Using MSBuild:

    Bash

    ```
    msbuild /p:Configuration=Release /p:DeployOnBuild=true
    /p:PublishProfile=FolderProfile
    ```

Publish to an MSDeploy endpoint from the command line

The following example uses an ASP.NET Core web app created by Visual Studio named *AzureWebApp*. An Azure Apps publish profile is added with Visual Studio. For more information on how to create a profile, see the Publish profiles section.

To deploy the app using a publish profile, execute the `msbuild` command from a Visual Studio **Developer Command Prompt**. The command prompt is available in the *Visual Studio* folder of the **Start** menu on the Windows taskbar. For easier access, you can add the command prompt to the **Tools** menu in Visual Studio. For more information, see Developer Command Prompt for Visual Studio.

MSBuild uses the following command syntax:

Bash

```
msbuild {PATH}
    /p:DeployOnBuild=true
    /p:PublishProfile={PROFILE}
    /p:Username={USERNAME}
    /p:Password={PASSWORD}
```

- `{PATH}`: Path to the app's project file.
- `{PROFILE}`: Name of the publish profile.
- `{USERNAME}`: MSDeploy username. The `{USERNAME}` can be found in the publish profile.
- `{PASSWORD}`: MSDeploy password. Obtain the `{PASSWORD}` from the *{PROFILE}.PublishSettings* file. Download the *.PublishSettings* file from either:
  - **Solution Explorer**: Select **View** > **Cloud Explorer**. Connect with your Azure subscription. Open **App Services**. Right-click the app. Select **Download Publish Profile**.
  - Azure portal: Select **Get publish profile** in the web app's **Overview** panel.

The following example uses a publish profile named *AzureWebApp - Web Deploy*:

Bash

```
msbuild "AzureWebApp.csproj"
    /p:DeployOnBuild=true
    /p:PublishProfile="AzureWebApp - Web Deploy"
    /p:Username="$AzureWebApp"
    /p:Password="........."
```

A publish profile can also be used with the .NET CLI's dotnet msbuild command from a Windows command shell:

.NET CLI

```
dotnet msbuild "AzureWebApp.csproj"
    /p:DeployOnBuild=true
    /p:PublishProfile="AzureWebApp - Web Deploy"
```

```
    /p:Username="$AzureWebApp"
    /p:Password="........."
```

> **Important**
>
> The `dotnet msbuild` command is a cross-platform command and can compile ASP.NET Core apps on macOS and Linux. However, MSBuild on macOS and Linux isn't capable of deploying an app to Azure or other MSDeploy endpoints.

Set the environment

Include the `<EnvironmentName>` property in the publish profile (*.pubxml*) or project file to set the app's environment:

XML

```xml
<PropertyGroup>
  <EnvironmentName>Development</EnvironmentName>
</PropertyGroup>
```

If you require *web.config* transformations (for example, setting environment variables based on the configuration, profile, or environment), see Transform web.config.

Exclude files

When publishing ASP.NET Core web apps, the following assets are included:

- Build artifacts
- Folders and files matching the following globbing patterns:
  - `**\*.config` (for example, *web.config*)
  - `**\*.json` (for example, `appsettings.json`)
  - `wwwroot\**`

MSBuild supports globbing patterns. For example, the following `<Content>` element suppresses the copying of text (*.txt*) files in the *wwwroot\content* folder and its subfolders:

XML

```xml
<ItemGroup>
  <Content Update="wwwroot/content/**/*.txt" CopyToPublishDirectory="Never"
```

```
/>
</ItemGroup>
```

The preceding markup can be added to a publish profile or the `.csproj` file. When added to the `.csproj` file, the rule is added to all publish profiles in the project.

The following `<MsDeploySkipRules>` element excludes all files from the *wwwroot\content* folder:

XML

```
<ItemGroup>
  <MsDeploySkipRules Include="CustomSkipFolder">
    <ObjectName>dirPath</ObjectName>
    <AbsolutePath>wwwroot\\content</AbsolutePath>
  </MsDeploySkipRules>
</ItemGroup>
```

`<MsDeploySkipRules>` won't delete the *skip* targets from the deployment site. `<Content>` targeted files and folders are deleted from the deployment site. For example, suppose a deployed web app had the following files:

- `Views/Home/About1.cshtml`
- `Views/Home/About2.cshtml`
- `Views/Home/About3.cshtml`

If the following `<MsDeploySkipRules>` elements are added, those files wouldn't be deleted on the deployment site.

XML

```
<ItemGroup>
  <MsDeploySkipRules Include="CustomSkipFile">
    <ObjectName>filePath</ObjectName>
    <AbsolutePath>Views\\Home\\About1.cshtml</AbsolutePath>
  </MsDeploySkipRules>

  <MsDeploySkipRules Include="CustomSkipFile">
    <ObjectName>filePath</ObjectName>
    <AbsolutePath>Views\\Home\\About2.cshtml</AbsolutePath>
  </MsDeploySkipRules>

  <MsDeploySkipRules Include="CustomSkipFile">
    <ObjectName>filePath</ObjectName>
    <AbsolutePath>Views\\Home\\About3.cshtml</AbsolutePath>
  </MsDeploySkipRules>
</ItemGroup>
```

The preceding `<MsDeploySkipRules>` elements prevent the *skipped* files from being deployed. It won't delete those files once they're deployed.

The following `<Content>` element deletes the targeted files at the deployment site:

XML

```
<ItemGroup>
  <Content Update="Views/Home/About?.cshtml" CopyToPublishDirectory="Never"
/>
</ItemGroup>
```

Using command-line deployment with the preceding `<Content>` element yields a variation of the following output:

Console

```
MSDeployPublish:
  Starting Web deployment task from source:
manifest(C:\Webs\Web1\obj\Release\{TARGET FRAMEWORK
MONIKER}\PubTmp\Web1.SourceManifest.
  xml) to Destination: auto().
  Deleting file (Web11112\Views\Home\About1.cshtml).
  Deleting file (Web11112\Views\Home\About2.cshtml).
  Deleting file (Web11112\Views\Home\About3.cshtml).
  Updating file (Web11112\web.config).
  Updating file (Web11112\Web1.deps.json).
  Updating file (Web11112\Web1.dll).
  Updating file (Web11112\Web1.pdb).
  Updating file (Web11112\Web1.runtimeconfig.json).
  Successfully executed Web deployment task.
  Publish Succeeded.
Done Building Project "C:\Webs\Web1\Web1.csproj" (default targets).
```

Include files

The following sections outline different approaches for file inclusion at publish time. The General file inclusion section uses the `DotNetPublishFiles` item, which is provided by a publish targets file in the Web SDK. The Selective file inclusion section uses the `ResolvedFileToPublish` item, which is provided by a publish targets file in the .NET Core SDK. Because the Web SDK depends on the .NET Core SDK, either item can be used in an ASP.NET Core project.

General file inclusion

The following example's `<ItemGroup>` element demonstrates copying a folder located outside of the project directory to a folder of the published site. Any files added to the following markup's `<ItemGroup>` are included by default.

XML

```
<ItemGroup>
  <_CustomFiles Include="$(MSBuildProjectDirectory)/../images/**/*" />
  <DotNetPublishFiles Include="@(_CustomFiles)">
    <DestinationRelativePath>wwwroot/images/%(RecursiveDir)%(Filename)%
(Extension)</DestinationRelativePath>
  </DotNetPublishFiles>
</ItemGroup>
```

The preceding markup:

- Can be added to the `.csproj` file or the publish profile. If it's added to the `.csproj` file, it's included in each publish profile in the project.
- Declares a `_CustomFiles` item to store files matching the `Include` attribute's globbing pattern. The *images* folder referenced in the pattern is located outside of the project directory. A reserved property, named `$(MSBuildProjectDirectory)`, resolves to the project file's absolute path.
- Provides a list of files to the `DotNetPublishFiles` item. By default, the item's `<DestinationRelativePath>` element is empty. The default value is overridden in the markup and uses well-known item metadata such as `%(RecursiveDir)`. The inner text represents the *wwwroot/images* folder of the published site.

Selective file inclusion

The highlighted markup in the following example demonstrates:

- Copying a file located outside of the project into the published site's *wwwroot* folder. The file name of *ReadMe2.md* is maintained.
- Excluding the *wwwroot\Content* folder.
- Excluding *Views\Home\About2.cshtml*.

XML

```
<?xml version="1.0" encoding="utf-8"?>
<Project ToolsVersion="4.0"
         xmlns="http://schemas.microsoft.com/developer/msbuild/2003">
  <PropertyGroup>
    <WebPublishMethod>FileSystem</WebPublishMethod>
    <PublishProvider>FileSystem</PublishProvider>
    <LastUsedBuildConfiguration>Release</LastUsedBuildConfiguration>
```

```
    <LastUsedPlatform>Any CPU</LastUsedPlatform>
    <SiteUrlToLaunchAfterPublish />
    <LaunchSiteAfterPublish>True</LaunchSiteAfterPublish>
    <ExcludeApp_Data>False</ExcludeApp_Data>
    <PublishFramework />
    <ProjectGuid>afa9f185-7ce0-4935-9da1-ab676229d68a</ProjectGuid>
    <publishUrl>bin\Release\PublishOutput</publishUrl>
    <DeleteExistingFiles>False</DeleteExistingFiles>
  </PropertyGroup>
  <ItemGroup>
    <ResolvedFileToPublish Include="..\ReadMe2.md">
      <RelativePath>wwwroot\ReadMe2.md</RelativePath>
    </ResolvedFileToPublish>

    <Content Update="wwwroot\Content\**\*" CopyToPublishDirectory="Never" />
    <Content Update="Views\Home\About2.cshtml"
CopyToPublishDirectory="Never" />
  </ItemGroup>
</Project>
```

The preceding example uses the `ResolvedFileToPublish` item, whose default behavior is to always copy the files provided in the `Include` attribute to the published site. Override the default behavior by including a `<CopyToPublishDirectory>` child element with inner text of either `Never` or `PreserveNewest`. For example:

XML

```
<ResolvedFileToPublish Include="..\ReadMe2.md">
  <RelativePath>wwwroot\ReadMe2.md</RelativePath>
  <CopyToPublishDirectory>PreserveNewest</CopyToPublishDirectory>
</ResolvedFileToPublish>
```

For more deployment samples, see the Web SDK README file.

Run a target before or after publishing

The built-in `BeforePublish` and `AfterPublish` targets execute a target before or after the publish target. Add the following elements to the publish profile to log console messages both before and after publishing:

XML

```
<Target Name="CustomActionsBeforePublish" BeforeTargets="BeforePublish">
    <Message Text="Inside BeforePublish" Importance="high" />
  </Target>
  <Target Name="CustomActionsAfterPublish" AfterTargets="AfterPublish">
```

```
    <Message Text="Inside AfterPublish" Importance="high" />
</Target>
```

Publish to a server using an untrusted certificate

Add the `<AllowUntrustedCertificate>` property with a value of `True` to the publish profile:

XML

```
<PropertyGroup>
  <AllowUntrustedCertificate>True</AllowUntrustedCertificate>
</PropertyGroup>
```

The Kudu service

To view the files in an Azure App Service web app deployment, use the Kudu service. Append the `scm` token to the web app name. For example:

Expand table

URL	Result
`http://mysite.azurewebsites.net/`	Web App
`http://mysite.scm.azurewebsites.net/`	Kudu service

Select the Debug Console menu item to view, edit, delete, or add files.

ASP.NET Core directory structure

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

The *publish* directory contains the app's deployable assets produced by the dotnet publish command. The directory contains:

- Application files
- Configuration files
- Static assets
- Packages
- A runtime (self-contained deployment only)

Expand table

App Type	Directory Structure
Framework-dependent Executable (FDE)	• publish† ◦ Views† MVC apps; if views aren't precompiled ◦ Pages† MVC or Razor Pages apps, if pages aren't precompiled ◦ wwwroot† ◦ *.dll files ◦ {ASSEMBLY NAME}.deps.json ◦ {ASSEMBLY NAME}.dll ◦ {ASSEMBLY NAME}{.EXTENSION}.exe extension on Windows, no extension on macOS or Linux ◦ {ASSEMBLY NAME}.pdb ◦ {ASSEMBLY NAME}.runtimeconfig.json ◦ web.config (IIS deployments) ◦ createdump (Linux createdump utility) ◦ *.so (Linux shared object library) ◦ *.a (macOS archive) ◦ *.dylib (macOS dynamic library)

App Type	Directory Structure
Self-contained Deployment (SCD)	• publish† ◦ Views† MVC apps, if views aren't precompiled ◦ Pages† MVC or Razor Pages apps, if pages aren't precompiled ◦ wwwroot† ◦ *.dll files ◦ {ASSEMBLY NAME}.deps.json ◦ {ASSEMBLY NAME}.dll ◦ {ASSEMBLY NAME}{.EXTENSION} .exe extension on Windows, no extension on macOS or Linux ◦ {ASSEMBLY NAME}.pdb ◦ {ASSEMBLY NAME}.runtimeconfig.json ◦ web.config (IIS deployments)

†Indicates a directory

The *publish* directory represents the *content root path*, also called the *application base path*, of the deployment. Whatever name is given to the *publish* directory of the deployed app on the server, its location serves as the server's physical path to the hosted app.

The *wwwroot* directory, if present, only contains static assets.

ASP.NET Core security topics

Article • 11/05/2024

ASP.NET Core enables developers to configure and manage security. The following list provides links to security topics:

- Authentication
- Authorization
- Data protection
- HTTPS enforcement
- Safe storage of app secrets in development
- XSRF/CSRF prevention
- Cross Origin Resource Sharing (CORS)
- Cross-Site Scripting (XSS) attacks

These security features allow you to build robust and secure ASP.NET Core apps.

For Blazor security coverage, which adds to or supersedes the guidance in this node, see ASP.NET Core Blazor authentication and authorization and the other articles in Blazor's *Security and Identity* node.

ASP.NET Core security features

ASP.NET Core provides many tools and libraries to secure ASP.NET Core apps such as built-in identity providers and third-party identity services such as Facebook, Twitter, and LinkedIn. ASP.NET Core provides several approaches to store app secrets.

Authentication vs. Authorization

Authentication is a process in which a user provides credentials that are then compared to those stored in an operating system, database, app or resource. If they match, users authenticate successfully, and can then perform actions that they're authorized for, during an authorization process. The authorization refers to the process that determines what a user is allowed to do.

Another way to think of authentication is to consider it as a way to enter a space, such as a server, database, app or resource, while authorization is which actions the user can perform to which objects inside that space (server, database, or app).

Common Vulnerabilities in software

ASP.NET Core and EF contain features that help you secure your apps and prevent security breaches. The following list of links takes you to documentation detailing techniques to avoid the most common security vulnerabilities in web apps:

- Cross-Site Scripting (XSS) attacks
- SQL injection attacks
- Cross-Site Request Forgery (XSRF/CSRF) attacks
- Open redirect attacks

There are more vulnerabilities that you should be aware of. For more information, see the other articles in the **Security and Identity** section of the table of contents.

Secure authentication flows

We recommend using the most secure secure authentication option. For Azure services, the most secure authentication is managed identities.

Avoid Resource Owner Password Credentials Grant because it:

- Exposes the user's password to the client.
- Is a significant security risk.
- Should only be used when other authentication flows are not possible.

Managed identities are a secure way to authenticate to services without needing to store credentials in code, environment variables, or configuration files. Managed identities are available for Azure services, and can be used with Azure SQL, Azure Storage, and other Azure services:

- Managed identities in Microsoft Entra for Azure SQL
- Managed identities for App Service and Azure Functions
- Secure authentication flows

When the app is deployed to a test server, an environment variable can be used to set the connection string to a test database server. For more information, see Configuration. Environment variables are generally stored in plain, unencrypted text. If the machine or process is compromised, environment variables can be accessed by untrusted parties. We recommend against using environment variables to store a production connection string as it's not the most secure approach.

Configuration data guidelines:

- Never store passwords or other sensitive data in configuration provider code or in plain text configuration files. The Secret Manager tool can be used to store secrets in development.

- Don't use production secrets in development or test environments.
- Specify secrets outside of the project so that they can't be accidentally committed to a source code repository.

Configuration data guidelines:

- Never store passwords or other sensitive data in configuration provider code or in plain text configuration files. The Secret Manager tool can be used to store secrets in development.
- Don't use production secrets in development or test environments.
- Specify secrets outside of the project so that they can't be accidentally committed to a source code repository.

Overview of ASP.NET Core authentication

Article • 10/18/2023

By Mike Rousos

Authentication is the process of determining a user's identity. Authorization is the process of determining whether a user has access to a resource. In ASP.NET Core, authentication is handled by the authentication service, IAuthenticationService, which is used by authentication middleware. The authentication service uses registered authentication handlers to complete authentication-related actions. Examples of authentication-related actions include:

- Authenticating a user.
- Responding when an unauthenticated user tries to access a restricted resource.

The registered authentication handlers and their configuration options are called "schemes".

Authentication schemes are specified by registering authentication services in `Program.cs`:

- By calling a scheme-specific extension method after a call to AddAuthentication, such as AddJwtBearer or AddCookie. These extension methods use AuthenticationBuilder.AddScheme to register schemes with appropriate settings.
- Less commonly, by calling `AuthenticationBuilder.AddScheme` directly.

For example, the following code registers authentication services and handlers for cookie and JWT bearer authentication schemes:

C#

```
builder.Services.AddAuthentication(JwtBearerDefaults.AuthenticationScheme)
    .AddJwtBearer(JwtBearerDefaults.AuthenticationScheme,
        options => builder.Configuration.Bind("JwtSettings", options))
    .AddCookie(CookieAuthenticationDefaults.AuthenticationScheme,
        options => builder.Configuration.Bind("CookieSettings", options));
```

The `AddAuthentication` parameter JwtBearerDefaults.AuthenticationScheme is the name of the scheme to use by default when a specific scheme isn't requested.

If multiple schemes are used, authorization policies (or authorization attributes) can specify the authentication scheme (or schemes) they depend on to authenticate the

user. In the example above, the cookie authentication scheme could be used by specifying its name (CookieAuthenticationDefaults.AuthenticationScheme by default, though a different name could be provided when calling `AddCookie`).

In some cases, the call to `AddAuthentication` is automatically made by other extension methods. For example, when using ASP.NET Core Identity, `AddAuthentication` is called internally.

The Authentication middleware is added in `Program.cs` by calling UseAuthentication. Calling `UseAuthentication` registers the middleware that uses the previously registered authentication schemes. Call `UseAuthentication` before any middleware that depends on users being authenticated.

Authentication concepts

Authentication is responsible for providing the ClaimsPrincipal for authorization to make permission decisions against. There are multiple authentication scheme approaches to select which authentication handler is responsible for generating the correct set of claims:

- Authentication scheme
- The default authentication scheme, discussed in the next two sections.
- Directly set HttpContext.User.

When there is only a single authentication scheme registered, it becomes the default scheme. If multiple schemes are registered and the default scheme isn't specified, a scheme must be specified in the authorize attribute, otherwise, the following error is thrown:

> InvalidOperationException: No authenticationScheme was specified, and there was no DefaultAuthenticateScheme found. The default schemes can be set using either AddAuthentication(string defaultScheme) or AddAuthentication(Action<AuthenticationOptions> configureOptions).

`DefaultScheme`

When there is only a single authentication scheme registered, the single authentication scheme:

- Is automatically used as the DefaultScheme.
- Eliminates the need to specify the `DefaultScheme` in AddAuthentication(IServiceCollection) or

AddAuthenticationCore(IServiceCollection).

To disable automatically using the single authentication scheme as the `DefaultScheme`, call `AppContext.SetSwitch("Microsoft.AspNetCore.Authentication.SuppressAutoDefaultScheme")`.

Authentication scheme

The authentication scheme can select which authentication handler is responsible for generating the correct set of claims. For more information, see Authorize with a specific scheme.

An authentication scheme is a name that corresponds to:

- An authentication handler.
- Options for configuring that specific instance of the handler.

Schemes are useful as a mechanism for referring to the authentication, challenge, and forbid behaviors of the associated handler. For example, an authorization policy can use scheme names to specify which authentication scheme (or schemes) should be used to authenticate the user. When configuring authentication, it's common to specify the default authentication scheme. The default scheme is used unless a resource requests a specific scheme. It's also possible to:

- Specify different default schemes to use for authenticate, challenge, and forbid actions.
- Combine multiple schemes into one using policy schemes.

Authentication handler

An authentication handler:

- Is a type that implements the behavior of a scheme.
- Is derived from IAuthenticationHandler or AuthenticationHandler<TOptions>.
- Has the primary responsibility to authenticate users.

Based on the authentication scheme's configuration and the incoming request context, authentication handlers:

- Construct AuthenticationTicket objects representing the user's identity if authentication is successful.
- Return 'no result' or 'failure' if authentication is unsuccessful.

- Have methods for challenge and forbid actions for when users attempt to access resources:
  - They're unauthorized to access (forbid).
  - When they're unauthenticated (challenge).

`RemoteAuthenticationHandler<TOptions>` vs `AuthenticationHandler<TOptions>`

RemoteAuthenticationHandler<TOptions> is the class for authentication that requires a remote authentication step. When the remote authentication step is finished, the handler calls back to the `CallbackPath` set by the handler. The handler finishes the authentication step using the information passed to the HandleRemoteAuthenticateAsync callback path. OAuth 2.0 and OIDC both use this pattern. JWT and cookies don't since they can directly use the bearer header and cookie to authenticate. The remotely hosted provider in this case:

- Is the authentication provider.
- Examples include Facebook, Twitter, Google, Microsoft, and any other OIDC provider that handles authenticating users using the handlers mechanism.

Authenticate

An authentication scheme's authenticate action is responsible for constructing the user's identity based on request context. It returns an AuthenticateResult indicating whether authentication was successful and, if so, the user's identity in an authentication ticket. See AuthenticateAsync. Authenticate examples include:

- A cookie authentication scheme constructing the user's identity from cookies.
- A JWT bearer scheme deserializing and validating a JWT bearer token to construct the user's identity.

Challenge

An authentication challenge is invoked by Authorization when an unauthenticated user requests an endpoint that requires authentication. An authentication challenge is issued, for example, when an anonymous user requests a restricted resource or follows a login link. Authorization invokes a challenge using the specified authentication scheme(s), or the default if none is specified. See ChallengeAsync. Authentication challenge examples include:

- A cookie authentication scheme redirecting the user to a login page.

- A JWT bearer scheme returning a 401 result with a `www-authenticate: bearer` header.

A challenge action should let the user know what authentication mechanism to use to access the requested resource.

Forbid

An authentication scheme's forbid action is called by Authorization when an authenticated user attempts to access a resource they're not permitted to access. See ForbidAsync. Authentication forbid examples include:

- A cookie authentication scheme redirecting the user to a page indicating access was forbidden.
- A JWT bearer scheme returning a 403 result.
- A custom authentication scheme redirecting to a page where the user can request access to the resource.

A forbid action can let the user know:

- They're authenticated.
- They're not permitted to access the requested resource.

See the following links for differences between challenge and forbid:

- Challenge and forbid with an operational resource handler.
- Differences between challenge and forbid.

Authentication providers per tenant

ASP.NET Core doesn't have a built-in solution for multi-tenant authentication. While it's possible for customers to write one using the built-in features, we recommend customers consider Orchard Core, ABP Framework, or Finbuckle.MultiTenant for multi-tenant authentication.

Orchard Core is:

- An open-source, modular, and multi-tenant app framework built with ASP.NET Core.
- A content management system (CMS) built on top of that app framework.

See the Orchard Core source for an example of authentication providers per tenant.

ABP Framework supports various architectural patterns including modularity, microservices, domain driven design, and multi-tenancy. See ABP Framework source on GitHub.

Finbuckle.MultiTenant:

- Open source
- Provides tenant resolution
- Lightweight
- Provides data isolation
- Configure app behavior uniquely for each tenant

Additional resources

- Authorize with a specific scheme in ASP.NET Core
- Policy schemes in ASP.NET Core
- Create an ASP.NET Core app with user data protected by authorization
- Globally require authenticated users
- GitHub issue on using multiple authentication schemes

Choose an identity management solution

Article • 08/30/2023

Most web apps support authentication to ensure that users are who they claim to be. A *user* might be a person or another app. Management of access ensures users are only able to see and modify the information they're authorized to see and modify. For example, an end user shouldn't have access to the administrative section of a website. Identity management solutions are built to handle the requirements of authentication and authorization-related tasks. To learn more about identity management, see What is identity and access management?. Many identity management solutions for .NET web apps are available, each with different capabilities and requirements to use or install. This article provides guidance on how to choose the right solution.

Basic identity management with ASP.NET Core Identity

ASP.NET Core ships with a built-in authentication provider: ASP.NET Core Identity. The provider includes the APIs, UI, and backend database configuration to support managing user identities, storing user credentials, and granting or revoking permissions. Other features it supports include:

- External logins
- Two-factor authentication (2FA)
- Password management
- Account lockout and reactivation
- Authenticator apps

For most scenarios, this may be the only provider needed.

To learn more:

- Read the Introduction to Identity on ASP.NET Core
- Follow a tutorial to build your own secure .NET web app: Secure a .NET web app with the ASP.NET Core Identity framework.

In other scenarios, a server or service that manages authentication and identity may be beneficial.

Determine if an OIDC server is needed

Web apps require a way to *remember* past actions because the web, by default, is stateless. Otherwise, users would be forced to enter their credentials every time they navigated to a new page. The common solution for remembering state is *cookies*, a browser-based mechanism for storing data. The web server sends the initial cookie, then the browser stores it and sends it back with each request. This is done automatically without the need for the developer to write any code. Cookies are easy to use and built into the browser but are designed for use within a single website or web domain. The default solution that is built into ASP.NET Core uses cookie-based authentication.

Tokens are containers with metadata that are explicitly passed through the headers or body of HTTP requests. The main advantage of tokens over cookies is that they are not tied to a specific app or domain. Instead, tokens are usually *signed* with asymmetric cryptography. For example, OIDC servers issue tokens with information about identity using the JSON Web Token (JWT) format which includes signing. Asymmetric cryptography uses a combination of a private key known only to the signer, and a public key which everyone can know. Tokens may also be encrypted.

The signed token can't be tampered with due to the private key. The public key:

- Makes it possible to validate the token to ensure it hasn't been changed.
- Guarantees that it was generated by the entity holding the private key.

The main disadvantage to using tokens is that they require a service (typically an OIDC server) to both issue and provide validation for tokens. The service must be installed, configured, and maintained.

A common reason an OIDC server is required is for applications that expose web-based APIs that are consumed by other apps. For exposed web-based APIs, client UIs such as Single Page Applications (SPA), mobile clients, and desktop clients are considered to be part of the same app. SPA examples include Angular, React, and Blazor WebAssembly. If apps other than your web app or any client UIs must make a secure API call to your app, you'll likely want to use tokens. If you only have client UIs, ASP.NET Core Identity provides the option to acquire a token during authentication. The authentication token issued by ASP.NET Core Identity:

- Can be used by mobile and desktop clients. Cookies are preferred over tokens for both security and simplicity.
- Isn't suitable for managing access from third-party apps.

Another reason an OIDC server is required is for sharing sign-ins with other apps. Commonly referred to as *single sign on*, this feature enables users to:

- Sign in once with a web app's form.
- Use the resulting credentials to authenticate with other apps without having to sign-in again or choose a different password.

An OIDC server is typically preferred to provide a secure and scalable solution for single sign on.

For apps that don't share logins with other apps, the simplest way to quickly secure an app is to use the built-in ASP.NET Core Identity provider. Otherwise, an OIDC server provided by a third-party identity management solution is needed. OIDC servers are available as:

- Products you install on your server, called *self-host*.
- Containers run in a host like Docker.
- Web-based services you integrate with to manage identity.

Some solutions are free and open source, while others are commercially licensed. See identity management solutions for a list of available options. It's possible that your organization already uses an identity provider. In that case, it may make sense to use the existing provider instead of going with a different solution. All of the major solutions provide documentation for configuring ASP.NET Core to use their product or service.

Disconnected scenarios

Many solutions, such as Microsoft Entra ID, are cloud-based and require an Internet connection to work. If your environment doesn't allow Internet connectivity, you won't be able to use the service.

ASP.NET Core Identity works perfectly well in disconnected scenarios, such as:

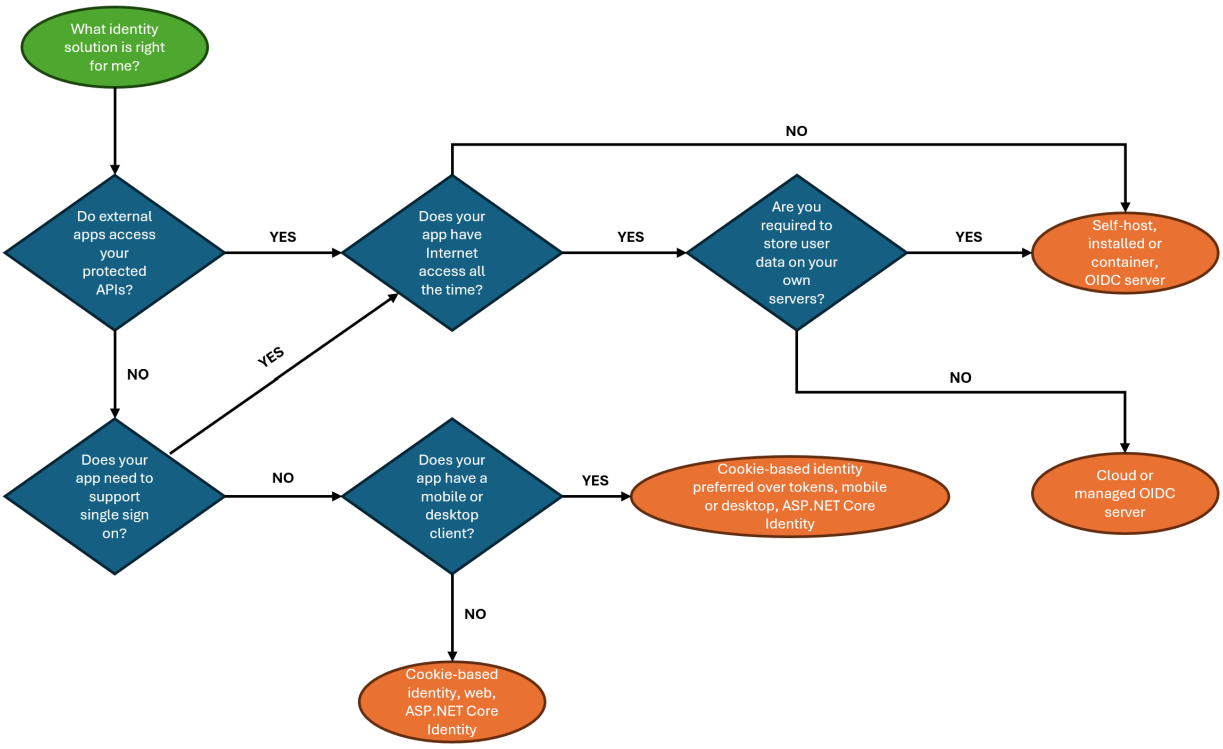
- The app can't access the Internet.
- The app must still function on the local network even if the Internet is disconnected.

If you require a full OIDC server for a disconnected scenario, choose one of the following options:

- A solution that allows you to install and run the service on your own machines.
- Run the authentication service locally as a container.

Decide where user data such as sign-ins are stored

Another important factor to consider is where the user sign-in data is stored. Many developers choose external, cloud-based services like Microsoft Entra ID to manage identity. A cloud-based service provider:



- Takes on the responsibilities of securely storing data.
- keeps the software up to date with the latest security patches and releases.
- Complies with privacy regulations.

Others prefer to store data on their own servers due to regulations, compliance, policy, or other reasons.

If the data is stored on your servers, you'll most likely need to choose an installable or container-based solution.

Identity vs OIDC server

Use the following diagram to help you decide whether to use the ASP.NET Core Identity system or an OIDC server for authentication and authorization:

The following table lists some of the things to consider when choosing your identity management solution.

Expand table

Feature	Self-host (infrastructure or container)	Cloud
App integration	Local solutions that are implemented as libraries or frameworks can often be integrated directly in your own app. Container-based solutions require a hand-off to occur between your web app and the container-based service.	Cloud-based solutions typically integrate at specific points in your sign-in flow and provide configuration to update the UI to match your theme, but the level of customization available is limited.
Configuration	Self host solutions require configuring the software for the environment in addition to setting up how you want to manage identities. Container-based solutions typically provide a web-based UI for configuration.	Cloud-based solutions typically provide a web-based UI for configuration.
Customization	Self-host solutions are usually highly customizable, including code-based changes. Although containerized solutions provide extensibility options, they are often more limited.	Cloud-based services allow customization, but it's typically limited to configuration-based changes.
Maintenance	Installed products require a dedicated resource to ensure all security patches are applied in a timely fashion and to manage upgrades. The upgrade and patch process for containers is usually lower-friction and involves simply installing the provided container image.	The service provider maintains their cloud-based solution, including applying needed patches and handling upgrades.
User credentials storage	You are responsible for data governance and handling breaches.	Managing the risks associated with handling user credentials, and complying with regulations. is delegated to the service provider.

For more information about available options, see Identity management solutions for ASP.NET Core.

Introduction to Identity on ASP.NET Core

Article • 08/30/2024

By Rick Anderson

ASP.NET Core Identity:

- Is an API that supports user interface (UI) login functionality.
- Manages users, passwords, profile data, roles, claims, tokens, email confirmation, and more.

Users can create an account with the login information stored in Identity or they can use an external login provider. Supported external login providers include Facebook, Google, Microsoft Account, and Twitter.

For information on how to globally require all users to be authenticated, see Require authenticated users.

The Identity source code is available on GitHub. Scaffold Identity and view the generated files to review the template interaction with Identity.

Identity is typically configured using a SQL Server database to store user names, passwords, and profile data. Alternatively, another persistent store can be used, for example, Azure Table Storage.

In this topic, you learn how to use Identity to register, log in, and log out a user. Note: the templates treat username and email as the same for users. For more detailed instructions about creating apps that use Identity, see Next Steps.

ASP.NET Core Identity isn't related to the Microsoft identity platform. Microsoft identity platform is:

- An evolution of the Azure Active Directory (Azure AD) developer platform.
- An alternative identity solution for authentication and authorization in ASP.NET Core apps.

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Microsoft Entra ID
- Azure Active Directory B2C (Azure AD B2C)
- Duende Identity Server

Duende Identity Server is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. Duende Identity Server enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

> **Important**
>
> Duende Software might require you to pay a license fee for production use of Duende Identity Server. For more information, see Migrate from ASP.NET Core 5.0 to 6.0.

For more information, see the Duende Identity Server documentation (Duende Software website).

View or download the sample code (how to download).

Create a Web app with authentication

Create an ASP.NET Core Web Application project with Individual User Accounts.

Visual Studio

- Select the **ASP.NET Core Web App** template. Name the project **WebApp1** to have the same namespace as the project download. Click **OK**.
- In the **Authentication type** input, select **Individual User Accounts**.

The generated project provides ASP.NET Core Identity as a Razor class library. The Identity Razor class library exposes endpoints with the `Identity` area. For example:

- /Identity/Account/Login
- /Identity/Account/Logout
- /Identity/Account/Manage

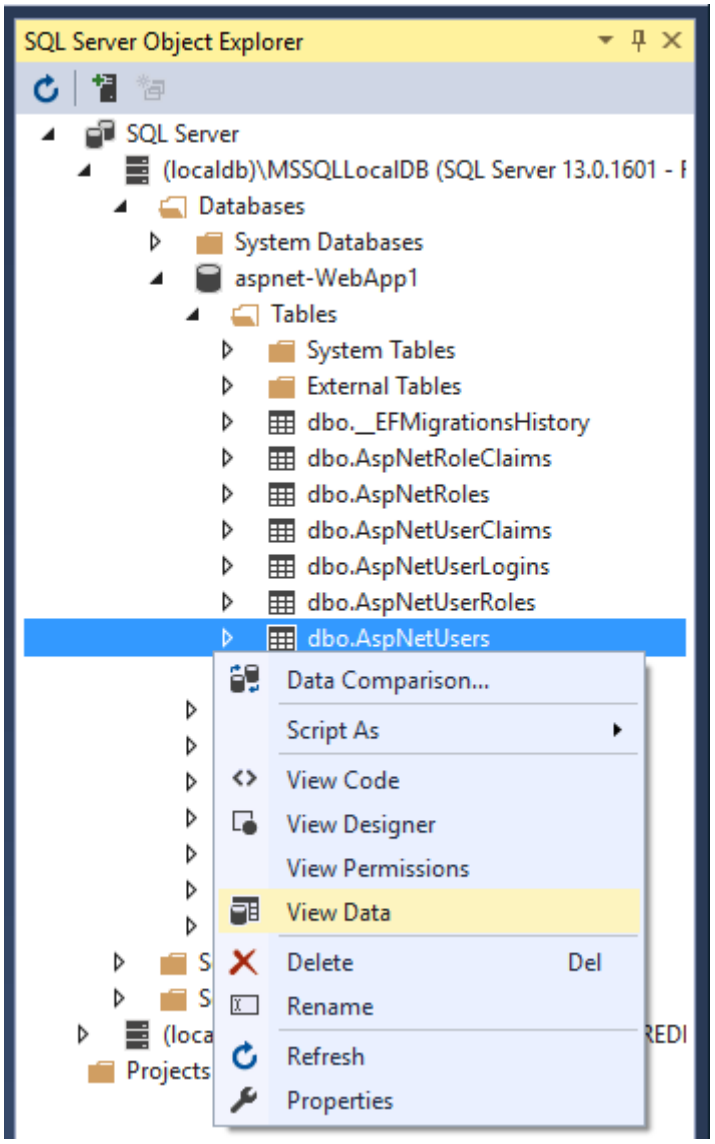
Apply migrations

Apply the migrations to initialize the database.

Visual Studio

Run the following command in the Package Manager Console (PMC):

```
Update-Database
```



Test Register and Login

Run the app and register a user. Depending on your screen size, you might need to select the navigation toggle button to see the **Register** and **Login** links.

View the Identity database

Visual Studio

- From the **View** menu, select **SQL Server Object Explorer** (SSOX).
- Navigate to **(localdb)MSSQLLocalDB(SQL Server 13)**. Right-click on **dbo.AspNetUsers** > **View Data**:

Configure Identity services

Services are added in `Program.cs`. The typical pattern is to call methods in the following order:

1. `Add{Service}`
2. `builder.Services.Configure{Service}`

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using WebApp1.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
```

```
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

builder.Services.Configure<IdentityOptions>(options =>
{
    // Password settings.
    options.Password.RequireDigit = true;
    options.Password.RequireLowercase = true;
    options.Password.RequireNonAlphanumeric = true;
    options.Password.RequireUppercase = true;
    options.Password.RequiredLength = 6;
    options.Password.RequiredUniqueChars = 1;

    // Lockout settings.
    options.Lockout.DefaultLockoutTimeSpan = TimeSpan.FromMinutes(5);
    options.Lockout.MaxFailedAccessAttempts = 5;
    options.Lockout.AllowedForNewUsers = true;

    // User settings.
    options.User.AllowedUserNameCharacters =
    "abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ0123456789-._@+";
    options.User.RequireUniqueEmail = false;
});

builder.Services.ConfigureApplicationCookie(options =>
{
    // Cookie settings
    options.Cookie.HttpOnly = true;
    options.ExpireTimeSpan = TimeSpan.FromMinutes(5);

    options.LoginPath = "/Identity/Account/Login";
    options.AccessDeniedPath = "/Identity/Account/AccessDenied";
    options.SlidingExpiration = true;
});

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();
```

```
app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The preceding code configures Identity with default option values. Services are made available to the app through dependency injection.

Identity is enabled by calling UseAuthentication. `UseAuthentication` adds authentication middleware to the request pipeline.

The template-generated app doesn't use authorization. `app.UseAuthorization` is included to ensure it's added in the correct order should the app add authorization. `UseRouting`, `UseAuthentication`, and `UseAuthorization` must be called in the order shown in the preceding code.

For more information on `IdentityOptions`, see IdentityOptions and Application Startup.

Scaffold Register, Login, LogOut, and RegisterConfirmation

Visual Studio

Add the `Register`, `Login`, `LogOut`, and `RegisterConfirmation` files. Follow the Scaffold identity into a Razor project with authorization instructions to generate the code shown in this section.

Examine Register

When a user clicks the **Register** button on the `Register` page, the `RegisterModel.OnPostAsync` action is invoked. The user is created by CreateAsync(TUser) on the `_userManager` object:

C#

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    ExternalLogins = (await
```

```
_signInManager.GetExternalAuthenticationSchemesAsync())
                                            .ToList();
    if (ModelState.IsValid)
    {
        var user = new IdentityUser { UserName = Input.Email, Email =
Input.Email };
        var result = await _userManager.CreateAsync(user, Input.Password);
        if (result.Succeeded)
        {
            _logger.LogInformation("User created a new account with
password.");

            var code = await
_userManager.GenerateEmailConfirmationTokenAsync(user);
            code =
WebEncoders.Base64UrlEncode(Encoding.UTF8.GetBytes(code));
            var callbackUrl = Url.Page(
                "/Account/ConfirmEmail",
                pageHandler: null,
                values: new { area = "Identity", userId = user.Id, code =
code },
                protocol: Request.Scheme);

            await _emailSender.SendEmailAsync(Input.Email, "Confirm your
email",
                $"Please confirm your account by <a
href='{HtmlEncoder.Default.Encode(callbackUrl)}'>clicking here</a>.");

            if (_userManager.Options.SignIn.RequireConfirmedAccount)
            {
                return RedirectToPage("RegisterConfirmation",
                                      new { email = Input.Email });
            }
            else
            {
                await _signInManager.SignInAsync(user, isPersistent: false);
                return LocalRedirect(returnUrl);
            }
        }
        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }

    // If we got this far, something failed, redisplay form
    return Page();
}
```

Disable default account verification

With the default templates, the user is redirected to the `Account.RegisterConfirmation` where they can select a link to have the account confirmed. The default `Account.RegisterConfirmation` is used ***only*** for testing, automatic account verification should be disabled in a production app.

To require a confirmed account and prevent immediate login at registration, set `DisplayConfirmAccountLink = false` in `/Areas/Identity/Pages/Account/RegisterConfirmation.cshtml.cs`:

C#

```
[AllowAnonymous]
public class RegisterConfirmationModel : PageModel
{
    private readonly UserManager<IdentityUser> _userManager;
    private readonly IEmailSender _sender;

    public RegisterConfirmationModel(UserManager<IdentityUser> userManager,
IEmailSender sender)
    {
        _userManager = userManager;
        _sender = sender;
    }

    public string Email { get; set; }

    public bool DisplayConfirmAccountLink { get; set; }

    public string EmailConfirmationUrl { get; set; }

    public async Task<IActionResult> OnGetAsync(string email, string
returnUrl = null)
    {
        if (email == null)
        {
            return RedirectToPage("/Index");
        }

        var user = await _userManager.FindByEmailAsync(email);
        if (user == null)
        {
            return NotFound($"Unable to load user with email '{email}'.");
        }

        Email = email;
        // Once you add a real email sender, you should remove this code
that lets you confirm the account
        DisplayConfirmAccountLink = false;
        if (DisplayConfirmAccountLink)
        {
            var userId = await _userManager.GetUserIdAsync(user);
            var code = await
```

```
_userManager.GenerateEmailConfirmationTokenAsync(user);
            code =
WebEncoders.Base64UrlEncode(Encoding.UTF8.GetBytes(code));
            EmailConfirmationUrl = Url.Page(
                "/Account/ConfirmEmail",
                pageHandler: null,
                values: new { area = "Identity", userId = userId, code =
code, returnUrl = returnUrl },
                protocol: Request.Scheme);
        }

        return Page();
    }
}
```

Log in

The Login form is displayed when:

- The **Log in** link is selected.
- A user attempts to access a restricted page that they aren't authorized to access **or** when they haven't been authenticated by the system.

When the form on the Login page is submitted, the `OnPostAsync` action is called. `PasswordSignInAsync` is called on the `_signInManager` object.

C#

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");

    if (ModelState.IsValid)
    {
        // This doesn't count login failures towards account lockout
        // To enable password failures to trigger account lockout,
        // set lockoutOnFailure: true
        var result = await _signInManager.PasswordSignInAsync(Input.Email,
                            Input.Password, Input.RememberMe,
lockoutOnFailure: true);
        if (result.Succeeded)
        {
            _logger.LogInformation("User logged in.");
            return LocalRedirect(returnUrl);
        }
        if (result.RequiresTwoFactor)
        {
            return RedirectToPage("./LoginWith2fa", new
            {
                ReturnUrl = returnUrl,
```

```
                RememberMe = Input.RememberMe
            });
        }
        if (result.IsLockedOut)
        {
            _logger.LogWarning("User account locked out.");
            return RedirectToPage("./Lockout");
        }
        else
        {
            ModelState.AddModelError(string.Empty, "Invalid login
attempt.");
            return Page();
        }
    }

    // If we got this far, something failed, redisplay form
    return Page();
}
```

For information on how to make authorization decisions, see Introduction to authorization in ASP.NET Core.

Log out

The **Log out** link invokes the `LogoutModel.OnPost` action.

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;
using System.Threading.Tasks;

namespace WebApp1.Areas.Identity.Pages.Account
{
    [AllowAnonymous]
    public class LogoutModel : PageModel
    {
        private readonly SignInManager<IdentityUser> _signInManager;
        private readonly ILogger<LogoutModel> _logger;

        public LogoutModel(SignInManager<IdentityUser> signInManager,
ILogger<LogoutModel> logger)
        {
            _signInManager = signInManager;
            _logger = logger;
        }
```

```
        public void OnGet()
        {
        }

        public async Task<IActionResult> OnPost(string returnUrl = null)
        {
            await _signInManager.SignOutAsync();
            _logger.LogInformation("User logged out.");
            if (returnUrl != null)
            {
                return LocalRedirect(returnUrl);
            }
            else
            {
                return RedirectToPage();
            }
        }
    }
}
```

In the preceding code, the code `return RedirectToPage();` needs to be a redirect so that the browser performs a new request and the identity for the user gets updated.

SignOutAsync clears the user's claims stored in a cookie.

Post is specified in the `Pages/Shared/_LoginPartial.cshtml`:

CSHTML

```
@using Microsoft.AspNetCore.Identity
@inject SignInManager<IdentityUser> SignInManager
@inject UserManager<IdentityUser> UserManager

<ul class="navbar-nav">
@if (SignInManager.IsSignedIn(User))
{
    <li class="nav-item">
        <a  class="nav-link text-dark" asp-area="Identity" asp-
page="/Account/Manage/Index"
                                                title="Manage">Hello
@User.Identity.Name!</a>
    </li>
    <li class="nav-item">
        <form class="form-inline" asp-area="Identity" asp-
page="/Account/Logout"
                                    asp-route-returnUrl="@Url.Page("/", new {
area = "" })"
                                    method="post" >
            <button  type="submit" class="nav-link btn btn-link text-
dark">Logout</button>
        </form>
    </li>
```

```
}
else
{
    <li class="nav-item">
        <a class="nav-link text-dark" asp-area="Identity" asp-
page="/Account/Register">Register</a>
    </li>
    <li class="nav-item">
        <a class="nav-link text-dark" asp-area="Identity" asp-
page="/Account/Login">Login</a>
    </li>
}
</ul>
```

Test Identity

The default web project templates allow anonymous access to the home pages. To test Identity, add [Authorize]:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;

namespace WebApp1.Pages
{
    [Authorize]
    public class PrivacyModel : PageModel
    {
        private readonly ILogger<PrivacyModel> _logger;

        public PrivacyModel(ILogger<PrivacyModel> logger)
        {
            _logger = logger;
        }

        public void OnGet()
        {
        }
    }
}
```

If you are signed in, sign out. Run the app and select the **Privacy** link. You are redirected to the login page.

Explore Identity

To explore Identity in more detail:

- Create full identity UI source
- Examine the source of each page and step through the debugger.

Identity Components

All the Identity-dependent NuGet packages are included in the ASP.NET Core shared framework.

The primary package for Identity is Microsoft.AspNetCore.Identity. This package contains the core set of interfaces for ASP.NET Core Identity, and is included by `Microsoft.AspNetCore.Identity.EntityFrameworkCore`.

Migrating to ASP.NET Core Identity

For more information and guidance on migrating your existing Identity store, see Migrate Authentication and Identity.

Setting password strength

See Configuration for a sample that sets the minimum password requirements.

AddDefaultIdentity and AddIdentity

AddDefaultIdentity was introduced in ASP.NET Core 2.1. Calling `AddDefaultIdentity` is similar to calling the following:

- AddIdentity
- AddDefaultUI
- AddDefaultTokenProviders

See AddDefaultIdentity source for more information.

Prevent publish of static Identity assets

To prevent publishing static Identity assets (stylesheets and JavaScript files for Identity UI) to the web root, add the following `ResolveStaticWebAssetsInputsDependsOn` property and `RemoveIdentityAssets` target to the app's project file:

XML

```xml
<PropertyGroup>

<ResolveStaticWebAssetsInputsDependsOn>RemoveIdentityAssets</ResolveStaticWebAssetsInputsDependsOn>
</PropertyGroup>

<Target Name="RemoveIdentityAssets">
  <ItemGroup>
    <StaticWebAsset Remove="@(StaticWebAsset)" Condition="%(SourceId) == 'Microsoft.AspNetCore.Identity.UI'" />
  </ItemGroup>
</Target>
```

Next Steps

- How to work with Roles in ASP.NET Core Identity

- See this GitHub issue for information on configuring Identity using SQLite.
- Configure Identity
- Create an ASP.NET Core app with user data protected by authorization
- Add, download, and delete user data to Identity in an ASP.NET Core project
- Enable QR code generation for TOTP authenticator apps in ASP.NET Core
- Migrate Authentication and Identity to ASP.NET Core
- Account confirmation and password recovery in ASP.NET Core
- Two-factor authentication with SMS in ASP.NET Core
- Host ASP.NET Core in a web farm

How to use Identity to secure a Web API backend for SPAs

Article • 09/10/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

ASP.NET Core Identity provides APIs that handle authentication, authorization, and identity management. The APIs make it possible to secure endpoints of a Web API backend with cookie-based authentication. A token-based option is available for clients that can't use cookies, but in using this you are responsible for ensuring the tokens are kept secure. We recommend using cookies for browser-based applications, because, by default, the browser automatically handles them without exposing them to JavaScript.

This article shows how to use Identity to secure a Web API backend for SPAs such as Angular, React, and Vue apps. The same backend APIs can be used to secure Blazor WebAssembly apps.

Prerequisites

The steps shown in this article add authentication and authorization to an ASP.NET Core Web API app that:

- Isn't already configured for authentication.
- Targets `net8.0` or later.
- Can be either minimal API or controller-based API.

Some of the testing instructions in this article use the Swagger UI that's included with the project template. The Swagger UI isn't required to use Identity with a Web API backend.

Install NuGet packages

Install the following NuGet packages:

- Microsoft.AspNetCore.Identity.EntityFrameworkCore - Enables Identity to work with Entity Framework Core (EF Core).
- One that enables EF Core to work with a database, such as one of the following packages:
  - Microsoft.EntityFrameworkCore.SqlServer or
  - Microsoft.EntityFrameworkCore.Sqlite or
  - Microsoft.EntityFrameworkCore.InMemory.

For the quickest way to get started, use the in-memory database.

Change the database later to SQLite or SQL Server to save user data between sessions when testing or for production use. That introduces some complexity compared to in-memory, as it requires the database to be created through migrations, as shown in the EF Core getting started tutorial.

Install these packages by using the NuGet package manager in Visual Studio or the dotnet add package CLI command.

Create an `IdentityDbContext`

Add a class named `ApplicationDbContext` that inherits from IdentityDbContext<TUser>:

C#

```
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;

public class ApplicationDbContext : IdentityDbContext<IdentityUser>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
options) :
        base(options)
    { }
}
```

The code shown provides a special constructor that makes it possible to configure the database for different environments.

Add one or more of the following `using` directives as needed when adding the code shown in these steps.

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;
using Microsoft.EntityFrameworkCore;
```

Configure the EF Core context

As noted earlier, the simplest way to get started is to use the in-memory database. With in-memory each run starts with a fresh database, and there's no need to use migrations. After the call to `WebApplication.CreateBuilder(args)`, add the following code to configure Identity to use an in-memory database:

C#

```
builder.Services.AddDbContext<ApplicationDbContext>(
    options => options.UseInMemoryDatabase("AppDb"));
```

To save user data between sessions when testing or for production use, change the database later to SQLite or SQL Server.

Add Identity services to the container

After the call to `WebApplication.CreateBuilder(args)`, call AddAuthorization to add services to the dependency injection (DI) container:

C#

```
builder.Services.AddAuthorization();
```

Activate Identity APIs

After the call to `WebApplication.CreateBuilder(args)`, call AddIdentityApiEndpoints<TUser>(IServiceCollection) and AddEntityFrameworkStores<TContext>(IdentityBuilder).

C#

```
builder.Services.AddIdentityApiEndpoints<IdentityUser>()
    .AddEntityFrameworkStores<ApplicationDbContext>();
```

By default, both cookies and proprietary tokens are activated. Cookies and tokens are issued at login if the `useCookies` query string parameter in the login endpoint is `true`.

Map Identity routes

After the call to `builder.Build()`, call MapIdentityApi<TUser>(IEndpointRouteBuilder) to map the Identity endpoints:

```
C#

app.MapIdentityApi<IdentityUser>();
```

Secure selected endpoints

To secure an endpoint, use the RequireAuthorization extension method on the `Map{Method}` call that defines the route. For example:

```
C#

app.MapGet("/weatherforecast", (HttpContext httpContext) =>
{
    var forecast = Enumerable.Range(1, 5).Select(index =>
        new WeatherForecast
        {
            Date = DateOnly.FromDateTime(DateTime.Now.AddDays(index)),
            TemperatureC = Random.Shared.Next(-20, 55),
            Summary = summaries[Random.Shared.Next(summaries.Length)]
        })
        .ToArray();
    return forecast;
})
.WithName("GetWeatherForecast")
.WithOpenApi()
.RequireAuthorization();
```

The `RequireAuthorization` method can also be used to:

- Secure Swagger UI endpoints, as shown in the following example:

  ```
  C#

  app.MapSwagger().RequireAuthorization();
  ```

- Secure with a specific claim or permission, as shown in the following example:

```C#
.RequireAuthorization("Admin");
```

In a controller-based web API project, secure endpoints by applying the [Authorize] attribute to a controller or action.

Test the API

A quick way to test authentication is to use the in-memory database and the Swagger UI that's included with the project template. The following steps show how to test the API with the Swagger UI. Make sure that the Swagger UI endpoints aren't secured.

Attempt to access a secured endpoint

- Run the app and navigate to the Swagger UI.
- Expand a secured endpoint, such as `/weatherforecast` in a project created by the web API template.
- Select **Try it out**.
- Select **Execute**. The response is `401 - not authorized`.

Test registration

- Expand `/register` and select **Try it out**.
- In the **Parameters** section of the UI, a sample request body is shown:

```JSON
{
  "email": "string",
  "password": "string"
}
```

- Replace "string" with a valid email address and password, and then select **Execute**.

  To comply with the default password validation rules, the password must be at least six characters long and contain at least one of each of the following characters:
  - Uppercase letter
  - Lowercase letter
  - Numeric digit

- Nonalphanumeric character

If you enter an invalid email address or a bad password, the result includes the validation errors. Here's an example of a response body with validation errors:

JSON

```
{
  "type": "https://tools.ietf.org/html/rfc9110#section-15.5.1",
  "title": "One or more validation errors occurred.",
  "status": 400,
  "errors": {
    "PasswordTooShort": [
      "Passwords must be at least 6 characters."
    ],
    "PasswordRequiresNonAlphanumeric": [
      "Passwords must have at least one non alphanumeric character."
    ],
    "PasswordRequiresDigit": [
      "Passwords must have at least one digit ('0'-'9')."
    ],
    "PasswordRequiresLower": [
      "Passwords must have at least one lowercase ('a'-'z')."
    ]
  }
}
```

The errors are returned in the ProblemDetails format so the client can parse them and display validation errors as needed.

A successful registration results in a `200 - OK` response.

Test login

- Expand `/login` and select **Try it out**. The example request body shows two additional parameters:

JSON

```
{
  "email": "string",
  "password": "string",
  "twoFactorCode": "string",
  "twoFactorRecoveryCode": "string"
}
```

The extra JSON properties aren't needed for this example and can be deleted. Set `useCookies` to `true`.

- Replace "string" with the email address and password that you used to register, and then select **Execute**.

  A successful login results in a `200 - OK` response with a cookie in the response header.

Retest the secured endpoint

After a successful login, rerun the secured endpoint. The authentication cookie is automatically sent with the request, and the endpoint is authorized. Cookie-based authentication is securely built-in to the browser and "just works."

Testing with nonbrowser clients

Some web clients might not include cookies in the header by default:

- If you're using a tool for testing APIs, you might need to enable cookies in the settings.
- The JavaScript `fetch` API doesn't include cookies by default. Enable them by setting `credentials` to the value `include` in the options.
- An `HttpClient` running in a Blazor WebAssembly app needs the `HttpRequestMessage` to include credentials, like the following example:

  ```
  C#

  request.SetBrowserRequestCredential(BrowserRequestCredentials.Include);
  ```

Use token-based authentication

We recommend using cookies in browser-based applications, because, by default, the browser automatically handles them without exposing them to JavaScript.

A custom token (one that is proprietary to the ASP.NET Core identity platform) is issued that can be used to authenticate subsequent requests. The token is passed in the `Authorization` header as a bearer token. A refresh token is also provided. This token allows the application to request a new token when the old one expires without forcing the user to log in again.

The tokens aren't standard JSON Web Tokens (JWTs). The use of custom tokens is intentional, as the built-in Identity API is meant primarily for simple scenarios. The token

option isn't intended to be a full-featured identity service provider or token server, but instead an alternative to the cookie option for clients that can't use cookies.

To use token-based authentication, set the `useCookies` query string parameter to `false` when calling the `/login` endpoint. Tokens use the *bearer* authentication scheme. Using the token returned from the call to `/login`, subsequent calls to protected endpoints should add the header `Authorization: Bearer <token>` where `<token>` is the access token. For more information, see Use the POST /login endpoint later in this article.

Log out

To provide a way for the user to log out, define a `/logout` endpoint like the following example:

C#

```
app.MapPost("/logout", async (SignInManager<IdentityUser> signInManager,
    [FromBody] object empty) =>
{
    if (empty != null)
    {
        await signInManager.SignOutAsync();
        return Results.Ok();
    }
    return Results.Unauthorized();
})
.WithOpenApi()
.RequireAuthorization();
```

Provide an empty JSON object (`{}`) in the request body when calling this endpoint. The following code is an example of a call to the logout endpoint:

TypeScript

```
public signOut() {
  return this.http.post('/logout', {}, {
    withCredentials: true,
    observe: 'response',
    responseType: 'text'
```

The `MapIdentityApi<TUser>` endpoints

The call to `MapIdentityApi<TUser>` adds the following endpoints to the app:

- POST /register
- POST /login
- POST /refresh
- GET /confirmEmail
- POST /resendConfirmationEmail
- POST /forgotPassword
- POST /resetPassword
- POST /manage/2fa
- GET /manage/info
- POST /manage/info

Use the `POST /register` endpoint

The request body must have Email and Password properties:

JSON

```
{
  "email": "string",
  "password": "string",
}
```

For more information, see:

- Test registration earlier in this article.
- RegisterRequest.

Use the `POST /login` endpoint

In the request body, Email and Password are required. If two-factor authentication (2FA) is enabled, either TwoFactorCode or TwoFactorRecoveryCode is required. If 2FA isn't enabled, omit both `twoFactorCode` and `twoFactorRecoveryCode`. For more information, see Use the POST /manage/2fa endpoint later in this article.

Here's a request body example with 2FA not enabled:

JSON

```
{
  "email": "string",
  "password": "string"
}
```

Here are request body examples with 2FA enabled:

- JSON

```
{
  "email": "string",
  "password": "string",
  "twoFactorCode": "string",
}
```

- JSON

```
{
  "email": "string",
  "password": "string",
  "twoFactorRecoveryCode": "string"
}
```

The endpoint expects a query string parameter:

- `useCookies` - Set to `true` for cookie-based authentication. Set to `false` or omit for token-based authentication.

For more information about cookie-based authentication, see Test login earlier in this article.

Token-based authentication

If `useCookies` is `false` or omitted, token-based authentication is enabled. The response body includes the following properties:

JSON

```
{
  "tokenType": "string",
  "accessToken": "string",
  "expiresIn": 0,
  "refreshToken": "string"
}
```

For more information about these properties, see AccessTokenResponse.

Put the access token in a header to make authenticated requests, as shown in the following example

HTTP

```
Authorization: Bearer {access token}
```

When the access token is about to expire, call the /refresh endpoint.

Use the `POST /refresh` endpoint

For use only with token-based authentication. Gets a new access token without forcing the user to log in again. Call this endpoint when the access token is about to expire.

The request body contains only the RefreshToken. Here's a request body example:

JSON

```
{
  "refreshToken": "string"
}
```

If the call is successful, the response body is a new AccessTokenResponse, as shown in the following example:

JSON

```
{
  "tokenType": "string",
  "accessToken": "string",
  "expiresIn": 0,
  "refreshToken": "string"
}
```

Use the `GET /confirmEmail` endpoint

If Identity is set up for email confirmation, a successful call to the `/register` endpoint sends an email that contains a link to the `/confirmEmail` endpoint. The link contains the following query string parameters:

- `userId`
- `code`
- `changedEmail` - Included only if the user changed the email address during registration.

Identity provides default text for the confirmation email. By default, the email subject is "Confirm your email" and the email body looks like the following example:

HTTP

```
 Please confirm your account by <a href='https://contoso.com/confirmEmail?
userId={user ID}&code={generated code}&changedEmail={new email
address}'>clicking here</a>.
```

If the RequireConfirmedEmail property is set to `true`, the user can't log in until the email address is confirmed by clicking the link in the email. The `/confirmEmail` endpoint:

- Confirms the email address and enables the user to log in.
- Returns the text "Thank you for confirming your email." in the response body.

To set up Identity for email confirmation, add code in `Program.cs` to set `RequireConfirmedEmail` to `true` and add a class that implements IEmailSender to the DI container. For example:

C#

```
builder.Services.Configure<IdentityOptions>(options =>
{
    options.SignIn.RequireConfirmedEmail = true;
});

builder.Services.AddTransient<IEmailSender, EmailSender>();
```

For more information, see Account confirmation and password recovery in ASP.NET Core.

Identity provides default text for the other emails that need to be sent as well, such as for 2FA and password reset. To customize these emails, provide a custom implementation of the `IEmailSender` interface. In the preceding example, `EmailSender` is a class that implements `IEmailSender`. For more information, including an example of a class that implements `IEmailSender`, see Account confirmation and password recovery in ASP.NET Core.

Use the `POST /resendConfirmationEmail` endpoint

Sends an email only if the address is valid for a registered user.

The request body contains only the Email. Here's a request body example:

JSON

```
{
  "email": "string"
}
```

For more information, see Use the GET /confirmEmail endpoint earlier in this article.

Use the `POST /forgotPassword` endpoint

Generates an email that contains a password reset code. Send that code to /resetPassword with a new password.

The request body contains only the Email. Here's an example:

JSON

```
{
  "email": "string"
}
```

For information about how to enable Identity to send emails, see Use the GET /confirmEmail endpoint.

Use the `POST /resetPassword` endpoint

Call this endpoint after getting a reset code by calling the `/forgotPassword` endpoint.

The request body requires Email, ResetCode, and NewPassword. Here's an example:

JSON

```
{
  "email": "string",
  "resetCode": "string",
  "newPassword": "string"
}
```

Use the `POST /manage/2fa` endpoint

Configures two-factor authentication (2FA) for the user. When 2FA is enabled, successful login requires a code produced by an authenticator app in addition to the email address and password.

Enable 2FA

To enable 2FA for the currently authenticated user:

- Call the `/manage/2fa` endpoint, sending an empty JSON object (`{}`) in the request body.
- The response body provides the SharedKey along with some other properties that aren't needed at this point. The shared key is used to set up the authenticator app. Response body example:

  JSON

  ```
  {
    "sharedKey": "string",
    "recoveryCodesLeft": 0,
    "recoveryCodes": null,
    "isTwoFactorEnabled": false,
    "isMachineRemembered": false
  }
  ```

- Use the shared key to get a Time-based one-time password (TOTP). For more information, see Enable QR code generation for TOTP authenticator apps in ASP.NET Core.
- Call the `/manage/2fa` endpoint, sending the TOTP and `"enable": true` in the request body. For example:

  JSON

  ```
  {
    "enable": true,
    "twoFactorCode": "string"
  }
  ```

- The response body confirms that IsTwoFactorEnabled is true and provides the RecoveryCodes. The recovery codes are used to log in when the authenticator app isn't available. Response body example after successfully enabling 2FA:

  JSON

  ```
  {
    "sharedKey": "string",
    "recoveryCodesLeft": 10,
    "recoveryCodes": [
      "string",
      "string",
  ```

```
      "string",
      "string",
      "string",
      "string",
      "string",
      "string",
      "string",
      "string"
    ],
    "isTwoFactorEnabled": true,
    "isMachineRemembered": false
  }
```

Log in with 2FA

Call the `/login` endpoint, sending the email address, password, and TOTP in the request body. For example:

JSON

```
{
  "email": "string",
  "password": "string",
  "twoFactorCode": "string"
}
```

If the user doesn't have access to the authenticator app, log in by calling the `/login` endpoint with one of the recovery codes that was provided when 2FA was enabled. The request body looks like the following example:

JSON

```
{
  "email": "string",
  "password": "string",
  "twoFactorRecoveryCode": "string"
}
```

Reset the recovery codes

To get a new collection of recovery codes, call this endpoint with ResetRecoveryCodes set to `true`. Here's a request body example:

JSON

```
{
  "resetRecoveryCodes": true
}
```

Reset the shared key

To get a new random shared key, call this endpoint with ResetSharedKey set to `true`. Here's a request body example:

JSON

```
{
  "resetSharedKey": true
}
```

Resetting the key automatically disables the two-factor login requirement for the authenticated user until it's re-enabled by a later request.

Forget the machine

To clear the cookie "remember me flag" if present, call this endpoint with ForgetMachine set to true. Here's a request body example:

JSON

```
{
  "forgetMachine": true
}
```

This endpoint has no impact on token-based authentication.

Use the `GET /manage/info` endpoint

Gets email address and email confirmation status of the logged-in user. Claims were omitted from this endpoint for security reasons. If claims are needed, use the server-side APIs to set up an endpoint for claims. Or instead of sharing all of the users' claims, provide a validation endpoint that accepts a claim and responds whether the user has it.

The request doesn't require any parameters. The response body includes the Email and IsEmailConfirmed properties, as in the following example:

JSON

```
{
  "email": "string",
  "isEmailConfirmed": true
}
```

Use the `POST /manage/info` endpoint

Updates the email address and password of the logged-in user. Send NewEmail, NewPassword, and OldPassword in the request body, as shown in the following example:

JSON

```
{
  "newEmail": "string",
  "newPassword": "string",
  "oldPassword": "string"
}
```

Here's an example of the response body:

JSON

```
{
  "email": "string",
  "isEmailConfirmed": false
}
```

Scaffold Identity in ASP.NET Core projects

Article • 07/23/2024

By Rick Anderson

Blazor Identity scaffolding

ASP.NET Core Identity scaffolding adds ASP.NET Core Identity to Blazor Web Apps and Blazor Server apps. After the scaffolder adds the Identity Razor components to the app, you can customize the components to suit your app's requirements.

Although the scaffolder generates the necessary C# code to scaffold Identity into the app, you must update the project's database with an Entity Framework (EF) Core database migration to complete the process. This article explains the steps required to migrate a database.

Inspect the changes after running the Identity scaffolder. We recommend using GitHub or another source control system that shows file changes with a revert changes feature.

Services are required when using two-factor authentication (2FA), account confirmation and password recovery, and other security features with Identity. Services or service stubs aren't generated when scaffolding Identity. Services to enable these features must be added manually.

Razor Pages and MVC Identity scaffolding

ASP.NET Core provides ASP.NET Core Identity as a Razor class library (RCL). Applications that include Identity can apply the scaffolder to selectively add the source code contained in the Identity RCL. You might want to generate source code so you can modify the code and change the behavior. For example, you could instruct the scaffolder to generate the code used in registration. Customized Identity code overrides the default implementation provided by the Identity RCL. To gain full control of the UI and not use the default RCL, see the Create full Identity UI source section.

Applications that do **not** include authentication can apply the scaffolder to add the RCL Identity package. You have the option of selecting Identity code to be generated.

Although the scaffolder generates most of the necessary code, you need to update your project to complete the process. This document explains the steps needed to complete

an Identity scaffolding update.

We recommend using a source control system that shows file differences and allows you to back out of changes. Inspect the changes after running the Identity scaffolder.

Services are required when using Two Factor Authentication, Account confirmation and password recovery, and other security features with Identity. Services or service stubs aren't generated when scaffolding Identity. Services to enable these features must be added manually. For example, see Require Email Confirmation.

Typically, apps created with individual accounts should ***not*** create a new data context.

Scaffold Identity into a Blazor project

This section applies to Blazor Web Apps and Blazor Server apps.

Run the Identity scaffolder:

Visual Studio

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity**. Select **Blazor Identity** in the center pane. Select the **Add** button.
- In the **Add Blazor Identity** dialog:
  - Select or add with the plus (+) button the database context class (**DbContext class**).
  - Select the database provider (**Database provider**), which defaults to SQL Server.
  - Select or add with the plus (+) button the user class (**User class**).
  - Select the **Add** button.

The generated Identity database code requires EF Core Migrations. The following steps explain how to create and apply a migration to the database.

Visual Studio

Visual Studio Connected Services are used to add an EF Core migration and update the database.

In **Solution Explorer**, double-click **Connected Services**. In the **SQL Server Express LocalDB** area of **Service Dependencies**, select the ellipsis (`...`) followed by **Add migration**.

Give the migration a **Migration name**, such as `CreateIdentitySchema`, which is a name that describes the migration. Wait for the database context to load in the **DbContext class names** field, which may take a few seconds. Select **Finish** to create the migration.

Select the **Close** button after the operation finishes.

Select the ellipsis (`...`) again followed by the **Update database** command.

The **Update database with the latest migration** dialog opens. Wait for the **DbContext class names** field to update and for prior migrations to load, which may take a few seconds. Select the **Finish** button.

Select the **Close** button after the operation finishes.

The update database command executes the `Up` method migrations that haven't been applied in a migration code file created by the scaffolder. In this case, the command executes the `Up` method in the `Migrations/{TIME STAMP}_{MIGRATION NAME}.cs` file, which creates the Identity tables, constraints, and indexes. The `{TIME STAMP}` placeholder is a time stamp, and the `{MIGRATION NAME}` placeholder is the migration name.

Client-side Blazor apps (Standalone Blazor WebAssembly)

Client-side Blazor apps (Standalone Blazor WebAssembly) use their own Identity UI approaches and can't use ASP.NET Core Identity scaffolding.

For more information, see the Blazor Security and Identity articles.

Scaffold Identity into a Razor project without existing authorization

Install the Microsoft.VisualStudio.Web.CodeGeneration.Design NuGet package.

> **Note**

For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Run the Identity scaffolder:

Visual Studio

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity**. Select **Identity** in the center pane. Select the **Add** button.
- In the **Add Identity** dialog, select the options you want.
  - If you have an existing, customized layout page for Identity (`_Layout.cshtml`), select your existing layout page to avoid overwriting your layout with incorrect markup by the scaffolder. For example, select either:
    - `Pages/Shared/_Layout.cshtml` for Razor Pages or Blazor Server projects with existing Razor Pages infrastructure.
    - `Views/Shared/_Layout.cshtml` for MVC projects or Blazor Server projects with existing MVC infrastructure.
  - For the data context (**DbContext class**):
    - Select your data context class. You must select at least one file to add your data context.
    - To create a data context and possibly create a new user class for Identity, select the + button. Accept the default value or specify a class (for example, `Contoso.Data.ApplicationDbContext` for a company named "Contoso"). To create a new user class, select the + button for **User class** and specify the class (for example, `ContosoUser` for a company named "Contoso").
  - Select the **Add** button to run the scaffolder.

Migrations, UseAuthentication, and layout

The generated Identity database code requires Entity Framework (EF) Core Migrations. If a migration to generate the Identity schema hasn't been created and applied to the database, create a migration and update the database.

Visual Studio

Visual Studio Connected Services are used to add an EF Core migration and update the database.

In **Solution Explorer**, double-click **Connected Services**. In the **SQL Server Express LocalDB** area of **Service Dependencies**, select the ellipsis (`...`) followed by **Add migration**.

Give the migration a **Migration name**, such as `CreateIdentitySchema`, which is a name that describes the migration. Wait for the database context to load in the **DbContext class names** field, which may take a few seconds. Select **Finish** to create the migration.

Select the **Close** button after the operation finishes.

Select the ellipsis (`...`) again followed by the **Update database** command.

The **Update database with the latest migration** dialog opens. Wait for the **DbContext class names** field to update and for prior migrations to load, which may take a few seconds. Select the **Finish** button.

Select the **Close** button after the operation finishes.

The update database command executes the `Up` method migrations that haven't been applied in a migration code file created by the scaffolder. In this case, the command executes the `Up` method in the `Migrations/{TIME STAMP}_{MIGRATION NAME}.cs` file, which creates the Identity tables, constraints, and indexes. The `{TIME STAMP}` placeholder is a time stamp, and the `{MIGRATION NAME}` placeholder is the migration name.

If the Identity schema has already been created but not applied to the database, only the command to update the database must be executed:

Visual Studio

In **Solution Explorer**, double-click **Connected Services**. In the **SQL Server Express LocalDB** area of **Service Dependencies**, select the ellipsis (`...`) followed by the **Update database** command.

The **Update database with the latest migration** dialog opens. Wait for the **DbContext class names** field to update and for prior migrations to load, which may take a few seconds. Select the **Finish** button.

Select the **Close** button after the operation finishes.

You can confirm the application of an Identity schema with the following command. The output of the command includes an "`applied`" column to show which migrations are applied to the database.

Visual Studio

In the Visual Studio **Package Manager Console**, execute Get-Migration:

PowerShell

```
Get-Migration
```

If more than one database context exists, specify the context with the `-Context` parameter.

Layout changes

Optional: Add the login partial (`_LoginPartial`) to the layout file:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - WebRPnoAuth2Auth</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" asp-append-version="true"
/>
    <link rel="stylesheet" href="~/WebRPnoAuth2Auth.styles.css" asp-append-
version="true" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-
light bg-white border-bottom box-shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-
page="/Index">WebRPnoAuth2Auth</a>
                <button class="navbar-toggler" type="button" data-bs-
toggle="collapse" data-bs-target=".navbar-collapse" aria-
controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle
navigation">
```

```
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex
justify-content-between">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Privacy">Privacy</a>
                        </li>
                    </ul>
                    <partial name="_LoginPartial" />
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2021 - WebRPnoAuth2Auth - <a asp-area="" asp-
page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```

Scaffold Identity into a Razor project with authorization

Install the Microsoft.VisualStudio.Web.CodeGeneration.Design NuGet package.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation).

Confirm correct package versions at NuGet.org.

Run the Identity scaffolder:

Visual Studio

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity**. Select **Identity** in the center pane. Select the **Add** button.
- In the **Add Identity** dialog, select the options you want.
  - If you have an existing, customized layout page for Identity (`_Layout.cshtml`), select your existing layout page to avoid overwriting your layout with incorrect markup by the scaffolder. For example, select either:
    - `Pages/Shared/_Layout.cshtml` for Razor Pages or Blazor Server projects with existing Razor Pages infrastructure.
    - `Views/Shared/_Layout.cshtml` for MVC projects or Blazor Server projects with existing MVC infrastructure.
  - For the data context (**DbContext class**):
    - Select your data context class. You must select at least one file to add your data context.
    - To create a data context and possibly create a new user class for Identity, select the + button. Accept the default value or specify a class (for example, `Contoso.Data.ApplicationDbContext` for a company named "Contoso"). To create a new user class, select the + button for **User class** and specify the class (for example, `ContosoUser` for a company named "Contoso").
  - Select the **Add** button to run the scaffolder.

Scaffold Identity into an MVC project without existing authorization

Install the Microsoft.VisualStudio.Web.CodeGeneration.Design NuGet package.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation).

Confirm correct package versions at NuGet.org.

Run the Identity scaffolder:

Visual Studio

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity**. Select **Identity** in the center pane. Select the **Add** button.
- In the **Add Identity** dialog, select the options you want.
  - If you have an existing, customized layout page for Identity (`_Layout.cshtml`), select your existing layout page to avoid overwriting your layout with incorrect markup by the scaffolder. For example, select either:
    - `Pages/Shared/_Layout.cshtml` for Razor Pages or Blazor Server projects with existing Razor Pages infrastructure.
    - `Views/Shared/_Layout.cshtml` for MVC projects or Blazor Server projects with existing MVC infrastructure.
  - For the data context (**DbContext class**):
    - Select your data context class. You must select at least one file to add your data context.
    - To create a data context and possibly create a new user class for Identity, select the + button. Accept the default value or specify a class (for example, `Contoso.Data.ApplicationDbContext` for a company named "Contoso"). To create a new user class, select the + button for **User class** and specify the class (for example, `ContosoUser` for a company named "Contoso").
  - Select the **Add** button to run the scaffolder.

Optional: Add the login partial (`_LoginPartial`) to the `Views/Shared/_Layout.cshtml` file:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - WebRPnoAuth2Auth</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" asp-append-version="true"
/>
```

```
    <link rel="stylesheet" href="~/WebRPnoAuth2Auth.styles.css" asp-append-
version="true" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-
light bg-white border-bottom box-shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-
page="/Index">WebRPnoAuth2Auth</a>
                <button class="navbar-toggler" type="button" data-bs-
toggle="collapse" data-bs-target=".navbar-collapse" aria-
controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle
navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex
justify-content-between">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Privacy">Privacy</a>
                        </li>
                    </ul>
                    <partial name="_LoginPartial" />
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2021 - WebRPnoAuth2Auth - <a asp-area="" asp-
page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```

The generated Identity database code requires Entity Framework (EF) Core Migrations. If a migration to generate the Identity schema hasn't been created and applied to the database, create a migration and update the database.

Visual Studio

Visual Studio Connected Services are used to add an EF Core migration and update the database.

In **Solution Explorer**, double-click **Connected Services**. In the **SQL Server Express LocalDB** area of **Service Dependencies**, select the ellipsis (`...`) followed by **Add migration**.

Give the migration a **Migration name**, such as `CreateIdentitySchema`, which is a name that describes the migration. Wait for the database context to load in the **DbContext class names** field, which may take a few seconds. Select **Finish** to create the migration.

Select the **Close** button after the operation finishes.

Select the ellipsis (`...`) again followed by the **Update database** command.

The **Update database with the latest migration** dialog opens. Wait for the **DbContext class names** field to update and for prior migrations to load, which may take a few seconds. Select the **Finish** button.

Select the **Close** button after the operation finishes.

The update database command executes the `Up` method migrations that haven't been applied in a migration code file created by the scaffolder. In this case, the command executes the `Up` method in the `Migrations/{TIME STAMP}_{MIGRATION NAME}.cs` file, which creates the Identity tables, constraints, and indexes. The `{TIME STAMP}` placeholder is a time stamp, and the `{MIGRATION NAME}` placeholder is the migration name.

If the Identity schema has already been created but not applied to the database, only the command to update the database must be executed:

Visual Studio

In **Solution Explorer**, double-click **Connected Services**. In the **SQL Server Express LocalDB** area of **Service Dependencies**, select the ellipsis (`...`) followed by the **Update database** command.

The **Update database with the latest migration** dialog opens. Wait for the **DbContext class names** field to update and for prior migrations to load, which may take a few seconds. Select the **Finish** button.

Select the **Close** button after the operation finishes.

You can confirm the application of an Identity schema with the following command. The output of the command includes an "`applied`" column to show which migrations are applied to the database.

Visual Studio

In the Visual Studio **Package Manager Console**, execute Get-Migration:

PowerShell

```
Get-Migration
```

If more than one database context exists, specify the context with the `-Context` parameter.

Add `MapRazorPages` to `Program.cs` as shown in the following highlighted code:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using WebMVCauth.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
```

```
}
else
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
app.MapRazorPages();

app.Run();
```

Scaffold Identity into an MVC project with authorization

Install the Microsoft.VisualStudio.Web.CodeGeneration.Design NuGet package.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Run the Identity scaffolder:

Visual Studio

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add New Scaffolded Item** dialog, select **Identity**. Select **Identity** in the center pane. Select the **Add** button.
- In the **Add Identity** dialog, select the options you want.
  - If you have an existing, customized layout page for Identity (`_Layout.cshtml`), select your existing layout page to avoid overwriting your

layout with incorrect markup by the scaffolder. For example, select either:
    - `Pages/Shared/_Layout.cshtml` for Razor Pages or Blazor Server projects with existing Razor Pages infrastructure.
    - `Views/Shared/_Layout.cshtml` for MVC projects or Blazor Server projects with existing MVC infrastructure.
  - For the data context (**DbContext class**):
    - Select your data context class. You must select at least one file to add your data context.
    - To create a data context and possibly create a new user class for Identity, select the + button. Accept the default value or specify a class (for example, `Contoso.Data.ApplicationDbContext` for a company named "Contoso"). To create a new user class, select the + button for **User class** and specify the class (for example, `ContosoUser` for a company named "Contoso").
  - Select the **Add** button to run the scaffolder.

Create full Identity UI source

To maintain full control of the Identity UI, run the Identity scaffolder and select **Override all files**.

Password configuration

If PasswordOptions are configured in `Startup.ConfigureServices`, [StringLength] attribute configuration might be required for the `Password` property in scaffolded Identity pages. `InputModel` `Password` properties are found in the following files:

- `Areas/Identity/Pages/Account/Register.cshtml.cs`
- `Areas/Identity/Pages/Account/ResetPassword.cshtml.cs`

Disable a page

This section shows how to disable the register page but the approach can be used to disable any page.

To disable user registration:

- Scaffold Identity. Include Account.Register, Account.Login, and Account.RegisterConfirmation. For example:

.NET CLI

```
dotnet aspnet-codegenerator identity -dc
RPauth.Data.ApplicationDbContext --files
"Account.Register;Account.Login;Account.RegisterConfirmation"
```

- Update `Areas/Identity/Pages/Account/Register.cshtml.cs` so users can't register from this endpoint:

C#

```
public class RegisterModel : PageModel
{
    public IActionResult OnGet()
    {
        return RedirectToPage("Login");
    }

    public IActionResult OnPost()
    {
        return RedirectToPage("Login");
    }
}
```

- Update `Areas/Identity/Pages/Account/Register.cshtml` to be consistent with the preceding changes:

CSHTML

```
@page
@model RegisterModel
@{
    ViewData["Title"] = "Go to Login";
}

<h1>@ViewData["Title"]</h1>

<li class="nav-item">
    <a class="nav-link text-dark" asp-area="Identity" asp-
page="/Account/Login">Login</a>
</li>
```

- Comment out or remove the registration link from `Areas/Identity/Pages/Account/Login.cshtml`

CSHTML

```
@*
<p>
    <a asp-page="./Register" asp-route-
returnUrl="@Model.ReturnUrl">Register as a new user</a>
</p>
*@
```

- Update the `Areas/Identity/Pages/Account/RegisterConfirmation` page.
  - Remove the code and links from the cshtml file.
  - Remove the confirmation code from the `PageModel`:

C#

```
[AllowAnonymous]
  public class RegisterConfirmationModel : PageModel
  {
      public IActionResult OnGet()
      {
          return Page();
      }
  }
```

Use another app to add users

Provide a mechanism to add users outside the web app. Options to add users include:

- A dedicated admin web app.
- A console app.

The following code outlines one approach to adding users:

- A list of users is read into memory.
- A strong unique password is generated for each user.
- The user is added to the Identity database.
- The user is notified and told to change the password.

C#

```
public class Program
{
    public static void Main(string[] args)
    {
        var host = CreateHostBuilder(args).Build();

        using (var scope = host.Services.CreateScope())
        {
            var services = scope.ServiceProvider;
```

```
            try
            {
                var context = services.GetRequiredService<AppDbCntx>();
                context.Database.Migrate();

                var config =
host.Services.GetRequiredService<IConfiguration>();
                var userList =
config.GetSection("userList").Get<List<string>>();

                SeedData.Initialize(services, userList).Wait();
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>
();
                logger.LogError(ex, "An error occurred adding users.");
            }
        }

        host.Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code outlines adding a user:

C#

```
public static async Task Initialize(IServiceProvider serviceProvider,
                                    List<string> userList)
{
    var userManager = serviceProvider.GetService<UserManager<IdentityUser>>
();

    foreach (var userName in userList)
    {
        var userPassword = GenerateSecurePassword();
        var userId = await EnsureUser(userManager, userName, userPassword);

        NotifyUser(userName, userPassword);
    }
}

private static async Task<string> EnsureUser(UserManager<IdentityUser>
```

```
userManager,
                                                string userName, string
userPassword)
{
    var user = await userManager.FindByNameAsync(userName);

    if (user == null)
    {
        user = new IdentityUser(userName)
        {
            EmailConfirmed = true
        };
        await userManager.CreateAsync(user, userPassword);
    }

    return user.Id;
}
```

A similar approach can be followed for production scenarios.

Prevent publish of static Identity assets

To prevent publishing static Identity assets to the web root, see Introduction to Identity on ASP.NET Core.

Add, download, and delete custom user data to Identity in an ASP.NET Core project

Article • 05/31/2024

By Rick Anderson

This article shows how to:

- Add custom user data to an ASP.NET Core web app.
- Mark the custom user data model with the PersonalDataAttribute attribute so it's automatically available for download and deletion. Making the data able to be downloaded and deleted helps meet GDPR requirements.

The project sample is created from a Razor Pages web app, but the instructions are similar for an ASP.NET Core MVC web app.

View or download sample code (how to download)

Prerequisites

.NET 6.0 SDK

Create a Razor web app

Visual Studio

- From the Visual Studio **File** menu, select **New** > **Project**. Name the project **WebApp1** if you want to it match the namespace of the download sample code.
- Select **ASP.NET Core Web Application** > **OK**
- Select **Web Application** > **OK**
- Build and run the project.

Run the Identity scaffolder

Visual Studio

- From **Solution Explorer**, right-click on the project > **Add** > **New Scaffolded Item**.
- From the left pane of the **Add Scaffold** dialog, select **Identity** > **Add**.
- In the **Add Identity** dialog, the following options:
  - Select the existing layout file `~/Pages/Shared/_Layout.cshtml`
  - Select the following files to override:
    - **Account/Register**
    - **Account/Manage/Index**
  - Select the + button to create a new **Data context class**. Accept the type (**WebApp1.Models.WebApp1Context** if the project is named **WebApp1**).
  - Select the + button to create a new **User class**. Accept the type (**WebApp1User** if the project is named **WebApp1**) > **Add**.
- Select **Add**.

Follow the instruction in Migrations, UseAuthentication, and layout to perform the following steps:

- Create a migration and update the database.
- Add `UseAuthentication` to Program.cs
- Add `<partial name="_LoginPartial" />` to the layout file.
- Test the app:
  - Register a user
  - Select the new user name (next to the **Logout** link). You might need to expand the window or select the navigation bar icon to show the user name and other links.
  - Select the **Personal Data** tab.
  - Select the **Download** button and examined the `PersonalData.json` file.
  - Test the **Delete** button, which deletes the logged on user.

Add custom user data to the Identity DB

Update the `IdentityUser` derived class with custom properties. If you named the project WebApp1, the file is named `Areas/Identity/Data/WebApp1User.cs`. Update the file with the following code:

C#

```
using Microsoft.AspNetCore.Identity;

namespace WebApp1.Areas.Identity.Data;

public class WebApp1User : IdentityUser
{
    [PersonalData]
    public string? Name { get; set; }
    [PersonalData]
    public DateTime DOB { get; set; }
}
```

Properties with the PersonalData attribute are:

- Deleted when the `Areas/Identity/Pages/Account/Manage/DeletePersonalData.cshtml` Razor Page calls `UserManager.Delete`.
- Included in the downloaded data by the `Areas/Identity/Pages/Account/Manage/DownloadPersonalData.cshtml` Razor Page.

Update the `Account/Manage/Index.cshtml` page

Update the `InputModel` in `Areas/Identity/Pages/Account/Manage/Index.cshtml.cs` with the following highlighted code:

C#

```
public class IndexModel : PageModel
{
    private readonly UserManager<WebApp1User> _userManager;
    private readonly SignInManager<WebApp1User> _signInManager;

    public IndexModel(
        UserManager<WebApp1User> userManager,
        SignInManager<WebApp1User> signInManager)
    {
        _userManager = userManager;
        _signInManager = signInManager;
    }

    /// <summary>
    ///     This API supports the ASP.NET Core Identity default UI
infrastructure and is not intended to be used
    ///     directly from your code. This API may change or be removed in
future releases.
    /// </summary>
    public string Username { get; set; }
```

```
    // Remaining API warnings ommited.

    [TempData]
    public string StatusMessage { get; set; }

    [BindProperty]
    public InputModel Input { get; set; }

    public class InputModel
    {

</div>

@section Scripts {
    <partial name="_ValidationScriptsPartial" />
}
```

Build the project.

Update the layout

See Layout changes for instructions to add sign-in and sign-out links to every page.

Add a migration for the custom user data

Visual Studio

In the Visual Studio **Package Manager Console**:

PowerShell

```
Add-Migration CustomUserData
Update-Database
```

Test create, view, download, delete custom user data

Test the app:

- Register a new user.
- View the custom user data on the `/Identity/Account/Manage` page.
- Download and view the users personal data from the `/Identity/Account/Manage/PersonalData` page.

Identity model customization in ASP.NET Core

Article • 10/29/2024

By Arthur Vickers

ASP.NET Core Identity provides a framework for managing and storing user accounts in ASP.NET Core apps. Identity is added to your project when **Individual User Accounts** is selected as the authentication mechanism. By default, Identity makes use of an Entity Framework (EF) Core data model. This article describes how to customize the Identity model.

Identity and EF Core Migrations

Before examining the model, it's useful to understand how Identity works with EF Core Migrations to create and update a database. At the top level, the process is:

1. Define or update a data model in code.
2. Add a Migration to translate this model into changes that can be applied to the database.
3. Check that the Migration correctly represents your intentions.
4. Apply the Migration to update the database to be in sync with the model.
5. Repeat steps 1 through 4 to further refine the model and keep the database in sync.

Use one of the following approaches to add and apply Migrations:

- The **Package Manager Console** (PMC) window if using Visual Studio. For more information, see EF Core PMC tools.
- The .NET CLI if using the command line. For more information, see EF Core .NET command line tools.
- Clicking the **Apply Migrations** button on the error page when the app is run.

ASP.NET Core has a development-time error page handler. The handler can apply migrations when the app is run. Production apps typically generate SQL scripts from the migrations and deploy database changes as part of a controlled app and database deployment.

When a new app using Identity is created, steps 1 and 2 above have already been completed. That is, the initial data model already exists, and the initial migration has

been added to the project. The initial migration still needs to be applied to the database. The initial migration can be applied via one of the following approaches:

- Run `Update-Database` in PMC.
- Run `dotnet ef database update` in a command shell.
- Click the **Apply Migrations** button on the error page when the app is run.

Repeat the preceding steps as changes are made to the model.

The Identity model

Entity types

The Identity model consists of the following entity types.

Expand table

Entity type	Description
`User`	Represents the user.
`Role`	Represents a role.
`UserClaim`	Represents a claim that a user possesses.
`UserToken`	Represents an authentication token for a user.
`UserLogin`	Associates a user with a login.
`RoleClaim`	Represents a claim that's granted to all users within a role.
`UserRole`	A join entity that associates users and roles.

Entity type relationships

The entity types are related to each other in the following ways:

- Each `User` can have many `UserClaims`.
- Each `User` can have many `UserLogins`.
- Each `User` can have many `UserTokens`.
- Each `Role` can have many associated `RoleClaims`.
- Each `User` can have many associated `Roles`, and each `Role` can be associated with many `Users`. This is a many-to-many relationship that requires a join table in the

database. The join table is represented by the `UserRole` entity.

Default model configuration

Identity defines many *context classes* that inherit from DbContext to configure and use the model. This configuration is done using the EF Core Code First Fluent API in the OnModelCreating method of the context class. The default configuration is:

C#

```
builder.Entity<TUser>(b =>
{
    // Primary key
    b.HasKey(u => u.Id);

    // Indexes for "normalized" username and email, to allow efficient
lookups
    b.HasIndex(u =>
u.NormalizedUserName).HasName("UserNameIndex").IsUnique();
    b.HasIndex(u => u.NormalizedEmail).HasName("EmailIndex");

    // Maps to the AspNetUsers table
    b.ToTable("AspNetUsers");

    // A concurrency token for use with the optimistic concurrency checking
    b.Property(u => u.ConcurrencyStamp).IsConcurrencyToken();

    // Limit the size of columns to use efficient database types
    b.Property(u => u.UserName).HasMaxLength(256);
    b.Property(u => u.NormalizedUserName).HasMaxLength(256);
    b.Property(u => u.Email).HasMaxLength(256);
    b.Property(u => u.NormalizedEmail).HasMaxLength(256);

    // The relationships between User and other entity types
    // Note that these relationships are configured with no navigation
properties

    // Each User can have many UserClaims
    b.HasMany<TUserClaim>().WithOne().HasForeignKey(uc =>
uc.UserId).IsRequired();

    // Each User can have many UserLogins
    b.HasMany<TUserLogin>().WithOne().HasForeignKey(ul =>
ul.UserId).IsRequired();

    // Each User can have many UserTokens
    b.HasMany<TUserToken>().WithOne().HasForeignKey(ut =>
ut.UserId).IsRequired();

    // Each User can have many entries in the UserRole join table
    b.HasMany<TUserRole>().WithOne().HasForeignKey(ur =>
ur.UserId).IsRequired();
```

```
});

builder.Entity<TUserClaim>(b =>
{
    // Primary key
    b.HasKey(uc => uc.Id);

    // Maps to the AspNetUserClaims table
    b.ToTable("AspNetUserClaims");
});

builder.Entity<TUserLogin>(b =>
{
    // Composite primary key consisting of the LoginProvider and the key to
use
    // with that provider
    b.HasKey(l => new { l.LoginProvider, l.ProviderKey });

    // Limit the size of the composite key columns due to common DB
restrictions
    b.Property(l => l.LoginProvider).HasMaxLength(128);
    b.Property(l => l.ProviderKey).HasMaxLength(128);

    // Maps to the AspNetUserLogins table
    b.ToTable("AspNetUserLogins");
});

builder.Entity<TUserToken>(b =>
{
    // Composite primary key consisting of the UserId, LoginProvider and
Name
    b.HasKey(t => new { t.UserId, t.LoginProvider, t.Name });

    // Limit the size of the composite key columns due to common DB
restrictions
    b.Property(t => t.LoginProvider).HasMaxLength(maxKeyLength);
    b.Property(t => t.Name).HasMaxLength(maxKeyLength);

    // Maps to the AspNetUserTokens table
    b.ToTable("AspNetUserTokens");
});

builder.Entity<TRole>(b =>
{
    // Primary key
    b.HasKey(r => r.Id);

    // Index for "normalized" role name to allow efficient lookups
    b.HasIndex(r => r.NormalizedName).HasName("RoleNameIndex").IsUnique();

    // Maps to the AspNetRoles table
    b.ToTable("AspNetRoles");

    // A concurrency token for use with the optimistic concurrency checking
    b.Property(r => r.ConcurrencyStamp).IsConcurrencyToken();
```

```
    // Limit the size of columns to use efficient database types
    b.Property(u => u.Name).HasMaxLength(256);
    b.Property(u => u.NormalizedName).HasMaxLength(256);

    // The relationships between Role and other entity types
    // Note that these relationships are configured with no navigation
properties

    // Each Role can have many entries in the UserRole join table
    b.HasMany<TUserRole>().WithOne().HasForeignKey(ur =>
ur.RoleId).IsRequired();

    // Each Role can have many associated RoleClaims
    b.HasMany<TRoleClaim>().WithOne().HasForeignKey(rc =>
rc.RoleId).IsRequired();
});

builder.Entity<TRoleClaim>(b =>
{
    // Primary key
    b.HasKey(rc => rc.Id);

    // Maps to the AspNetRoleClaims table
    b.ToTable("AspNetRoleClaims");
});

builder.Entity<TUserRole>(b =>
{
    // Primary key
    b.HasKey(r => new { r.UserId, r.RoleId });

    // Maps to the AspNetUserRoles table
    b.ToTable("AspNetUserRoles");
});
```

Model generic types

Identity defines default Common Language Runtime (CLR) types for each of the entity types listed above. These types are all prefixed with *Identity*:

- `IdentityUser`
- `IdentityRole`
- `IdentityUserClaim`
- `IdentityUserToken`
- `IdentityUserLogin`
- `IdentityRoleClaim`
- `IdentityUserRole`

Rather than using these types directly, the types can be used as base classes for the app's own types. The `DbContext` classes defined by Identity are generic, such that different CLR types can be used for one or more of the entity types in the model. These generic types also allow the `User` primary key (PK) data type to be changed.

When using Identity with support for roles, an IdentityDbContext class should be used. For example:

C#

```
// Uses all the built-in Identity types
// Uses `string` as the key type
public class IdentityDbContext
    : IdentityDbContext<IdentityUser, IdentityRole, string>
{
}

// Uses the built-in Identity types except with a custom User type
// Uses `string` as the key type
public class IdentityDbContext<TUser>
    : IdentityDbContext<TUser, IdentityRole, string>
        where TUser : IdentityUser
{
}

// Uses the built-in Identity types except with custom User and Role types
// The key type is defined by TKey
public class IdentityDbContext<TUser, TRole, TKey> : IdentityDbContext<
    TUser, TRole, TKey, IdentityUserClaim<TKey>, IdentityUserRole<TKey>,
    IdentityUserLogin<TKey>, IdentityRoleClaim<TKey>,
IdentityUserToken<TKey>>
        where TUser : IdentityUser<TKey>
        where TRole : IdentityRole<TKey>
        where TKey : IEquatable<TKey>
{
}

// No built-in Identity types are used; all are specified by generic
arguments
// The key type is defined by TKey
public abstract class IdentityDbContext<
    TUser, TRole, TKey, TUserClaim, TUserRole, TUserLogin, TRoleClaim,
TUserToken>
    : IdentityUserContext<TUser, TKey, TUserClaim, TUserLogin, TUserToken>
         where TUser : IdentityUser<TKey>
         where TRole : IdentityRole<TKey>
         where TKey : IEquatable<TKey>
         where TUserClaim : IdentityUserClaim<TKey>
         where TUserRole : IdentityUserRole<TKey>
         where TUserLogin : IdentityUserLogin<TKey>
```

```
        where TRoleClaim : IdentityRoleClaim<TKey>
        where TUserToken : IdentityUserToken<TKey>
```

It's also possible to use Identity without roles (only claims), in which case an IdentityUserContext<TUser> class should be used:

C#

```
// Uses the built-in non-role Identity types except with a custom User type
// Uses `string` as the key type
public class IdentityUserContext<TUser>
    : IdentityUserContext<TUser, string>
        where TUser : IdentityUser
{
}

// Uses the built-in non-role Identity types except with a custom User type
// The key type is defined by TKey
public class IdentityUserContext<TUser, TKey> : IdentityUserContext<
    TUser, TKey, IdentityUserClaim<TKey>, IdentityUserLogin<TKey>,
    IdentityUserToken<TKey>>
        where TUser : IdentityUser<TKey>
        where TKey : IEquatable<TKey>
{
}

// No built-in Identity types are used; all are specified by generic
arguments, with no roles
// The key type is defined by TKey
public abstract class IdentityUserContext<
    TUser, TKey, TUserClaim, TUserLogin, TUserToken> : DbContext
        where TUser : IdentityUser<TKey>
        where TKey : IEquatable<TKey>
        where TUserClaim : IdentityUserClaim<TKey>
        where TUserLogin : IdentityUserLogin<TKey>
        where TUserToken : IdentityUserToken<TKey>
{
}
```

Customize the model

The starting point for model customization is to derive from the appropriate context type. See the Model generic types section. This context type is customarily called `ApplicationDbContext` and is created by the ASP.NET Core templates.

The context is used to configure the model in two ways:

- Supplying entity and key types for the generic type parameters.

- Overriding `OnModelCreating` to modify the mapping of these types.

When overriding `OnModelCreating`, `base.OnModelCreating` should be called first; the overriding configuration should be called next. EF Core generally has a last-one-wins policy for configuration. For example, if the `ToTable` method for an entity type is called first with one table name and then again later with a different table name, the table name in the second call is used.

NOTE: If the `DbContext` doesn't derive from `IdentityDbContext`, `AddEntityFrameworkStores` may not infer the correct POCO types for `TUserClaim`, `TUserLogin`, and `TUserToken`. If `AddEntityFrameworkStores` doesn't infer the correct POCO types, a workaround is to directly add the correct types via `services.AddScoped<IUser/RoleStore<TUser>` and `UserStore<...>>`.

Custom user data

Custom user data is supported by inheriting from `IdentityUser`. It's customary to name this type `ApplicationUser`:

C#

```
public class ApplicationUser : IdentityUser
{
    public string CustomTag { get; set; }
}
```

Use the `ApplicationUser` type as a generic argument for the context:

C#

```
public class ApplicationDbContext : IdentityDbContext<ApplicationUser>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
options)
        : base(options)
    {
    }

    protected override void OnModelCreating(ModelBuilder builder)
    {
        base.OnModelCreating(builder);
    }
}
```

There's no need to override `OnModelCreating` in the `ApplicationDbContext` class. EF Core maps the `CustomTag` property by convention. However, the database needs to be updated to create a new `CustomTag` column. To create the column, add a migration, and then update the database as described in Identity and EF Core Migrations.

Update `Pages/Shared/_LoginPartial.cshtml` and replace `IdentityUser` with `ApplicationUser`:

CSHTML

```
@using Microsoft.AspNetCore.Identity
@using WebApp1.Areas.Identity.Data
@inject SignInManager<ApplicationUser> SignInManager
@inject UserManager<ApplicationUser> UserManager
```

Update `Areas/Identity/IdentityHostingStartup.cs` or `Startup.ConfigureServices` and replace `IdentityUser` with `ApplicationUser`.

C#

```
services.AddDefaultIdentity<ApplicationUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();
```

Calling AddDefaultIdentity is equivalent to the following code:

C#

```
services.AddAuthentication(o =>
{
    o.DefaultScheme = IdentityConstants.ApplicationScheme;
    o.DefaultSignInScheme = IdentityConstants.ExternalScheme;
})
.AddIdentityCookies(o => { });

services.AddIdentityCore<TUser>(o =>
{
    o.Stores.MaxLengthForKeys = 128;
    o.SignIn.RequireConfirmedAccount = true;
})
.AddDefaultUI()
.AddDefaultTokenProviders();
```

Identity is provided as a Razor class library. For more information, see Scaffold Identity in ASP.NET Core projects. Consequently, the preceding code requires a call to

AddDefaultUI. If the Identity scaffolder was used to add Identity files to the project, remove the call to `AddDefaultUI`. For more information, see:

- Scaffold Identity
- Add, download, and delete custom user data to Identity

Change the primary key type

A change to the PK column's data type after the database has been created is problematic on many database systems. Changing the PK typically involves dropping and re-creating the table. Therefore, key types should be specified in the initial migration when the database is created.

Follow these steps to change the PK type:

1. If the database was created before the PK change, run `Drop-Database` (PMC) or `dotnet ef database drop` (.NET CLI) to delete it.

2. After confirming deletion of the database, remove the initial migration with `Remove-Migration` (PMC) or `dotnet ef migrations remove` (.NET CLI).

3. Update the `ApplicationDbContext` class to derive from IdentityDbContext<TUser,TRole,TKey>. Specify the new key type for `TKey`. For example, to use a `Guid` key type:

   C#

   ```
   public class ApplicationDbContext
       : IdentityDbContext<IdentityUser<Guid>, IdentityRole<Guid>, Guid>
   {
       public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
   options)
           : base(options)
       {
       }
   }
   ```

   In the preceding code, the generic classes IdentityUser<TKey> and IdentityRole<TKey> must be specified to use the new key type.

   `Startup.ConfigureServices` must be updated to use the generic user:

   C#

   ```
   services.AddDefaultIdentity<IdentityUser<Guid>>(options =>
   options.SignIn.RequireConfirmedAccount = true)
   ```

```
        .AddEntityFrameworkStores<ApplicationDbContext>();
```

4. If a custom `ApplicationUser` class is being used, update the class to inherit from `IdentityUser`. For example:

```
C#

using System;
using Microsoft.AspNetCore.Identity;

public class ApplicationUser : IdentityUser<Guid>
{
    public string CustomTag { get; set; }
}
```

Update `ApplicationDbContext` to reference the custom `ApplicationUser` class:

```
C#

public class ApplicationDbContext
    : IdentityDbContext<ApplicationUser, IdentityRole<Guid>, Guid>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
options)
        : base(options)
    {
    }
}
```

Register the custom database context class when adding the Identity service in `Startup.ConfigureServices`:

```
C#

services.AddDefaultIdentity<ApplicationUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();
```

The primary key's data type is inferred by analyzing the DbContext object.

Identity is provided as a Razor class library. For more information, see Scaffold Identity in ASP.NET Core projects. Consequently, the preceding code requires a call to AddDefaultUI. If the Identity scaffolder was used to add Identity files to the project, remove the call to `AddDefaultUI`.

5. If a custom `ApplicationRole` class is being used, update the class to inherit from `IdentityRole<TKey>`. For example:

```
C#

using System;
using Microsoft.AspNetCore.Identity;

public class ApplicationRole : IdentityRole<Guid>
{
    public string Description { get; set; }
}
```

Update `ApplicationDbContext` to reference the custom `ApplicationRole` class. For example, the following class references a custom `ApplicationUser` and a custom `ApplicationRole`:

```
C#

using System;
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;
using Microsoft.EntityFrameworkCore;

public class ApplicationDbContext :
    IdentityDbContext<ApplicationUser, ApplicationRole, Guid>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
options)
        : base(options)
    {
    }
}
```

Register the custom database context class when adding the Identity service in `Startup.ConfigureServices`:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
```

```
    services.AddIdentity<ApplicationUser, ApplicationRole>()
            .AddEntityFrameworkStores<ApplicationDbContext>()
            .AddDefaultUI()
            .AddDefaultTokenProviders();

    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
}
```

The primary key's data type is inferred by analyzing the DbContext object.

Identity is provided as a Razor class library. For more information, see Scaffold Identity in ASP.NET Core projects. Consequently, the preceding code requires a call to AddDefaultUI. If the Identity scaffolder was used to add Identity files to the project, remove the call to `AddDefaultUI`.

Add navigation properties

Changing the model configuration for relationships can be more difficult than making other changes. Care must be taken to replace the existing relationships rather than create new, additional relationships. In particular, the changed relationship must specify the same foreign key (FK) property as the existing relationship. For example, the relationship between `Users` and `UserClaims` is, by default, specified as follows:

C#

```
builder.Entity<TUser>(b =>
{
    // Each User can have many UserClaims
    b.HasMany<TUserClaim>()
     .WithOne()
     .HasForeignKey(uc => uc.UserId)
     .IsRequired();
});
```

The FK for this relationship is specified as the `UserClaim.UserId` property. `HasMany` and `WithOne` are called without arguments to create the relationship without navigation properties.

Add a navigation property to `ApplicationUser` that allows associated `UserClaims` to be referenced from the user:

C#

```
public class ApplicationUser : IdentityUser
{
    public virtual ICollection<IdentityUserClaim<string>> Claims { get; set;
}
}
```

The `TKey` for `IdentityUserClaim<TKey>` is the type specified for the PK of users. In this case, `TKey` is `string` because the defaults are being used. It's **not** the PK type for the `UserClaim` entity type.

Now that the navigation property exists, it must be configured in `OnModelCreating`:

C#

```
public class ApplicationDbContext : IdentityDbContext<ApplicationUser>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
options)
        : base(options)
    {
    }

    protected override void OnModelCreating(ModelBuilder modelBuilder)
    {
        base.OnModelCreating(modelBuilder);

        modelBuilder.Entity<ApplicationUser>(b =>
        {
            // Each User can have many UserClaims
            b.HasMany(e => e.Claims)
                .WithOne()
                .HasForeignKey(uc => uc.UserId)
                .IsRequired();
        });
    }
}
```

Notice that relationship is configured exactly as it was before, only with a navigation property specified in the call to `HasMany`.

The navigation properties only exist in the EF model, not the database. Because the FK for the relationship hasn't changed, this kind of model change doesn't require the database to be updated. This can be checked by adding a migration after making the change. The `Up` and `Down` methods are empty.

Add all User navigation properties

Using the section above as guidance, the following example configures unidirectional navigation properties for all relationships on User:

C#

```
public class ApplicationUser : IdentityUser
{
    public virtual ICollection<IdentityUserClaim<string>> Claims { get; set;
}
    public virtual ICollection<IdentityUserLogin<string>> Logins { get; set;
}
    public virtual ICollection<IdentityUserToken<string>> Tokens { get; set;
}
    public virtual ICollection<IdentityUserRole<string>> UserRoles { get;
set; }
}
```

C#

```
public class ApplicationDbContext : IdentityDbContext<ApplicationUser>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
options)
        : base(options)
    {
    }

    protected override void OnModelCreating(ModelBuilder modelBuilder)
    {
        base.OnModelCreating(modelBuilder);

        modelBuilder.Entity<ApplicationUser>(b =>
        {
            // Each User can have many UserClaims
            b.HasMany(e => e.Claims)
                .WithOne()
                .HasForeignKey(uc => uc.UserId)
                .IsRequired();

            // Each User can have many UserLogins
            b.HasMany(e => e.Logins)
                .WithOne()
                .HasForeignKey(ul => ul.UserId)
                .IsRequired();

            // Each User can have many UserTokens
            b.HasMany(e => e.Tokens)
                .WithOne()
                .HasForeignKey(ut => ut.UserId)
                .IsRequired();

            // Each User can have many entries in the UserRole join table
```

```
            b.HasMany(e => e.UserRoles)
                .WithOne()
                .HasForeignKey(ur => ur.UserId)
                .IsRequired();
        });
    }
}
```

Add User and Role navigation properties

Using the section above as guidance, the following example configures navigation properties for all relationships on User and Role:

C#

```
public class ApplicationUser : IdentityUser
{
    public virtual ICollection<IdentityUserClaim<string>> Claims { get; set;
}
    public virtual ICollection<IdentityUserLogin<string>> Logins { get; set;
}
    public virtual ICollection<IdentityUserToken<string>> Tokens { get; set;
}
    public virtual ICollection<ApplicationUserRole> UserRoles { get; set; }
}

public class ApplicationRole : IdentityRole
{
    public virtual ICollection<ApplicationUserRole> UserRoles { get; set; }
}

public class ApplicationUserRole : IdentityUserRole<string>
{
    public virtual ApplicationUser User { get; set; }
    public virtual ApplicationRole Role { get; set; }
}
```

C#

```
public class ApplicationDbContext
    : IdentityDbContext<
        ApplicationUser, ApplicationRole, string,
        IdentityUserClaim<string>, ApplicationUserRole,
IdentityUserLogin<string>,
        IdentityRoleClaim<string>, IdentityUserToken<string>>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
options)
        : base(options)
    {
```

```
    }

    protected override void OnModelCreating(ModelBuilder modelBuilder)
    {
        base.OnModelCreating(modelBuilder);

        modelBuilder.Entity<ApplicationUser>(b =>
        {
            // Each User can have many UserClaims
            b.HasMany(e => e.Claims)
                .WithOne()
                .HasForeignKey(uc => uc.UserId)
                .IsRequired();

            // Each User can have many UserLogins
            b.HasMany(e => e.Logins)
                .WithOne()
                .HasForeignKey(ul => ul.UserId)
                .IsRequired();

            // Each User can have many UserTokens
            b.HasMany(e => e.Tokens)
                .WithOne()
                .HasForeignKey(ut => ut.UserId)
                .IsRequired();

            // Each User can have many entries in the UserRole join table
            b.HasMany(e => e.UserRoles)
                .WithOne(e => e.User)
                .HasForeignKey(ur => ur.UserId)
                .IsRequired();
        });

        modelBuilder.Entity<ApplicationRole>(b =>
        {
            // Each Role can have many entries in the UserRole join table
            b.HasMany(e => e.UserRoles)
                .WithOne(e => e.Role)
                .HasForeignKey(ur => ur.RoleId)
                .IsRequired();
        });

    }
}
```

Notes:

- This example also includes the `UserRole` join entity, which is needed to navigate the many-to-many relationship from Users to Roles.
- Remember to change the types of the navigation properties to reflect that `Application{...}` types are now being used instead of `Identity{...}` types.

- Remember to use the `Application{...}` in the generic `ApplicationContext` definition.

Add all navigation properties

Using the section above as guidance, the following example configures navigation properties for all relationships on all entity types:

C#

```
public class ApplicationUser : IdentityUser
{
    public virtual ICollection<ApplicationUserClaim> Claims { get; set; }
    public virtual ICollection<ApplicationUserLogin> Logins { get; set; }
    public virtual ICollection<ApplicationUserToken> Tokens { get; set; }
    public virtual ICollection<ApplicationUserRole> UserRoles { get; set; }
}

public class ApplicationRole : IdentityRole
{
    public virtual ICollection<ApplicationUserRole> UserRoles { get; set; }
    public virtual ICollection<ApplicationRoleClaim> RoleClaims { get; set;
}
}

public class ApplicationUserRole : IdentityUserRole<string>
{
    public virtual ApplicationUser User { get; set; }
    public virtual ApplicationRole Role { get; set; }
}

public class ApplicationUserClaim : IdentityUserClaim<string>
{
    public virtual ApplicationUser User { get; set; }
}

public class ApplicationUserLogin : IdentityUserLogin<string>
{
    public virtual ApplicationUser User { get; set; }
}

public class ApplicationRoleClaim : IdentityRoleClaim<string>
{
    public virtual ApplicationRole Role { get; set; }
}

public class ApplicationUserToken : IdentityUserToken<string>
{
    public virtual ApplicationUser User { get; set; }
}
```

C#

```
public class ApplicationDbContext
    : IdentityDbContext<
        ApplicationUser, ApplicationRole, string,
        ApplicationUserClaim, ApplicationUserRole, ApplicationUserLogin,
        ApplicationRoleClaim, ApplicationUserToken>
{
    public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
options)
        : base(options)
    {
    }

    protected override void OnModelCreating(ModelBuilder modelBuilder)
    {
        base.OnModelCreating(modelBuilder);

        modelBuilder.Entity<ApplicationUser>(b =>
        {
            // Each User can have many UserClaims
            b.HasMany(e => e.Claims)
                .WithOne(e => e.User)
                .HasForeignKey(uc => uc.UserId)
                .IsRequired();

            // Each User can have many UserLogins
            b.HasMany(e => e.Logins)
                .WithOne(e => e.User)
                .HasForeignKey(ul => ul.UserId)
                .IsRequired();

            // Each User can have many UserTokens
            b.HasMany(e => e.Tokens)
                .WithOne(e => e.User)
                .HasForeignKey(ut => ut.UserId)
                .IsRequired();

            // Each User can have many entries in the UserRole join table
            b.HasMany(e => e.UserRoles)
                .WithOne(e => e.User)
                .HasForeignKey(ur => ur.UserId)
                .IsRequired();
        });

        modelBuilder.Entity<ApplicationRole>(b =>
        {
            // Each Role can have many entries in the UserRole join table
            b.HasMany(e => e.UserRoles)
                .WithOne(e => e.Role)
                .HasForeignKey(ur => ur.RoleId)
                .IsRequired();

            // Each Role can have many associated RoleClaims
```

```
            b.HasMany(e => e.RoleClaims)
                .WithOne(e => e.Role)
                .HasForeignKey(rc => rc.RoleId)
                .IsRequired();
        });
    }
}
```

Use composite keys

The preceding sections demonstrated changing the type of key used in the Identity model. Changing the Identity key model to use composite keys isn't supported or recommended. Using a composite key with Identity involves changing how the Identity manager code interacts with the model. This customization is beyond the scope of this document.

Change table/column names and facets

To change the names of tables and columns, call `base.OnModelCreating`. Then, add configuration to override any of the defaults. For example, to change the name of all the Identity tables:

C#

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    base.OnModelCreating(modelBuilder);

    modelBuilder.Entity<IdentityUser>(b =>
    {
        b.ToTable("MyUsers");
    });

    modelBuilder.Entity<IdentityUserClaim<string>>(b =>
    {
        b.ToTable("MyUserClaims");
    });

    modelBuilder.Entity<IdentityUserLogin<string>>(b =>
    {
        b.ToTable("MyUserLogins");
    });

    modelBuilder.Entity<IdentityUserToken<string>>(b =>
    {
        b.ToTable("MyUserTokens");
    });
```

```
    modelBuilder.Entity<IdentityRole>(b =>
    {
        b.ToTable("MyRoles");
    });

    modelBuilder.Entity<IdentityRoleClaim<string>>(b =>
    {
        b.ToTable("MyRoleClaims");
    });

    modelBuilder.Entity<IdentityUserRole<string>>(b =>
    {
        b.ToTable("MyUserRoles");
    });
}
```

These examples use the default Identity types. If using an app type such as `ApplicationUser`, configure that type instead of the default type.

The following example changes some column names:

C#

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    base.OnModelCreating(modelBuilder);

    modelBuilder.Entity<IdentityUser>(b =>
    {
        b.Property(e => e.Email).HasColumnName("EMail");
    });

    modelBuilder.Entity<IdentityUserClaim<string>>(b =>
    {
        b.Property(e => e.ClaimType).HasColumnName("CType");
        b.Property(e => e.ClaimValue).HasColumnName("CValue");
    });
}
```

Some types of database columns can be configured with certain *facets* (for example, the maximum `string` length allowed). The following example sets column maximum lengths for several `string` properties in the model:

C#

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    base.OnModelCreating(modelBuilder);

    modelBuilder.Entity<IdentityUser>(b =>
```

```
    {
        b.Property(u => u.UserName).HasMaxLength(128);
        b.Property(u => u.NormalizedUserName).HasMaxLength(128);
        b.Property(u => u.Email).HasMaxLength(128);
        b.Property(u => u.NormalizedEmail).HasMaxLength(128);
    });

    modelBuilder.Entity<IdentityUserToken<string>>(b =>
    {
        b.Property(t => t.LoginProvider).HasMaxLength(128);
        b.Property(t => t.Name).HasMaxLength(128);
    });
}
```

Map to a different schema

Schemas can behave differently across database providers. For SQL Server, the default is to create all tables in the *dbo* schema. The tables can be created in a different schema. For example:

C#

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    base.OnModelCreating(modelBuilder);

    modelBuilder.HasDefaultSchema("notdbo");
}
```

Lazy loading

In this section, support for lazy-loading proxies in the Identity model is added. Lazy-loading is useful since it allows navigation properties to be used without first ensuring they're loaded.

Entity types can be made suitable for lazy-loading in several ways, as described in the EF Core documentation. For simplicity, use lazy-loading proxies, which requires:

- Installation of the Microsoft.EntityFrameworkCore.Proxies package.
- A call to UseLazyLoadingProxies inside AddDbContext.
- Public entity types with `public virtual` navigation properties.

The following example demonstrates calling `UseLazyLoadingProxies` in `Startup.ConfigureServices`:

C#

```
services
    .AddDbContext<ApplicationDbContext>(
        b => b.UseSqlServer(connectionString)
              .UseLazyLoadingProxies())
    .AddDefaultIdentity<ApplicationUser>()
    .AddEntityFrameworkStores<ApplicationDbContext>();
```

Refer to the preceding examples for guidance on adding navigation properties to the entity types.

> ⚠ **Warning**
>
> This article shows the use of connection strings. With a local database the user doesn't have to be authenticated, but in production, connection strings sometimes include a password to authenticate. A resource owner password credential (ROPC) is a security risk that should be avoided in production databases. Production apps should use the most secure authentication flow available. For more information on authentication for apps deployed to test or production environments, see Secure authentication flows.

Configure ASP.NET Core Identity

Article • 03/09/2024

ASP.NET Core Identity uses default values for settings such as password policy, lockout, and cookie configuration. These settings can be overridden at application startup.

Identity options

The IdentityOptions class represents the options that can be used to configure the Identity system. IdentityOptions must be set **after** calling AddIdentity or AddDefaultIdentity.

Claims Identity

IdentityOptions.ClaimsIdentity specifies the ClaimsIdentityOptions with the properties shown in the following table.

Expand table

Property	Description	Default
RoleClaimType	Gets or sets the claim type used for a role claim.	ClaimTypes.Role
SecurityStampClaimType	Gets or sets the claim type used for the security stamp claim.	`AspNet.Identity.SecurityStamp`
UserIdClaimType	Gets or sets the claim type used for the user identifier claim.	ClaimTypes.NameIdentifier
UserNameClaimType	Gets or sets the claim type used for the user name claim.	ClaimTypes.Name

Lockout

Lockout is set in the PasswordSignInAsync method:

C#

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl ??= Url.Content("~/");

    ExternalLogins = (await
```

```
_signInManager.GetExternalAuthenticationSchemesAsync()).ToList();

    if (ModelState.IsValid)
    {
        // This doesn't count login failures towards account lockout
        // To enable password failures to trigger account lockout, set
lockoutOnFailure: true
        var result = await _signInManager.PasswordSignInAsync(Input.Email,
             Input.Password, Input.RememberMe,
             lockoutOnFailure: false);
        if (result.Succeeded)
        {
            _logger.LogInformation("User logged in.");
            return LocalRedirect(returnUrl);
        }
        if (result.RequiresTwoFactor)
        {
            return RedirectToPage("./LoginWith2fa", new { ReturnUrl =
returnUrl, RememberMe = Input.RememberMe });
        }
        if (result.IsLockedOut)
        {
            _logger.LogWarning("User account locked out.");
            return RedirectToPage("./Lockout");
        }
        else
        {
            ModelState.AddModelError(string.Empty, "Invalid login
attempt.");
            return Page();
        }
    }

    // If we got this far, something failed, redisplay form
    return Page();
}
```

The preceding code is based on the Login Identity template.

Lockout options are set in `Program.cs`:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using RPauth.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
```

```
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>

options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

builder.Services.Configure<IdentityOptions>(options =>
{
    // Default Lockout settings.
    options.Lockout.DefaultLockoutTimeSpan = TimeSpan.FromMinutes(5);
    options.Lockout.MaxFailedAccessAttempts = 5;
    options.Lockout.AllowedForNewUsers = true;
});

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The preceding code sets the IdentityOptions LockoutOptions with default values.

A successful authentication resets the failed access attempts count and resets the clock.

IdentityOptions.Lockout specifies the LockoutOptions with the properties shown in the table.

Expand table

Property	Description	Default
AllowedForNewUsers	Determines if a new user can be locked out.	`true`

Property	Description	Default
DefaultLockoutTimeSpan	The amount of time a user is locked out when a lockout occurs.	5 minutes
MaxFailedAccessAttempts	The number of failed access attempts until a user is locked out, if lockout is enabled.	5

Password

By default, Identity requires that passwords contain an uppercase character, lowercase character, a digit, and a non-alphanumeric character. Passwords must be at least six characters long.

Passwords are configured with:

- PasswordOptions in `Program.cs`.
- [StringLength] attributes of `Password` properties if Identity is scaffolded into the app. `InputModel` `Password` properties are found in the following files:
  - `Areas/Identity/Pages/Account/Register.cshtml.cs`
  - `Areas/Identity/Pages/Account/ResetPassword.cshtml.cs`

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using RPauth.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
                                options.SignIn.RequireConfirmedAccount =
true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();
```

```
builder.Services.Configure<IdentityOptions>(options =>
{
    // Default Password settings.
    options.Password.RequireDigit = true;
    options.Password.RequireLowercase = true;
    options.Password.RequireNonAlphanumeric = true;
    options.Password.RequireUppercase = true;
    options.Password.RequiredLength = 6;
    options.Password.RequiredUniqueChars = 1;
});

var app = builder.Build();

// Remaining code removed for brevity.
```

IdentityOptions.Password specifies the PasswordOptions with the properties shown in the table.

Expand table

Property	Description	Default
RequireDigit	Requires a number between 0-9 in the password.	`true`
RequiredLength	The minimum length of the password.	6
RequireLowercase	Requires a lowercase character in the password.	`true`
RequireNonAlphanumeric	Requires a non-alphanumeric character in the password.	`true`
RequiredUniqueChars	Only applies to ASP.NET Core 2.0 or later. Requires the number of distinct characters in the password.	1
RequireUppercase	Requires an uppercase character in the password.	`true`

Sign-in

The following code sets `SignIn` settings (to default values):

C#

```
builder.Services.Configure<IdentityOptions>(options =>
{
    // Default SignIn settings.
    options.SignIn.RequireConfirmedEmail = false;
    options.SignIn.RequireConfirmedPhoneNumber = false;
});
```

IdentityOptions.SignIn specifies the SignInOptions with the properties shown in the table.

Expand table

Property	Description	Default
RequireConfirmedEmail	Requires a confirmed email to sign in.	`false`
RequireConfirmedPhoneNumber	Requires a confirmed phone number to sign in.	`false`

Tokens

IdentityOptions.Tokens specifies the TokenOptions with the properties shown in the table.

Expand table

Property	Description
AuthenticatorTokenProvider	Gets or sets the `AuthenticatorTokenProvider` used to validate two-factor sign-ins with an authenticator.
ChangeEmailTokenProvider	Gets or sets the `ChangeEmailTokenProvider` used to generate tokens used in email change confirmation emails.
ChangePhoneNumberTokenProvider	Gets or sets the `ChangePhoneNumberTokenProvider` used to generate tokens used when changing phone numbers.
EmailConfirmationTokenProvider	Gets or sets the token provider used to generate tokens used in account confirmation emails.
PasswordResetTokenProvider	Gets or sets the IUserTwoFactorTokenProvider<TUser> used to generate tokens used in password reset emails.
ProviderMap	Used to construct a User Token Provider with the key used as the provider's name.

User

C#

```
builder.Services.Configure<IdentityOptions>(options =>
{
    // Default User settings.
    options.User.AllowedUserNameCharacters =
```

```
"abcdefghijklmnopqrstuvwxyzABCDEFGHIJKLMNOPQRSTUVWXYZ0123456789-._@+";
    options.User.RequireUniqueEmail = false;

});
```

IdentityOptions.User specifies the UserOptions with the properties shown in the table.

Expand table

Property	Description	Default
AllowedUserNameCharacters	Allowed characters in the username.	abcdefghijklmnopqrstuvwxyz ABCDEFGHIJKLMNOPQRSTUVWXYZ 0123456789 -._@+
RequireUniqueEmail	Requires each user to have a unique email.	`false`

Cookie settings

Configure the app's cookie in `Program.cs`. ConfigureApplicationCookie must be called **after** calling `AddIdentity` or `AddDefaultIdentity`.

C#

```
builder.Services.ConfigureApplicationCookie(options =>
{
    options.AccessDeniedPath = "/Identity/Account/AccessDenied";
    options.Cookie.Name = "YourAppCookieName";
    options.Cookie.HttpOnly = true;
    options.ExpireTimeSpan = TimeSpan.FromMinutes(60);
    options.LoginPath = "/Identity/Account/Login";
    // ReturnUrlParameter requires
    //using Microsoft.AspNetCore.Authentication.Cookies;
    options.ReturnUrlParameter =
CookieAuthenticationDefaults.ReturnUrlParameter;
    options.SlidingExpiration = true;
});
```

For more information, see CookieAuthenticationOptions.

Password Hasher options

PasswordHasherOptions gets and sets options for password hashing.

Expand table

Option	Description
CompatibilityMode	The compatibility mode used when hashing new passwords. Defaults to IdentityV3. The first byte of a hashed password, called a *format marker*, specifies the version of the hashing algorithm used to hash the password. When verifying a password against a hash, the VerifyHashedPassword method selects the correct algorithm based on the first byte. A client is able to authenticate regardless of which version of the algorithm was used to hash the password. Setting the compatibility mode affects the hashing of *new passwords*.
IterationCount	The number of iterations used when hashing passwords using PBKDF2. This value is only used when the CompatibilityMode is set to IdentityV3. The value must be a positive integer and defaults to `100000`.

In the following example, the IterationCount is set to `12000` in `Program.cs`:

C#

```
// using Microsoft.AspNetCore.Identity;

builder.Services.Configure<PasswordHasherOptions>(option =>
{
    option.IterationCount = 12000;
});
```

Globally require all users to be authenticated

For information on how to globally require all users to be authenticated, see Require authenticated users.

ISecurityStampValidator and SignOut everywhere

Apps need to react to events involving security sensitive actions by regenerating the users ClaimsPrincipal. For example, the `ClaimsPrincipal` should be regenerated when joining a role, changing the password, or other security sensitive events. Identity uses the ISecurityStampValidator interface to regenerate the `ClaimsPrincipal`. The default implementation of Identity registers a SecurityStampValidator with the main application cookie and the two-factor cookie. The validator hooks into the OnValidatePrincipal event of each cookie to call into Identity to verify that the user's security stamp claim is

unchanged from what's stored in the cookie. The validator calls in at regular intervals. The call interval is a tradeoff between hitting the datastore too frequently and not often enough. Checking with a long interval results in stale claims. Call `userManager.UpdateSecurityStampAsync(user)` to force existing cookies to be invalided the next time they are checked. Most of the Identity UI account and manage pages call `userManager.UpdateSecurityStampAsync(user)` after changing the password or adding a login. Apps can call `userManager.UpdateSecurityStampAsync(user)` to implement a sign out everywhere action.

Changing the validation interval is shown in the following highlighted code:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using WebClaimsPrincipal.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection")
    ?? throw new InvalidOperationException("'DefaultConnection' not
found.");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();

// Force Identity's security stamp to be validated every minute.
builder.Services.Configure<SecurityStampValidatorOptions>(o =>
                    o.ValidationInterval = TimeSpan.FromMinutes(1));

builder.Services.AddRazorPages();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
```

```
app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Custom storage providers for ASP.NET Core Identity

Article • 10/29/2024

By Steve Smith

ASP.NET Core Identity is an extensible system which enables you to create a custom storage provider and connect it to your app. This topic describes how to create a customized storage provider for ASP.NET Core Identity. It covers the important concepts for creating your own storage provider, but isn't a step-by-step walk through. See Identity model customization to customize an Identity model.

Introduction

By default, the ASP.NET Core Identity system stores user information in a SQL Server database using Entity Framework Core. For many apps, this approach works well. However, you may prefer to use a different persistence mechanism or data schema. For example:

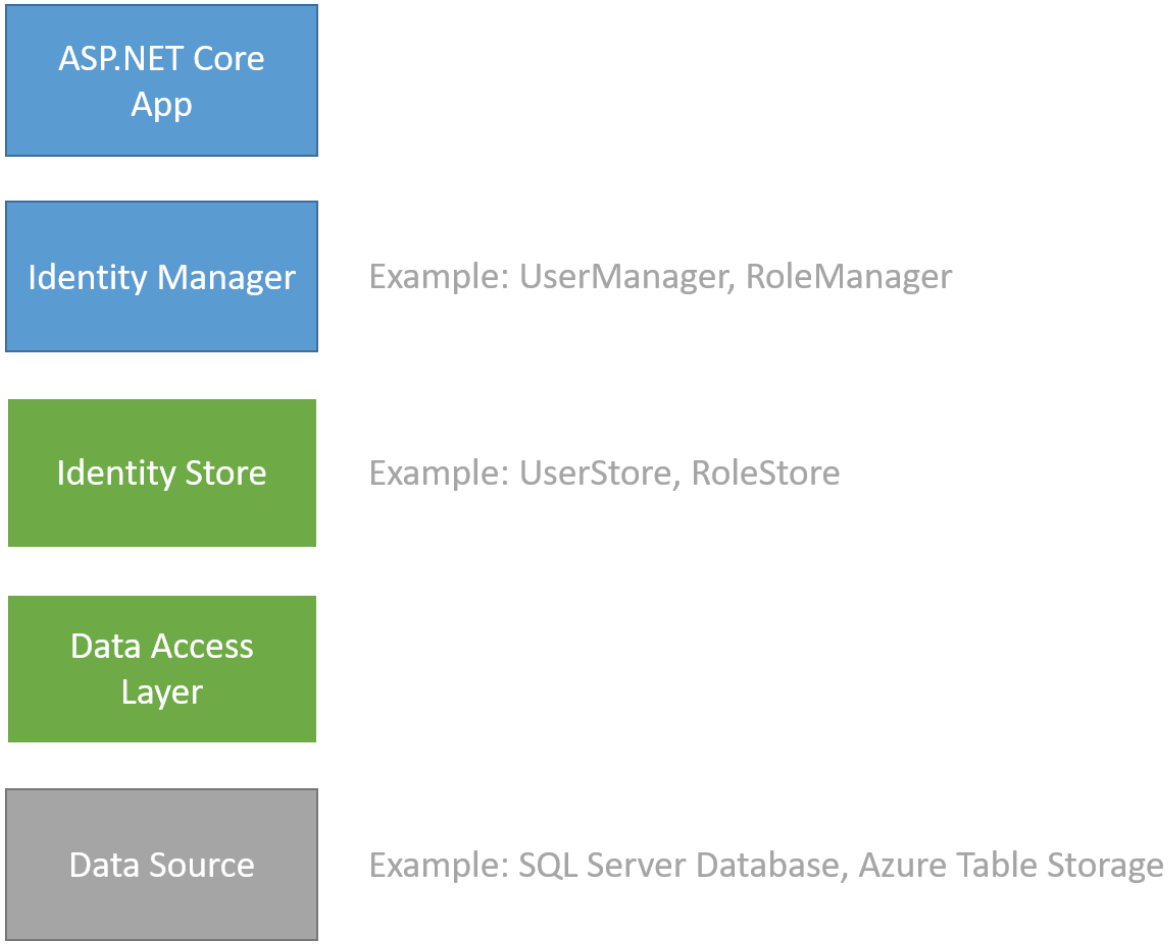
- You use Azure Table Storage or another data store.
- Your database tables have a different structure.
- You may wish to use a different data access approach, such as Dapper.

In each of these cases, you can write a customized provider for your storage mechanism and plug that provider into your app.

ASP.NET Core Identity is included in project templates in Visual Studio with the "Individual User Accounts" option.

When using the .NET CLI, add `-au Individual`:

.NET CLI



```
dotnet new mvc -au Individual
```

The ASP.NET Core Identity architecture

ASP.NET Core Identity consists of classes called managers and stores. *Managers* are high-level classes which an app developer uses to perform operations, such as creating an Identity user. *Stores* are lower-level classes that specify how entities, such as users

and roles, are persisted. Stores follow the repository pattern and are closely coupled with the persistence mechanism. Managers are decoupled from stores, which means you can replace the persistence mechanism without changing your application code (except for configuration).

The following diagram shows how a web app interacts with the managers, while stores interact with the data access layer.

To create a custom storage provider, create the data source, the data access layer, and the store classes that interact with this data access layer (the green and grey boxes in the diagram above). You don't need to customize the managers or your app code that interacts with them (the blue boxes above).

When creating a new instance of `UserManager` or `RoleManager` you provide the type of the user class and pass an instance of the store class as an argument. This approach enables you to plug your customized classes into ASP.NET Core.

Reconfigure app to use new storage provider shows how to instantiate `UserManager` and `RoleManager` with a customized store.

ASP.NET Core Identity stores data types

ASP.NET Core Identity data types are detailed in the following sections:

Users

Registered users of your web site. The IdentityUser type may be extended or used as an example for your own custom type. You don't need to inherit from a particular type to implement your own custom identity storage solution.

User Claims

A set of statements (or Claims) about the user that represent the user's identity. Can enable greater expression of the user's identity than can be achieved through roles.

User Logins

Information about the external authentication provider (like Facebook or a Microsoft account) to use when logging in a user. Example

Roles

Authorization groups for your site. Includes the role Id and role name (like "Admin" or "Employee"). Example

The data access layer

This topic assumes you are familiar with the persistence mechanism that you are going to use and how to create entities for that mechanism. This topic doesn't provide details about how to create the repositories or data access classes; it provides some suggestions about design decisions when working with ASP.NET Core Identity.

You have a lot of freedom when designing the data access layer for a customized store provider. You only need to create persistence mechanisms for features that you intend to use in your app. For example, if you are not using roles in your app, you don't need to create storage for roles or user role associations. Your technology and existing infrastructure may require a structure that's very different from the default implementation of ASP.NET Core Identity. In your data access layer, you provide the logic to work with the structure of your storage implementation.

The data access layer provides the logic to save the data from ASP.NET Core Identity to a data source. The data access layer for your customized storage provider might include the following classes to store user and role information.

Context class

Encapsulates the information to connect to your persistence mechanism and execute queries. Several data classes require an instance of this class, typically provided through dependency injection. Example.

User Storage

Stores and retrieves user information (such as user name and password hash). Example

Role Storage

Stores and retrieves role information (such as the role name). Example

UserClaims Storage

Stores and retrieves user claim information (such as the claim type and value). Example

UserLogins Storage

Stores and retrieves user login information (such as an external authentication provider). Example

UserRole Storage

Stores and retrieves which roles are assigned to which users. Example

TIP: Only implement the classes you intend to use in your app.

In the data access classes, provide code to perform data operations for your persistence mechanism. For example, within a custom provider, you might have the following code to create a new user in the *store* class:

C#

```
public async Task<IdentityResult> CreateAsync(ApplicationUser user,
    CancellationToken cancellationToken = default(CancellationToken))
{
    cancellationToken.ThrowIfCancellationRequested();
    if (user == null) throw new ArgumentNullException(nameof(user));

    return await _usersTable.CreateAsync(user);
}
```

The implementation logic for creating the user is in the `_usersTable.CreateAsync` method, shown below.

Customize the user class

When implementing a storage provider, create a user class which is equivalent to the IdentityUser class.

At a minimum, your user class must include an `Id` and a `UserName` property.

The `IdentityUser` class defines the properties that the `UserManager` calls when performing requested operations. The default type of the `Id` property is a string, but you can inherit from `IdentityUser<TKey, TUserClaim, TUserRole, TUserLogin, TUserToken>` and specify a different type. The framework expects the storage implementation to handle data type conversions.

Customize the user store

Create a `UserStore` class that provides the methods for all data operations on the user. This class is equivalent to the UserStore<TUser> class. In your `UserStore` class, implement `IUserStore<TUser>` and the optional interfaces required. You select which optional interfaces to implement based on the functionality provided in your app.

Optional interfaces

- IUserRoleStore
- IUserClaimStore
- IUserPasswordStore
- IUserSecurityStampStore
- IUserEmailStore
- IUserPhoneNumberStore
- IQueryableUserStore
- IUserLoginStore
- IUserTwoFactorStore
- IUserLockoutStore

The optional interfaces inherit from `IUserStore<TUser>`. You can see a partially implemented sample user store in the sample app.

Within the `UserStore` class, you use the data access classes that you created to perform operations. These are passed in using dependency injection. For example, in the SQL Server with Dapper implementation, the `UserStore` class has the `CreateAsync` method which uses an instance of `DapperUsersTable` to insert a new record:

```
C#

public async Task<IdentityResult> CreateAsync(ApplicationUser user)
{
    string sql = "INSERT INTO dbo.CustomUser " +
        "VALUES (@id, @Email, @EmailConfirmed, @PasswordHash, @UserName)";

    int rows = await _connection.ExecuteAsync(sql, new { user.Id,
user.Email, user.EmailConfirmed, user.PasswordHash, user.UserName });

    if(rows > 0)
    {
        return IdentityResult.Success;
    }
    return IdentityResult.Failed(new IdentityError { Description = $"Could
not insert user {user.Email}." });
}
```

Interfaces to implement when customizing user store

- **IUserStore**
  The IUserStore<TUser> interface is the only interface you must implement in the user store. It defines methods for creating, updating, deleting, and retrieving users.
- **IUserClaimStore**
  The IUserClaimStore<TUser> interface defines the methods you implement to enable user claims. It contains methods for adding, removing and retrieving user claims.
- **IUserLoginStore**
  The IUserLoginStore<TUser> defines the methods you implement to enable external authentication providers. It contains methods for adding, removing and retrieving user logins, and a method for retrieving a user based on the login information.
- **IUserRoleStore**
  The IUserRoleStore<TUser> interface defines the methods you implement to map a user to a role. It contains methods to add, remove, and retrieve a user's roles, and a method to check if a user is assigned to a role.
- **IUserPasswordStore**
  The IUserPasswordStore<TUser> interface defines the methods you implement to

persist hashed passwords. It contains methods for getting and setting the hashed password, and a method that indicates whether the user has set a password.

- **IUserSecurityStampStore**
  The IUserSecurityStampStore<TUser> interface defines the methods you implement to use a security stamp for indicating whether the user's account information has changed. This stamp is updated when a user changes the password, or adds or removes logins. It contains methods for getting and setting the security stamp.
- **IUserTwoFactorStore**
  The IUserTwoFactorStore<TUser> interface defines the methods you implement to support two factor authentication. It contains methods for getting and setting whether two factor authentication is enabled for a user.
- **IUserPhoneNumberStore**
  The IUserPhoneNumberStore<TUser> interface defines the methods you implement to store user phone numbers. It contains methods for getting and setting the phone number and whether the phone number is confirmed.
- **IUserEmailStore**
  The IUserEmailStore<TUser> interface defines the methods you implement to store user email addresses. It contains methods for getting and setting the email address and whether the email is confirmed.
- **IUserLockoutStore**
  The IUserLockoutStore<TUser> interface defines the methods you implement to store information about locking an account. It contains methods for tracking failed access attempts and lockouts.
- **IQueryableUserStore**
  The IQueryableUserStore<TUser> interface defines the members you implement to provide a queryable user store.

You implement only the interfaces that are needed in your app. For example:

C#

```
public class UserStore : IUserStore<IdentityUser>,
                         IUserClaimStore<IdentityUser>,
                         IUserLoginStore<IdentityUser>,
                         IUserRoleStore<IdentityUser>,
                         IUserPasswordStore<IdentityUser>,
                         IUserSecurityStampStore<IdentityUser>
{
    // interface implementations not shown
}
```

IdentityUserClaim, IdentityUserLogin, and IdentityUserRole

The `Microsoft.AspNet.Identity.EntityFramework` namespace contains implementations of the IdentityUserClaim, IdentityUserLogin, and IdentityUserRole classes. If you are using these features, you may want to create your own versions of these classes and define the properties for your app. However, sometimes it's more efficient to not load these entities into memory when performing basic operations (such as adding or removing a user's claim). Instead, the backend store classes can execute these operations directly on the data source. For example, the `UserStore.GetClaimsAsync` method can call the `userClaimTable.FindByUserId(user.Id)` method to execute a query on that table directly and return a list of claims.

Customize the role class

When implementing a role storage provider, you can create a custom role type. It need not implement a particular interface, but it must have an `Id` and typically it will have a `Name` property.

The following is an example role class:

C#

```
using System;

namespace CustomIdentityProviderSample.CustomProvider
{
    public class ApplicationRole
    {
        public Guid Id { get; set; } = Guid.NewGuid();
        public string Name { get; set; }
    }
}
```

Customize the role store

You can create a `RoleStore` class that provides the methods for all data operations on roles. This class is equivalent to the RoleStore<TRole> class. In the `RoleStore` class, you implement the `IRoleStore<TRole>` and optionally the `IQueryableRoleStore<TRole>` interface.

- **IRoleStore<TRole>**
  The IRoleStore<TRole> interface defines the methods to implement in the role store class. It contains methods for creating, updating, deleting, and retrieving roles.
- **RoleStore<TRole>**
  To customize `RoleStore`, create a class that implements the `IRoleStore<TRole>` interface.

Reconfigure app to use a new storage provider

Once you have implemented a storage provider, you configure your app to use it. If your app used the default provider, replace it with your custom provider.

1. Remove the `Microsoft.AspNetCore.EntityFramework.Identity` NuGet package.
2. If the storage provider resides in a separate project or package, add a reference to it.
3. Replace all references to `Microsoft.AspNetCore.EntityFramework.Identity` with a using statement for the namespace of your storage provider.
4. Change the `AddIdentity` method to use the custom types. You can create your own extension methods for this purpose. See IdentityServiceCollectionExtensions for an example.
5. If you are using Roles, update the `RoleManager` to use your `RoleStore` class.
6. Update the connection string and credentials to your app's configuration.

> ⚠ **Warning**
>
> This article shows the use of connection strings. With a local database the user doesn't have to be authenticated, but in production, connection strings sometimes include a password to authenticate. A resource owner password credential (ROPC) is a security risk that should be avoided in production databases. Production apps should use the most secure authentication flow available. For more information on authentication for apps deployed to test or production environments, see Secure authentication flows.

Example:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add identity types
```

```
builder.Services.AddIdentity<ApplicationUser, ApplicationRole>()
    .AddDefaultTokenProviders();

// Identity Services
builder.Services.AddTransient<IUserStore<ApplicationUser>, CustomUserStore>
();
builder.Services.AddTransient<IRoleStore<ApplicationRole>, CustomRoleStore>
();
var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddTransient<SqlConnection>(e => new
SqlConnection(connectionString));
builder.Services.AddTransient<DapperUsersTable>();

// additional configuration

builder.Services.AddRazorPages();

var app = builder.Build();
```

Account confirmation and password recovery in ASP.NET Core

Article • 09/18/2024

By Rick Anderson, Ponant, and Joe Audette

This tutorial shows how to build an ASP.NET Core app with email confirmation and password reset. This tutorial is **not** a beginning topic. You should be familiar with:

- ASP.NET Core
- Authentication
- Entity Framework Core

For Blazor guidance, which adds to or supersedes the guidance in this article, see Account confirmation and password recovery in ASP.NET Core Blazor.

Prerequisites

- .NET Core 6.0 SDK or later
- Successfully send email from a C# console app.

Create and test a web app with authentication

Run the following commands to create a web app with authentication.

.NET CLI

```
dotnet new webapp -au Individual -o WebPWrecover
cd WebPWrecover
dotnet run
```

Register user with simulated email confirmation

Run the app, select the **Register** link, and register a user. Once registered, you are redirected to the to `/Identity/Account/RegisterConfirmation` page which contains a link to simulate email confirmation:

- Select the `Click here to confirm your account` link.
- Select the **Login** link and sign-in with the same credentials.

- Select the `Hello YourEmail@provider.com!` link, which redirects to the `/Identity/Account/Manage/PersonalData` page.
- Select the **Personal data** tab on the left, and then select **Delete**.

The `Click here to confirm your account` link is displayed because an IEmailSender has not been implemented and registered with the dependency injection container. See the RegisterConfirmation source.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Configure an email provider

In this tutorial, SendGrid is used to send email. A SendGrid account and key is needed to send email. We recommend using SendGrid or another email service to send email rather than SMTP. SMTP is difficult to secure and set up correctly.

The SendGrid account may require adding a Sender.

Create a class to fetch the secure email key. For this sample, create `Services/AuthMessageSenderOptions.cs`:

C#

```
namespace WebPWrecover.Services;

public class AuthMessageSenderOptions
{
    public string? SendGridKey { get; set; }
}
```

Configure SendGrid user secrets

Set the `SendGridKey` with the secret-manager tool. For example:

.NET CLI

```
dotnet user-secrets set SendGridKey <key>

Successfully saved SendGridKey to the secret store.
```

On Windows, Secret Manager stores keys/value pairs in a `secrets.json` file in the `%APPDATA%/Microsoft/UserSecrets/<WebAppName-userSecretsId>` directory.

The contents of the `secrets.json` file aren't encrypted. The following markup shows the `secrets.json` file. The `SendGridKey` value has been removed.

JSON

```
{
  "SendGridKey": "<key removed>"
}
```

For more information, see the Options pattern and configuration.

Install SendGrid

This tutorial shows how to add email notifications through SendGrid, but other email providers can be used.

Install the `SendGrid` NuGet package:

Visual Studio

From the Package Manager Console, enter the following command:

PowerShell

```
Install-Package SendGrid
```

See Get Started with SendGrid for Free to register for a free SendGrid account.

Implement IEmailSender

To Implement `IEmailSender`, create `Services/EmailSender.cs` with code similar to the following:

C#

```
using Microsoft.AspNetCore.Identity.UI.Services;
using Microsoft.Extensions.Options;
using SendGrid;
using SendGrid.Helpers.Mail;

namespace WebPWrecover.Services;

public class EmailSender : IEmailSender
{
    private readonly ILogger _logger;

    public EmailSender(IOptions<AuthMessageSenderOptions> optionsAccessor,
                       ILogger<EmailSender> logger)
    {
        Options = optionsAccessor.Value;
        _logger = logger;
    }

    public AuthMessageSenderOptions Options { get; } //Set with Secret
Manager.

    public async Task SendEmailAsync(string toEmail, string subject, string
message)
    {
        if (string.IsNullOrEmpty(Options.SendGridKey))
        {
            throw new Exception("Null SendGridKey");
        }
        await Execute(Options.SendGridKey, subject, message, toEmail);
    }

    public async Task Execute(string apiKey, string subject, string message,
string toEmail)
    {
        var client = new SendGridClient(apiKey);
        var msg = new SendGridMessage()
        {
            From = new EmailAddress("Joe@contoso.com", "Password Recovery"),
            Subject = subject,
            PlainTextContent = message,
            HtmlContent = message
        };
        msg.AddTo(new EmailAddress(toEmail));

        // Disable click tracking.
        // See https://sendgrid.com/docs/User_Guide/Settings/tracking.html
        msg.SetClickTracking(false, false);
        var response = await client.SendEmailAsync(msg);
        _logger.LogInformation(response.IsSuccessStatusCode
                               ? $"Email to {toEmail} queued successfully!"
                               : $"Failure Email to {toEmail}");
    }
}
```

Configure app to support email

Add the following code to the `Program.cs` file:

- Add `EmailSender` as a transient service.
- Register the `AuthMessageSenderOptions` configuration instance.

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Identity.UI.Services;
using Microsoft.EntityFrameworkCore;
using WebPWrecover.Data;
using WebPWrecover.Services;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlite(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

builder.Services.AddTransient<IEmailSender, EmailSender>();
builder.Services.Configure<AuthMessageSenderOptions>(builder.Configuration);

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();
```

```
app.Run();
```

Disable default account verification when Account.RegisterConfirmation has been scaffolded

This section only applies when `Account.RegisterConfirmation` is scaffolded. Skip this section if you have not scaffolded `Account.RegisterConfirmation`.

The user is redirected to the `Account.RegisterConfirmation` where they can select a link to have the account confirmed. The default `Account.RegisterConfirmation` is used ***only*** for testing, automatic account verification should be disabled in a production app.

To require a confirmed account and prevent immediate login at registration, set `DisplayConfirmAccountLink = false` in the scaffolded `/Areas/Identity/Pages/Account/RegisterConfirmation.cshtml.cs` file:

C#

```
// Licensed to the .NET Foundation under one or more agreements.
// The .NET Foundation licenses this file to you under the MIT license.
#nullable disable

using System;
using System.Text;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Identity.UI.Services;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.WebUtilities;

namespace WebPWrecover.Areas.Identity.Pages.Account
{
    [AllowAnonymous]
    public class RegisterConfirmationModel : PageModel
    {
        private readonly UserManager<IdentityUser> _userManager;
        private readonly IEmailSender _sender;

        public RegisterConfirmationModel(UserManager<IdentityUser>
userManager, IEmailSender sender)
        {
            _userManager = userManager;
            _sender = sender;
        }

        /// <summary>
```

```
        ///     This API supports the ASP.NET Core Identity default UI
infrastructure and is not intended to be used
        ///     directly from your code. This API may change or be removed
in future releases.
        /// </summary>
        public string Email { get; set; }

        /// <summary>
        ///     This API supports the ASP.NET Core Identity default UI
infrastructure and is not intended to be used
        ///     directly from your code. This API may change or be removed
in future releases.
        /// </summary>
        public bool DisplayConfirmAccountLink { get; set; }

        /// <summary>
        ///     This API supports the ASP.NET Core Identity default UI
infrastructure and is not intended to be used
        ///     directly from your code. This API may change or be removed
in future releases.
        /// </summary>
        public string EmailConfirmationUrl { get; set; }

        public async Task<IActionResult> OnGetAsync(string email, string
returnUrl = null)
        {
            if (email == null)
            {
                return RedirectToPage("/Index");
            }
            returnUrl = returnUrl ?? Url.Content("~/");

            var user = await _userManager.FindByEmailAsync(email);
            if (user == null)
            {
                return NotFound($"Unable to load user with email
'{email}'.");
            }

            Email = email;
            // Once you add a real email sender, you should remove this code
that lets you confirm the account
            DisplayConfirmAccountLink = false;
            if (DisplayConfirmAccountLink)
            {
                var userId = await _userManager.GetUserIdAsync(user);
                var code = await
_userManager.GenerateEmailConfirmationTokenAsync(user);
                code =
WebEncoders.Base64UrlEncode(Encoding.UTF8.GetBytes(code));
                EmailConfirmationUrl = Url.Page(
                    "/Account/ConfirmEmail",
                    pageHandler: null,
                    values: new { area = "Identity", userId = userId, code =
code, returnUrl = returnUrl },
```

```
                    protocol: Request.Scheme);
            }

            return Page();
        }
    }
}
```

This step is only necessary when `Account.RegisterConfirmation` is scaffolded. The non-scaffolded RegisterConfirmation automatically detects when an IEmailSender has been implemented and registered with the dependency injection container.

Register, confirm email, and reset password

Run the web app, and test the account confirmation and password recovery flow.

- Run the app and register a new user
- Check your email for the account confirmation link. See Debug email if you don't get the email.
- Click the link to confirm your email.
- Sign in with your email and password.
- Sign out.

Test password reset

- If you're signed in, select **Logout**.
- Select the **Log in** link and select the **Forgot your password?** link.
- Enter the email you used to register the account.
- An email with a link to reset your password is sent. Check your email and click the link to reset your password. After your password has been successfully reset, you can sign in with your email and new password.

Resend email confirmation

Select the **Resend email confirmation** link on the **Login** page.

Change email and activity timeout

The default inactivity timeout is 14 days. The following code sets the inactivity timeout to 5 days:

```
C#
```

```
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Identity.UI.Services;
using Microsoft.EntityFrameworkCore;
using WebPWrecover.Data;
using WebPWrecover.Services;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlite(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

builder.Services.AddTransient<IEmailSender, EmailSender>();
builder.Services.Configure<AuthMessageSenderOptions>(builder.Configuration);

builder.Services.ConfigureApplicationCookie(o => {
    o.ExpireTimeSpan = TimeSpan.FromDays(5);
    o.SlidingExpiration = true;
});

var app = builder.Build();

// Code removed for brevity
```

Change all data protection token lifespans

The following code changes all data protection tokens timeout period to 3 hours:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Identity.UI.Services;
using Microsoft.EntityFrameworkCore;
using WebPWrecover.Data;
using WebPWrecover.Services;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlite(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
```

```
builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

builder.Services.AddTransient<IEmailSender, EmailSender>();
builder.Services.Configure<AuthMessageSenderOptions>(builder.Configuration);

builder.Services.Configure<DataProtectionTokenProviderOptions>(o =>
       o.TokenLifespan = TimeSpan.FromHours(3));

var app = builder.Build();

// Code removed for brevity.
```

The built in Identity user tokens (see AspNetCore/src/Identity/Extensions.Core/src/TokenOptions.cs)have a one day timeout.

Change the email token lifespan

The default token lifespan of the Identity user tokens is one day. This section shows how to change the email token lifespan.

Add a custom DataProtectorTokenProvider<TUser> and DataProtectionTokenProviderOptions:

C#

```
public class CustomEmailConfirmationTokenProvider<TUser>
                                : DataProtectorTokenProvider<TUser> where
TUser : class
{
    public CustomEmailConfirmationTokenProvider(
        IDataProtectionProvider dataProtectionProvider,
        IOptions<EmailConfirmationTokenProviderOptions> options,
        ILogger<DataProtectorTokenProvider<TUser>> logger)
                                    : base(dataProtectionProvider,
options, logger)
    {

    }
}
public class EmailConfirmationTokenProviderOptions :
DataProtectionTokenProviderOptions
{
    public EmailConfirmationTokenProviderOptions()
    {
        Name = "EmailDataProtectorTokenProvider";
        TokenLifespan = TimeSpan.FromHours(4);
```

```
    }
}
```

Add the custom provider to the service container:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Identity.UI.Services;
using Microsoft.EntityFrameworkCore;
using WebPWrecover.Data;
using WebPWrecover.Services;
using WebPWrecover.TokenProviders;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlite(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(config =>
{
    config.SignIn.RequireConfirmedEmail = true;
    config.Tokens.ProviderMap.Add("CustomEmailConfirmation",
        new TokenProviderDescriptor(
            typeof(CustomEmailConfirmationTokenProvider<IdentityUser>)));
    config.Tokens.EmailConfirmationTokenProvider =
"CustomEmailConfirmation";
}).AddEntityFrameworkStores<ApplicationDbContext>();

builder.Services.AddTransient<CustomEmailConfirmationTokenProvider<IdentityU
ser>>();

builder.Services.AddRazorPages();

builder.Services.AddTransient<IEmailSender, EmailSender>();
builder.Services.Configure<AuthMessageSenderOptions>(builder.Configuration);

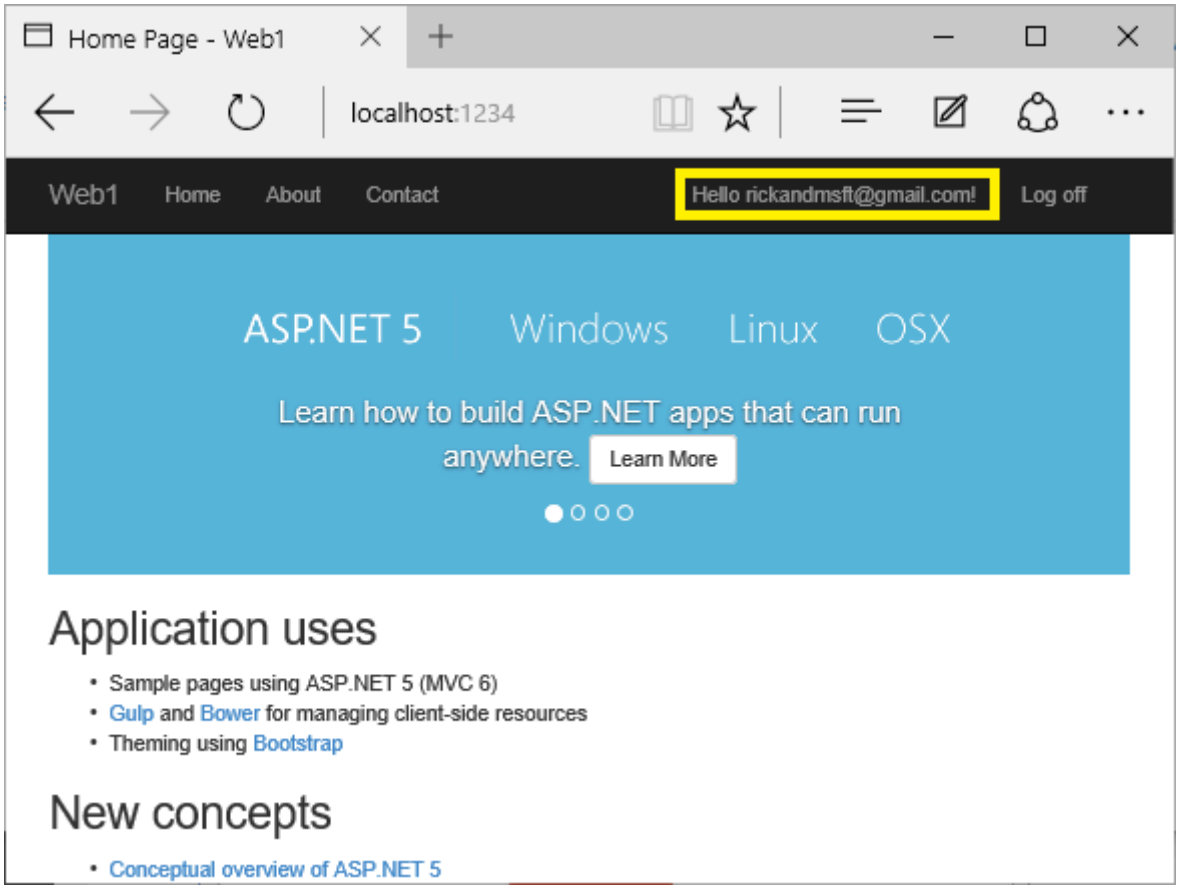
var app = builder.Build();

// Code removed for brevity.
```

Debug email

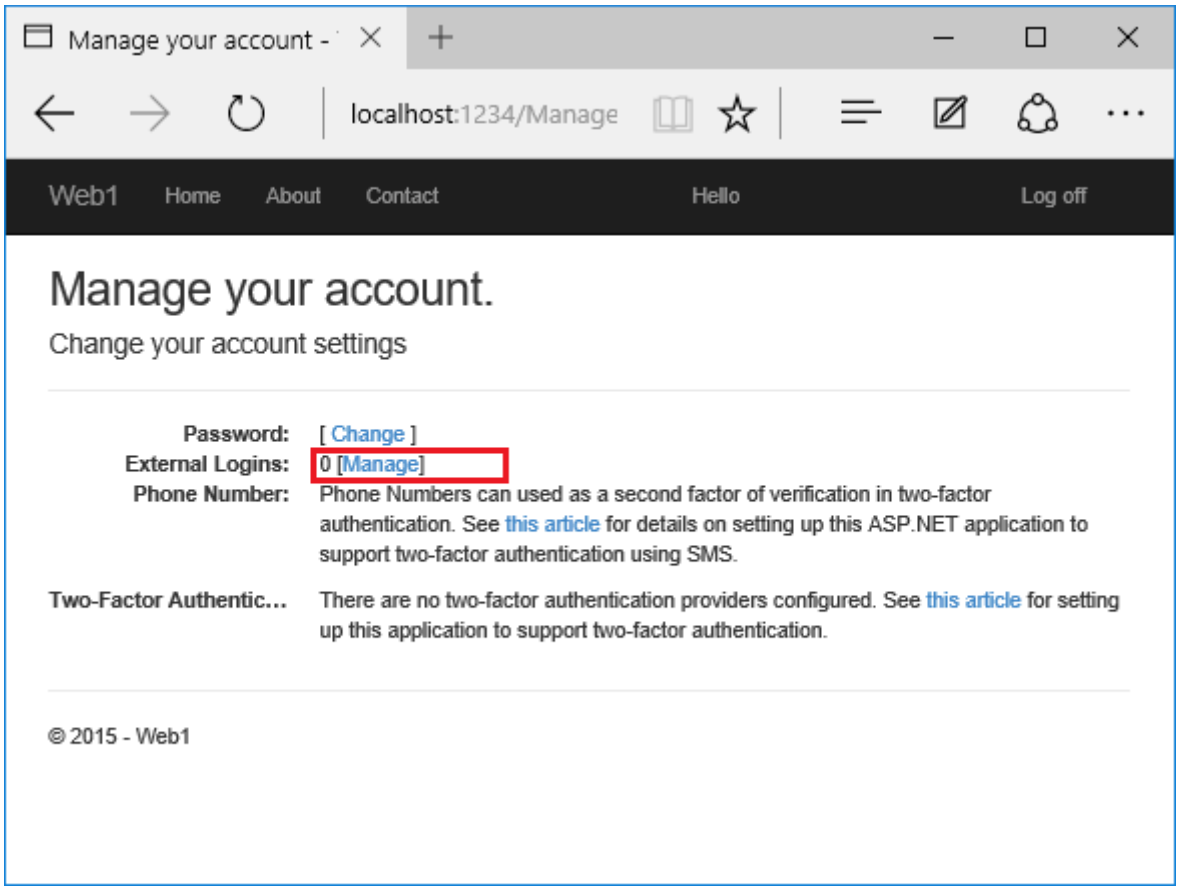
If you can't get email working:

- Set a breakpoint in `EmailSender.Execute` to verify `SendGridClient.SendEmailAsync` is called.



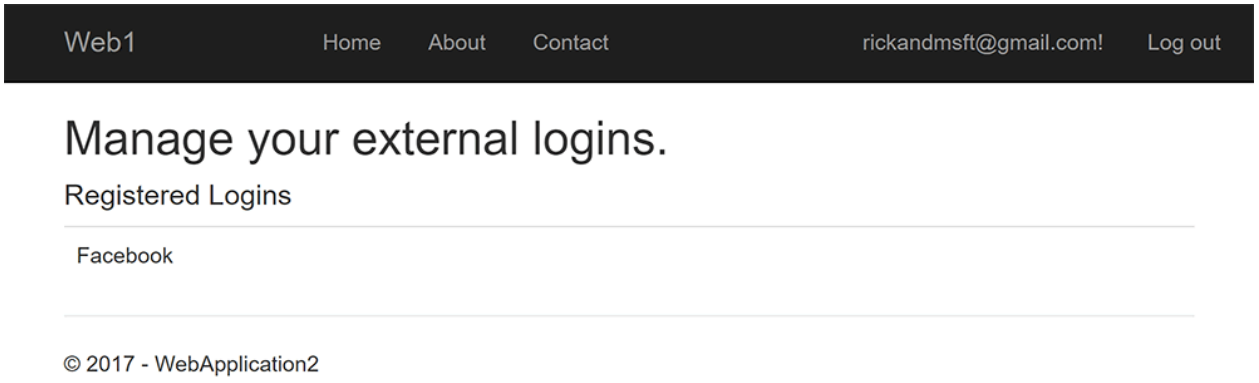
- Create a console app to send email using similar code to `EmailSender.Execute`.
- Review the Email Activity page.
- Check your spam folder.
- Try another email alias on a different email provider (Microsoft, Yahoo, Gmail, etc.)
- Try sending to different email accounts.

A security best practice is to **not** use production secrets in test and development. If you publish the app to Azure, set the SendGrid secrets as application settings in the Azure Web App portal. The configuration system is set up to read keys from environment variables.



Combine social and local login accounts

To complete this section, you must first enable an external authentication provider. See Facebook, Google, and external provider authentication.



You can combine local and social accounts by clicking on your email link. In the following sequence, "RickAndMSFT@gmail.com" is first created as a local login; however, you can create the account as a social login first, then add a local login.

Click on the **Manage** link. Note the 0 external (social logins) associated with this account.

Click the link to another login service and accept the app requests. In the following image, Facebook is the external authentication provider:

The two accounts have been combined. You are able to sign in with either account. You might want your users to add local accounts in case their social login authentication service is down, or more likely they've lost access to their social account.

Enable account confirmation after a site has users

Enabling account confirmation on a site with users locks out all the existing users. Existing users are locked out because their accounts aren't confirmed. To work around existing user lockout, use one of the following approaches:

- Update the database to mark all existing users as being confirmed.
- Confirm existing users. For example, batch-send emails with confirmation links.

Enable QR code generation for TOTP authenticator apps in ASP.NET Core

Article • 08/16/2024

ASP.NET Core ships with support for authenticator applications for individual authentication. Two factor authentication (2FA) authenticator apps, using a Time-based One-time Password Algorithm (TOTP), are the industry recommended approach for 2FA. 2FA using TOTP is preferred to SMS 2FA. An authenticator app provides a 6 to 8 digit code which users must enter after confirming their username and password. Typically an authenticator app is installed on a smartphone.

> ⚠ **Warning**
>
> An ASP.NET Core TOTP code should be kept secret because it can be used to authenticate successfully multiple times before it expires.

The ASP.NET Core web app templates support authenticators but don't provide support for QR code generation. QR code generators ease the setup of 2FA. This document provides guidance for Razor Pages and MVC apps on how to add QR code generation to the 2FA configuration page. For guidance that applies to Blazor Web Apps, see Enable QR code generation for TOTP authenticator apps in an ASP.NET Core Blazor Web App.

Two-factor authentication does not happen using an external authentication provider, such as Google or Facebook. External logins are protected by whatever mechanism the external login provider provides. Consider, for example, the Microsoft authentication provider requires a hardware key or another 2FA approach. If the default templates enforced "local" 2FA then users would be required to satisfy two 2FA approaches, which is not a commonly used scenario.

Adding QR codes to the 2FA configuration page

These instructions use `qrcode.js` from the https://davidshimjs.github.io/qrcodejs/ repo.

- Download the qrcode.js JavaScript library to the `wwwroot\lib` folder in your project.

- Follow the instructions in Scaffold Identity to generate `/Areas/Identity/Pages/Account/Manage/EnableAuthenticator.cshtml`.
- In `/Areas/Identity/Pages/Account/Manage/EnableAuthenticator.cshtml`, locate the `Scripts` section at the end of the file:

CSHTML

```
@section Scripts {
    @await Html.PartialAsync("_ValidationScriptsPartial")
}
```

- Create a new JavaScript file called `qr.js` in `wwwroot/js` and add the following code to generate the QR Code:

JavaScript

```
window.addEventListener("load", () => {
  const uri = document.getElementById("qrCodeData").getAttribute('data-
url');
  new QRCode(document.getElementById("qrCode"),
    {
      text: uri,
      width: 150,
      height: 150
    });
});
```

- Update the `Scripts` section to add a reference to the `qrcode.js` library previously downloaded.
- Add the `qr.js` file with the call to generate the QR code:

CSHTML

```
@section Scripts {
    @await Html.PartialAsync("_ValidationScriptsPartial")

    <script type="text/javascript" src="~/lib/qrcode.js"></script>
    <script type="text/javascript" src="~/js/qr.js"></script>
}
```

- Delete the paragraph which links you to these instructions.

Run your app and ensure that you can scan the QR code and validate the code the authenticator proves.

Change the site name in the QR code

The site name in the QR code is taken from the project name you choose when initially creating your project. You can change it by looking for the `GenerateQrCodeUri(string email, string unformattedKey)` method in the `/Areas/Identity/Pages/Account/Manage/EnableAuthenticator.cshtml.cs`.

The default code from the template looks as follows:

```C#
private string GenerateQrCodeUri(string email, string unformattedKey)
{
    return string.Format(
        AuthenticatorUriFormat,
        _urlEncoder.Encode("Razor Pages"),
        _urlEncoder.Encode(email),
        unformattedKey);
}
```

The second parameter in the call to `string.Format` is your site name, taken from your solution name. It can be changed to any value, but it must always be URL encoded.

Using a different QR Code library

You can replace the QR Code library with your preferred library. The HTML contains a `qrCode` element into which you can place a QR Code by whatever mechanism your library provides.

The correctly formatted URL for the QR Code is available in the:

- `AuthenticatorUri` property of the model.
- `data-url` property in the `qrCodeData` element.

TOTP client and server time skew

TOTP (Time-based One-Time Password) authentication depends on both the server and authenticator device having an accurate time. Tokens only last for 30 seconds. If TOTP 2FA logins are failing, check that the server time is accurate, and preferably synchronized to an accurate NTP service.

Facebook, Google, and external provider authentication in ASP.NET Core

Article • 09/05/2024

By Valeriy Novytskyy and Rick Anderson

This tutorial demonstrates how to build an ASP.NET Core app that enables users to sign in using OAuth 2.0 with credentials from external authentication providers.

Facebook, Twitter, Google, and Microsoft providers are covered in the following sections and use the starter project created in this article. Other providers are available in third-party packages such as OpenIddict, AspNet.Security.OAuth.Providers and AspNet.Security.OpenId.Providers.

Enabling users to sign in with their existing credentials:

- Is convenient for the users.
- Shifts many of the complexities of managing the sign-in process onto a third party.

Create a New ASP.NET Core Project

Visual Studio

- Select the **ASP.NET Core Web App** template. Select **OK**.
- In the **Authentication type** input, select **Individual Accounts**.

Apply migrations

- Run the app and select the **Register** link.
- Enter the email and password for the new account, and then select **Register**.
- Follow the instructions to apply migrations.

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information

usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Use SecretManager to store tokens assigned by login providers

Social login providers assign **Application Id** and **Application Secret** tokens during the registration process. The exact token names vary by provider. These tokens represent the credentials your app uses to access their API. The tokens constitute the "user secrets" that can be linked to your app configuration with the help of Secret Manager. User secrets are a more secure alternative to storing the tokens in a configuration file, such as `appsettings.json`.

> **Important**
>
> Secret Manager is for development purposes only. You can store and protect Azure test and production secrets with the **Azure Key Vault configuration provider**.

Follow the steps in Safe storage of app secrets in development in ASP.NET Core topic to store tokens assigned by each login provider below.

Setup login providers required by your application

Use the following topics to configure your application to use the respective providers:

- Facebook instructions
- Twitter instructions
- Google instructions

- Microsoft instructions
- Other provider instructions

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods from AddAuthentication:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using WebApplication16.Data;

var builder = WebApplication.CreateBuilder(args);
var config = builder.Configuration;

var connectionString = config.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
                                    options.SignIn.RequireConfirmedAccount =
true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();
```

```
builder.Services.AddAuthentication()
    .AddGoogle(options =>
    {
        IConfigurationSection googleAuthNSection =
        config.GetSection("Authentication:Google");
        options.ClientId = googleAuthNSection["ClientId"];
        options.ClientSecret = googleAuthNSection["ClientSecret"];
    })
    .AddFacebook(options =>
    {
        IConfigurationSection FBAuthNSection =
        config.GetSection("Authentication:FB");
        options.ClientId = FBAuthNSection["ClientId"];
        options.ClientSecret = FBAuthNSection["ClientSecret"];
    })
    .AddMicrosoftAccount(microsoftOptions =>
    {
        microsoftOptions.ClientId =
config["Authentication:Microsoft:ClientId"];
        microsoftOptions.ClientSecret =
config["Authentication:Microsoft:ClientSecret"];
    })
    .AddTwitter(twitterOptions =>
    {
        twitterOptions.ConsumerKey =
config["Authentication:Twitter:ConsumerAPIKey"];
        twitterOptions.ConsumerSecret =
config["Authentication:Twitter:ConsumerSecret"];
        twitterOptions.RetrieveUserDetails = true;
    });
```

```
var app = builder.Build();

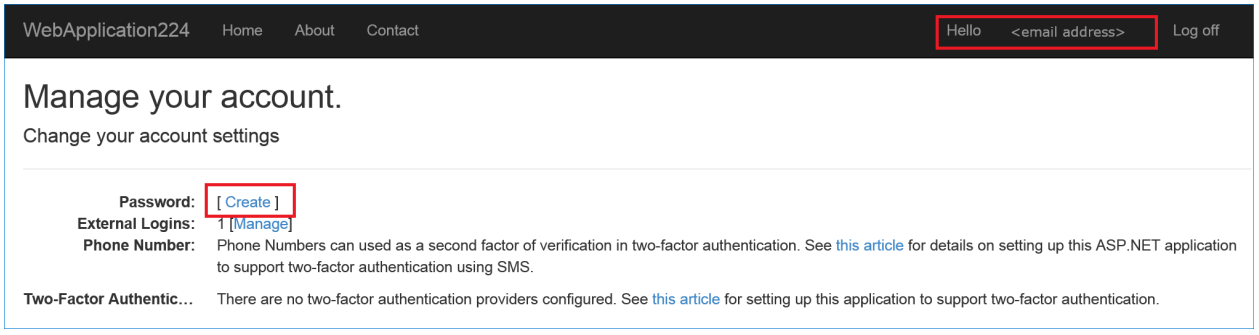
if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

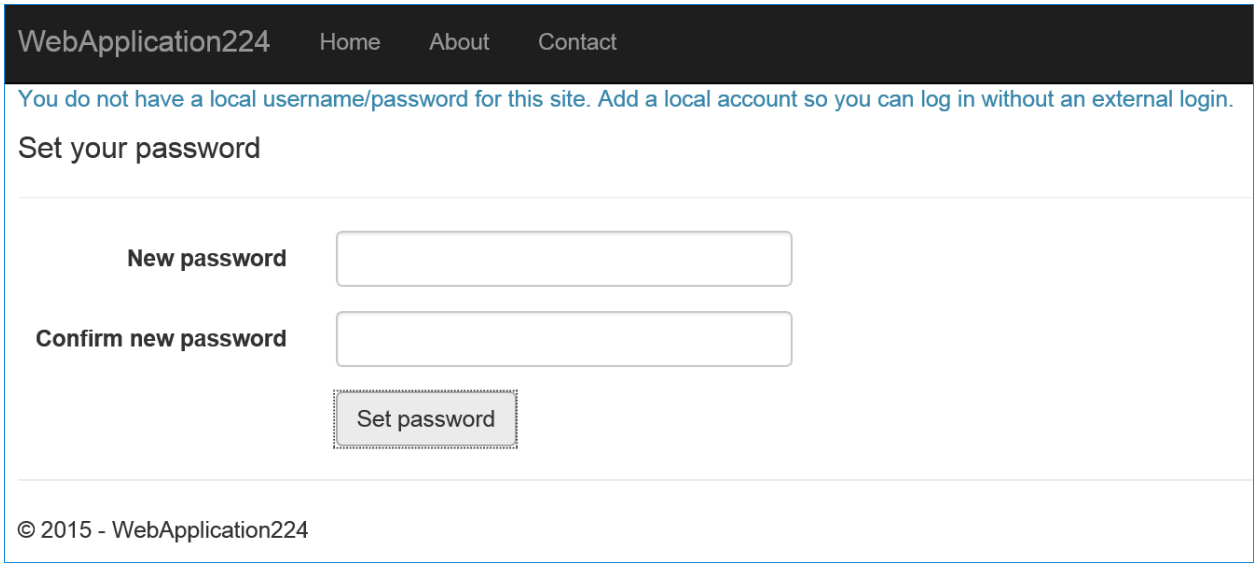
app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();
app.MapDefaultControllerRoute();



app.Run();
```

Optionally set password



When you register with an external login provider, you don't have a password registered with the app. This alleviates you from creating and remembering a password for the site, but it also makes you dependent on the external login provider. If the external login provider is unavailable, you won't be able to sign in to the web site.

To create a password and sign in using your email that you set during the sign in process with external providers:

- Select the **Hello <email alias>** link at the top-right corner to navigate to the **Manage** view.

- Select **Create**

- Set a valid password and you can use this to sign in with your email.

Additional information

- Sign in with Apple Example Integration
- See this GitHub issue for information on how to customize the login buttons.

- Persist additional data about the user and their access and refresh tokens. For more information, see Persist additional claims and tokens from external providers in ASP.NET Core.

Google external login setup in ASP.NET Core

Article • 02/10/2023

By Valeriy Novytskyy and Rick Anderson

This tutorial shows you how to enable users to sign in with their Google account using the ASP.NET Core project created on the previous page.

Create the Google OAuth 2.0 Client ID and secret

- Follow the guidance in Integrating Google Sign-In into your web app (Google documentation).
- Go to Google API & Services.
- A **Project** must exist first, you may have to create one. Once a project is selected, enter the **Dashboard**.
- In the **Oauth consent screen** of the **Dashboard**:
  - Select **User Type - External** and **CREATE**.
  - In the **App information** dialog, Provide an **app name** for the app, **user support email**, and **developer contact information**.
  - Step through the **Scopes** step.
  - Step through the **Test users** step.
  - Review the **OAuth consent screen** and go back to the app **Dashboard**.
- In the **Credentials** tab of the application Dashboard, select **CREATE CREDENTIALS** > **OAuth client ID**.
- Select **Application type** > **Web application**, choose a **name**.
- In the **Authorized redirect URIs** section, select **ADD URI** to set the redirect URI. Example redirect URI: `https://localhost:{PORT}/signin-google`, where the `{PORT}` placeholder is the app's port.
- Select the **CREATE** button.
- Save the **Client ID** and **Client Secret** for use in the app's configuration.
- When deploying the site, either:

- Update the app's redirect URI in the **Google Console** to the app's deployed redirect URI.
- Create a new Google API registration in the **Google Console** for the production app with its production redirect URI.

Store the Google client ID and secret

Store sensitive settings such as the Google client ID and secret values with Secret Manager. For this sample, use the following steps:

1. Initialize the project for secret storage per the instructions at Enable secret storage.
2. Store the sensitive settings in the local secret store with the secret keys `Authentication:Google:ClientId` and `Authentication:Google:ClientSecret`:

   .NET CLI

   ```
   dotnet user-secrets set "Authentication:Google:ClientId" "<client-id>"
   dotnet user-secrets set "Authentication:Google:ClientSecret" "<client-secret>"
   ```

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

You can manage your API credentials and usage in the API Console.

Configure Google authentication

Add the Microsoft.AspNetCore.Authentication.Google NuGet package to the app.

Add the Authentication service to the `Program`:

C#

```
var builder = WebApplication.CreateBuilder(args);
var services = builder.Services;
var configuration = builder.Configuration;

services.AddAuthentication().AddGoogle(googleOptions =>
    {
```

```
        googleOptions.ClientId =
configuration["Authentication:Google:ClientId"];
        googleOptions.ClientSecret =
configuration["Authentication:Google:ClientSecret"];
    });
```

The call to AddIdentity configures the default scheme settings. The AddAuthentication(IServiceCollection, String) overload sets the DefaultScheme property. The AddAuthentication(IServiceCollection, Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

AuthenticationBuilder extension methods that register an authentication handler may only be called once per authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

Sign in with Google

- Run the app and select **Log in**. An option to sign in with Google appears.
- Select the **Google** button, which redirects to Google for authentication.
- After entering your Google credentials, you are redirected back to the web site.

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

```
C#

services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

For more information on configuration options supported by Google authentication, see the GoogleOptions API reference . This can be used to request different information about the user.

Change the default callback URI

The URI segment `/signin-google` is set as the default callback of the Google authentication provider. You can change the default callback URI while configuring the Google authentication middleware via the inherited RemoteAuthenticationOptions.CallbackPath property of the GoogleOptions class.

Troubleshooting

- If the sign-in doesn't work and you aren't getting any errors, switch to development mode to make the issue easier to debug.
- If Identity isn't configured by calling `services.AddIdentity` in `ConfigureServices`, attempting to authenticate results in *ArgumentException: The 'SignInScheme' option must be provided*. The project template used in this tutorial ensures Identity is configured.
- If the site database has not been created by applying the initial migration, you get *A database operation failed while processing the request* error. Select **Apply Migrations** to create the database, and refresh the page to continue past the error.
- HTTP 500 error after successfully authenticating the request by the OAuth 2.0 provider such as Google: See this GitHub issue .
- How to implement external authentication with Google for React and other SPA apps: See this GitHub issue .

Next steps

- This article showed how you can authenticate with Google. You can follow a similar approach to authenticate with other providers listed on the previous page.
- Once you publish the app to Azure, reset the `ClientSecret` in the Google API Console.
- Set the `Authentication:Google:ClientId` and `Authentication:Google:ClientSecret` as application settings in the Azure portal. The configuration system is set up to read keys from environment variables.

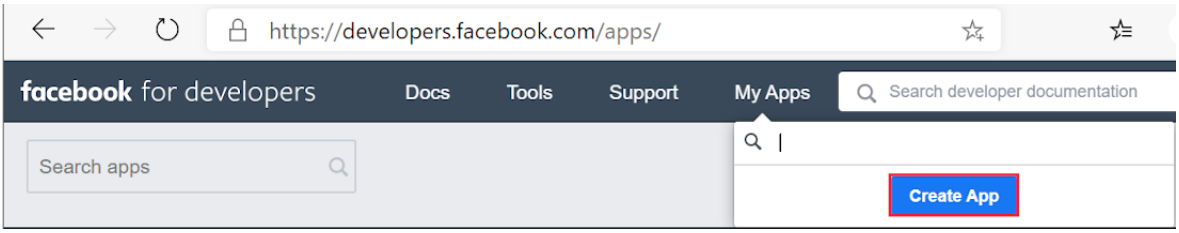
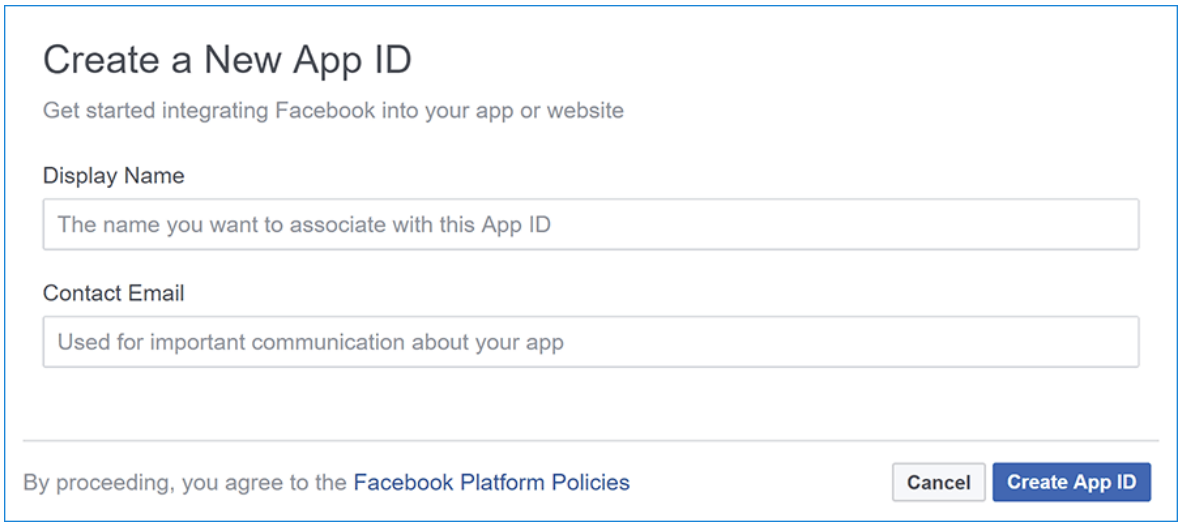
Facebook external login setup in ASP.NET Core



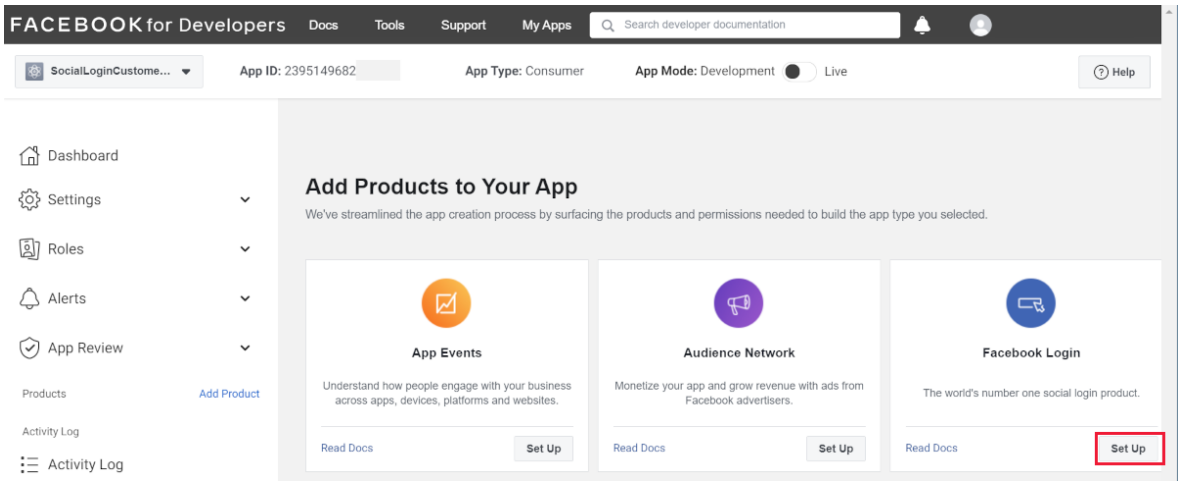
Article • 06/03/2022

By Valeriy Novytskyy and Rick Anderson

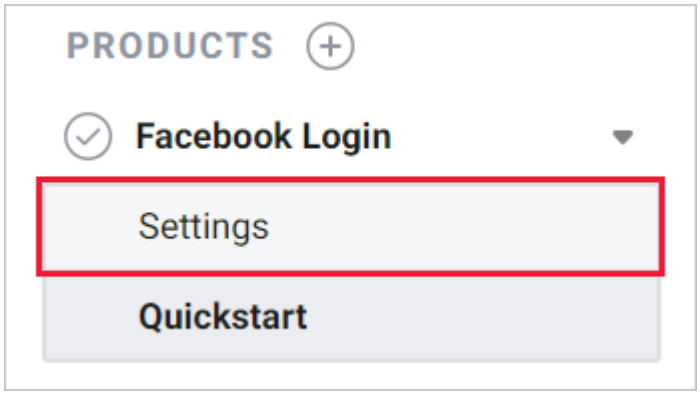


This tutorial with code examples shows how to enable your users to sign in with their Facebook account using a sample ASP.NET Core project created on the previous page. We start by creating a Facebook App ID by following the official steps.

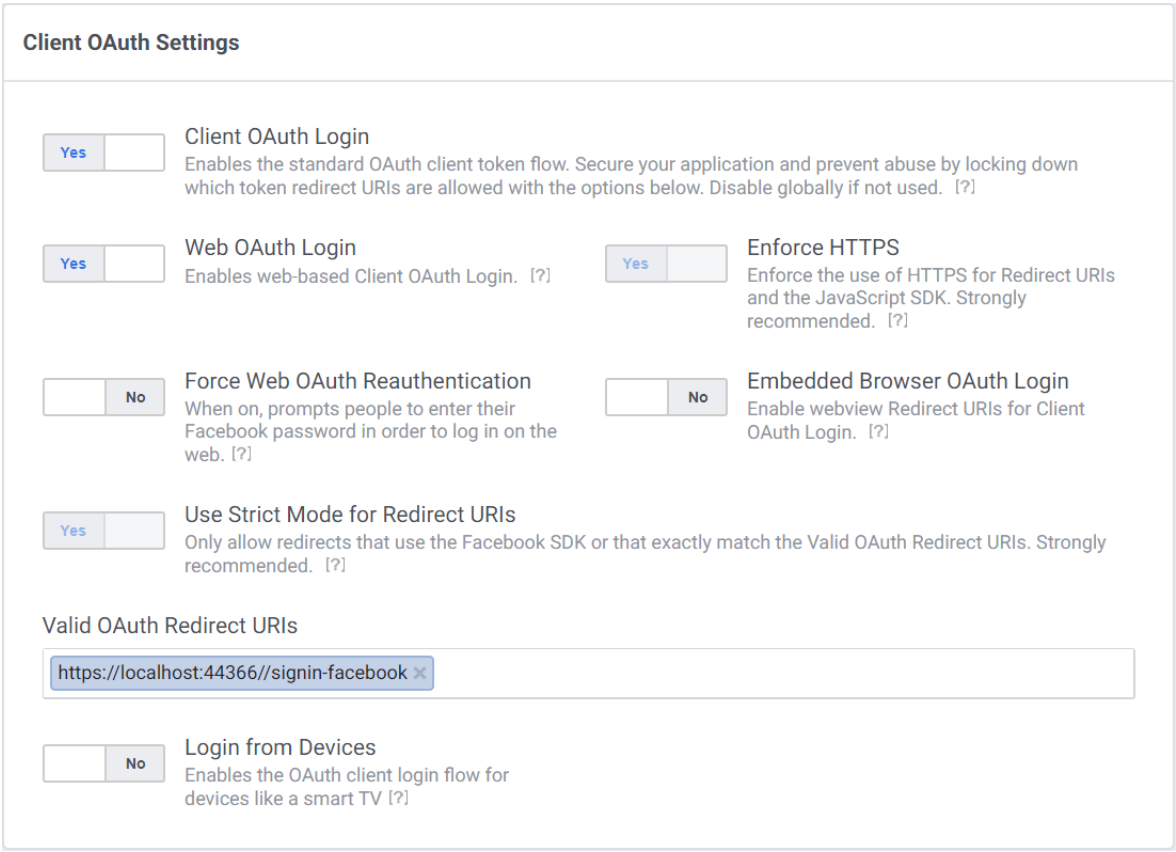
Create the app in Facebook



- Add the Microsoft.AspNetCore.Authentication.Facebook NuGet package to the project.
- Navigate to the Facebook Developers app page and sign in. If you don't already have a Facebook account, use the **Sign up for Facebook** link on the login page to create one. Once you have a Facebook account, follow the instructions to register as a Facebook Developer.
- From the **My Apps** menu select **Create App**. The **Create an app** form appears.



- Select an app type that best fits your project. For this project, select **Consumer**, and then **Next**. A new App ID is created.
- Fill out the form and tap the **Create App** button.



- On the **Add Products to Your App** page, select **Set Up** on the **Facebook Login** card.

- The **Quickstart** wizard launches with **Choose a Platform** as the first page. Bypass the wizard for now by clicking the **FaceBook Login Settings** link in the menu on the lower left:

- The **Client OAuth Settings** page is presented:

- Enter your development URI with */signin-facebook* appended into the **Valid OAuth Redirect URIs** field (for example: `https://localhost:44320/signin-facebook`). The Facebook authentication configured later in this tutorial will automatically handle requests at */signin-facebook* route to implement the OAuth flow.

> ⓘ **Note**
>
> The URI */signin-facebook* is set as the default callback of the Facebook authentication provider. You can change the default callback URI while configuring the Facebook authentication middleware via the inherited **RemoteAuthenticationOptions.CallbackPath** property of the **FacebookOptions** class.

- Select **Save Changes**.
- Select **Settings** > **Basic** link in the left navigation.
- Make a note of your `App ID` and your `App Secret`. You will add both into your ASP.NET Core application in the next section:
- When deploying the site you need to revisit the **Facebook Login** setup page, and register a new public URI.

Store the Facebook app ID and secret

Store sensitive settings such as the Facebook app ID and secret values with Secret Manager. For this sample, use the following steps:

1. Initialize the project for secret storage per the instructions at Enable secret storage.
2. Store the sensitive settings in the local secret store with the secret keys `Authentication:Facebook:AppId` and `Authentication:Facebook:AppSecret`:

   .NET CLI

   ```
   dotnet user-secrets set "Authentication:Facebook:AppId" "<app-id>"
   dotnet user-secrets set "Authentication:Facebook:AppSecret" "<app-
   secret>"
   ```

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

Configure Facebook Authentication

Add the Authentication service to the `Program`:

C#

```
var builder = WebApplication.CreateBuilder(args);
var services = builder.Services;
var configuration = builder.Configuration;

services.AddAuthentication().AddFacebook(facebookOptions =>
    {
        facebookOptions.AppId =
configuration["Authentication:Facebook:AppId"];
        facebookOptions.AppSecret =
configuration["Authentication:Facebook:AppSecret"];
    });
```

The AddAuthentication(IServiceCollection, String) overload sets the DefaultScheme property. The AddAuthentication(IServiceCollection, Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default

authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

AuthenticationBuilder extension methods that register an authentication handler may only be called once per authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

Sign in with Facebook

- Run the app and select **Log in**.
- Under **Use another service to log in.**, select Facebook.
- You are redirected to **Facebook** for authentication.
- Enter your Facebook credentials.
- You are redirected back to your site where you can set your email.

You are now logged in using your Facebook credentials:

React to cancel authorize external sign-in

AccessDeniedPath can provide a redirect path to the user agent when the user doesn't approve the requested authorization demand.

The following code sets the `AccessDeniedPath` to `"/AccessDeniedPathInfo"`:

C#

```
services.AddAuthentication().AddFacebook(options =>
{
    options.AppId = Configuration["Authentication:Facebook:AppId"];
    options.AppSecret = Configuration["Authentication:Facebook:AppSecret"];
    options.AccessDeniedPath = "/AccessDeniedPathInfo";
});
```

We recommend the `AccessDeniedPath` page contains the following information:

- Remote authentication was canceled.
- This app requires authentication.
- To try sign-in again, select the Login link.

Test AccessDeniedPath

- Navigate to facebook.com
- If you are signed in, you must sign out.

- Run the app and select Facebook sign-in.
- Select **Not now**. You are redirected to the specified `AccessDeniedPath` page.

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

C#

```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

For more information on configuration options supported by Facebook authentication, see the FacebookOptions API reference. Configuration options can be used to:

- Request different information about the user.
- Add query string arguments to customize the login experience.

Troubleshooting

- **ASP.NET Core 2.x only:** If Identity isn't configured by calling `services.AddIdentity` in `ConfigureServices`, attempting to authenticate will result in *ArgumentException: The 'SignInScheme' option must be provided*. The project template used in this tutorial ensures that this is done.
- If the site database has not been created by applying the initial migration, you get *A database operation failed while processing the request* error. Tap **Apply Migrations** to create the database and refresh to continue past the error.

Next steps

- This article showed how you can authenticate with Facebook. You can follow a similar approach to authenticate with other providers listed on the previous page.
- Once you publish your web site to Azure web app, you should reset the `AppSecret` in the Facebook developer portal.
- Set the `Authentication:Facebook:AppId` and `Authentication:Facebook:AppSecret` as application settings in the Azure portal. The configuration system is set up to read keys from environment variables.

Collaborate with us on GitHub

Microsoft Account external login setup with ASP.NET Core

Article • 06/03/2022

By Valeriy Novytskyy and Rick Anderson

This sample shows you how to enable users to sign in with their work, school, or personal Microsoft account using the ASP.NET Core 6.0 project created on the previous page.

Create the app in Microsoft Developer Portal

- Add the Microsoft.AspNetCore.Authentication.MicrosoftAccount NuGet package to the project.
- Navigate to the Azure portal - App registrations page and create or sign into a Microsoft account:

If you don't have a Microsoft account, select **Create one**. After signing in, you are redirected to the **App registrations** page:

- Select **New registration**
- Enter a **Name**.
- Select an option for **Supported account types**.
  - The `MicrosoftAccount` package supports App Registrations created using "Accounts in any organizational directory" or "Accounts in any organizational directory and Microsoft accounts" options by default.
  - To use other options, set `AuthorizationEndpoint` and `TokenEndpoint` members of `MicrosoftAccountOptions` used to initialize the Microsoft Account authentication to the URLs displayed on **Endpoints** page of the App Registration after it is created (available by clicking Endpoints on the **Overview** page).
- Under **Redirect URI**, enter your development URL with `/signin-microsoft` appended. For example, `https://localhost:5001/signin-microsoft`. The Microsoft authentication scheme configured later in this sample will automatically handle requests at `/signin-microsoft` route to implement the OAuth flow.
- Select **Register**

Create client secret

- In the left pane, select **Certificates & secrets**.
- Under **Client secrets**, select **New client secret**
  - Add a description for the client secret.
  - Select the **Add** button.
- Under **Client secrets**, copy the value of the client secret.

The URI segment `/signin-microsoft` is set as the default callback of the Microsoft authentication provider. You can change the default callback URI while configuring the Microsoft authentication middleware via the inherited RemoteAuthenticationOptions.CallbackPath property of the MicrosoftAccountOptions class.

Store the Microsoft client ID and secret

Store sensitive settings such as the Microsoft **Application (client) ID** found on the **Overview** page of the App Registration and **Client Secret** you created on the **Certificates & secrets page** with Secret Manager. For this sample, use the following steps:

1. Initialize the project for secret storage per the instructions at Enable secret storage.
2. Store the sensitive settings in the local secret store with the secret keys `Authentication:Microsoft:ClientId` and `Authentication:Microsoft:ClientSecret`:

   .NET CLI

   ```
   dotnet user-secrets set "Authentication:Microsoft:ClientId" "<client-id>"
   dotnet user-secrets set "Authentication:Microsoft:ClientSecret" "<client-secret>"
   ```

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

Configure Microsoft Account Authentication

Add the Authentication service to the `Program`:

C#

```
var builder = WebApplication.CreateBuilder(args);
var services = builder.Services;
var configuration = builder.Configuration;

services.AddAuthentication().AddMicrosoftAccount(microsoftOptions =>
    {
        microsoftOptions.ClientId =
configuration["Authentication:Microsoft:ClientId"];
        microsoftOptions.ClientSecret =
configuration["Authentication:Microsoft:ClientSecret"];
    });
```

The AddAuthentication(IServiceCollection, String) overload sets the DefaultScheme property. The AddAuthentication(IServiceCollection, Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

AuthenticationBuilder extension methods that register an authentication handler may only be called once per authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

For more information about configuration options supported by Microsoft Account authentication, see the MicrosoftAccountOptions API reference. This can be used to request different information about the user.

Sign in with Microsoft Account

- Run the app and select **Log in**. An option to sign in with Microsoft appears.
- Select to sign in with Microsoft. You are redirected to Microsoft for authentication. After signing in with your Microsoft Account, you will be prompted to let the app access your info:
- Select **Yes**. You are redirected back to the web site where you can set your email.

You are now logged in using your Microsoft credentials.

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

C#

```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Troubleshooting

- If the Microsoft Account provider redirects you to a sign in error page, note the error title and description query string parameters directly following the `#` (hashtag) in the Uri.

  Although the error message seems to indicate a problem with Microsoft authentication, the most common cause is your application Uri not matching any of the **Redirect URIs** specified for the **Web** platform.

- If Identity isn't configured by calling `services.AddIdentity` in `ConfigureServices`, attempting to authenticate will result in *ArgumentException: The 'SignInScheme' option must be provided*. The project template used in this sample ensures that this is done.

- If the site database has not been created by applying the initial migration, you will get *A database operation failed while processing the request* error. Tap **Apply Migrations** to create the database and refresh to continue past the error.

Next steps

- This article showed how you can authenticate with Microsoft. You can follow a similar approach to authenticate with other providers listed on the previous page.
- Once you publish your web site to Azure web app, create a new client secrets in the Microsoft Developer Portal.
- Set the `Authentication:Microsoft:ClientId` and `Authentication:Microsoft:ClientSecret` as application settings in the Azure portal. The configuration system is set up to read keys from environment variables.

Twitter external sign-in setup with ASP.NET Core

Article • 09/05/2024

By Valeriy Novytskyy and Rick Anderson

This sample shows how to enable users to sign in with their Twitter account using a sample ASP.NET Core project created on the previous page.

> **Note**
>
> The Microsoft.AspNetCore.Authentication.Twitter package described below uses the OAuth 1.0 APIs provided by Twitter. Twitter has since added OAuth 2.0 APIs with a different set of functionality. The OpenIddict and AspNet.Security.OAuth.Twitter packages are community implementations that use the new OAuth 2.0 APIs.

Create the app in Twitter

- Add the Microsoft.AspNetCore.Authentication.Twitter NuGet package to the project.
- Navigate to twitter developer portal Dashboard and sign in. If you don't already have a Twitter account, use the **Sign up now** link to create one.
- If you don't have a project, create one.
- Select + **Add app**. Fill out the **App name** then record the generated API Key, API Key Secret and Bearer Token. These will be needed later.
- In the **App Settings** page, select **Edit** in the **Authentication settings** section, then:
  - Enable 3-legged OAuth
  - Request email address from users
  - Fill out the required fields and select **Save**

> **Note**

Microsoft.AspNetCore.Identity requires users to have an email address by default. For Callback URLs during development, use `https://localhost:{PORT}/signin-twitter`, where the `{PORT}` placeholder is the app's port.

> **Note**
>
> The URI segment `/signin-twitter` is set as the default callback of the Twitter authentication provider. You can change the default callback URI while configuring the Twitter authentication middleware via the inherited RemoteAuthenticationOptions.CallbackPath property of the TwitterOptions class.

Store the Twitter consumer API key and secret

Store sensitive settings such as the Twitter consumer API key and secret with Secret Manager. For this sample, use the following steps:

1. Initialize the project for secret storage per the instructions at Enable secret storage.
2. Store the sensitive settings in the local secret store with the secrets keys `Authentication:Twitter:ConsumerKey` and `Authentication:Twitter:ConsumerSecret`:

.NET CLI

```
dotnet user-secrets set "Authentication:Twitter:ConsumerAPIKey" "
<consumer-api-key>"
dotnet user-secrets set "Authentication:Twitter:ConsumerSecret" "
<consumer-secret>"
```

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. For example, the `:` separator is not supported by Bash. The double underscore, `__`, is:

- Supported by all platforms.
- Automatically replaced by a colon, `:`.

These tokens can be found on the **Keys and Access Tokens** tab after creating a new Twitter application:

Configure Twitter Authentication

C#

```
var builder = WebApplication.CreateBuilder(args);
var services = builder.Services;
var configuration = builder.Configuration;

services.AddAuthentication().AddTwitter(twitterOptions =>
    {
        twitterOptions.ConsumerKey =
configuration["Authentication:Twitter:ConsumerAPIKey"];
        twitterOptions.ConsumerSecret =
configuration["Authentication:Twitter:ConsumerSecret"];
    });
```

The AddAuthentication(IServiceCollection, String) overload sets the DefaultScheme property. The AddAuthentication(IServiceCollection, Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

AuthenticationBuilder extension methods that register an authentication handler may only be called once per authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

C#

```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

For more information on configuration options supported by Twitter authentication, see the TwitterOptions API reference. This can be used to request different information about the user.

Sign in with Twitter

Run the app and select **Log in**. An option to sign in with Twitter appears:

Selecting **Twitter** redirects to Twitter for authentication:

After entering your Twitter credentials, you are redirected back to the web site where you can set your email.

You are now logged in using your Twitter credentials:

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Troubleshooting

- **ASP.NET Core 2.x only:** If Identity isn't configured by calling `services.AddIdentity` in `ConfigureServices`, attempting to authenticate will result in *ArgumentException: The 'SignInScheme' option must be provided*. The project template used in this sample ensures Identity is configured.
- If the site database has not been created by applying the initial migration, you will get *A database operation failed while processing the request* error. Tap **Apply Migrations** to create the database and refresh to continue past the error.

Next steps

- This article showed how you can authenticate with Twitter. You can follow a similar approach to authenticate with other providers listed on the previous page.

- Once you publish your web site to Azure web app, you should reset the `ConsumerSecret` in the Twitter developer portal.

- Set the `Authentication:Twitter:ConsumerKey` and `Authentication:Twitter:ConsumerSecret` as application settings in the Azure portal. The configuration system is set up to read keys from environment variables.

External OAuth authentication providers

Article • 09/05/2024

By Rick Anderson, Pranav Rastogi, and Valeriy Novytskyy

The following list includes common external OAuth authentication providers that work with ASP.NET Core apps. Third-party NuGet packages, such as the ones maintained by OpenIddict or aspnet-contrib, can be used to complement the authentication providers implemented by the ASP.NET Core team.

- LinkedIn
- Instagram
- Reddit (Instructions)
- Github (Instructions)
- Yahoo (Instructions)
- Tumblr (Instructions)
- Pinterest (Instructions)
- Pocket (Instructions)
- Flickr (Instructions)
- Dribbble (Instructions)
- Vimeo (Instructions)
- SoundCloud (Instructions)
- VK (Instructions)

Multiple authentication providers

When the app requires multiple providers, chain the provider extension methods behind AddAuthentication:

C#

```
services.AddAuthentication()
    .AddMicrosoftAccount(microsoftOptions => { ... })
    .AddGoogle(googleOptions => { ... })
```

```
    .AddTwitter(twitterOptions => { ... })
    .AddFacebook(facebookOptions => { ... });
```

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Persist additional claims and tokens from external providers in ASP.NET Core

Article • 09/07/2023

An ASP.NET Core app can establish additional claims and tokens from external authentication providers, such as Facebook, Google, Microsoft, and Twitter. Each provider reveals different information about users on its platform, but the pattern for receiving and transforming user data into additional claims is the same.

Prerequisites

Decide which external authentication providers to support in the app. For each provider, register the app and obtain a client ID and client secret. For more information, see Facebook and Google authentication in ASP.NET Core. The sample app uses the Google authentication provider.

Set the client ID and client secret

The OAuth authentication provider establishes a trust relationship with an app using a client ID and client secret. Client ID and client secret values are created for the app by the external authentication provider when the app is registered with the provider. Each external provider that the app uses must be configured independently with the provider's client ID and client secret. For more information, see the external authentication provider topics that apply:

- Facebook authentication
- Google authentication
- Microsoft authentication
- Twitter authentication
- Other authentication providers
- OpenIdConnect

Optional claims sent in the ID or access token from the authentication provider are usually configured in the provider's online portal. For example, Microsoft Entra ID permits assigning optional claims to the app's ID token in the app registration's **Token configuration** blade. For more information, see How to: Provide optional claims to your app (Azure documentation). For other providers, consult their external documentation sets.

The sample app configures the Google authentication provider with a client ID and client secret provided by Google:

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using WebGoogOauth.Data;

var builder = WebApplication.CreateBuilder(args);
var configuration = builder.Configuration;

builder.Services.AddAuthentication().AddGoogle(googleOptions =>
{
    googleOptions.ClientId =
configuration["Authentication:Google:ClientId"];
    googleOptions.ClientSecret =
configuration["Authentication:Google:ClientSecret"];

    googleOptions.ClaimActions.MapJsonKey("urn:google:picture", "picture",
"url");
    googleOptions.ClaimActions.MapJsonKey("urn:google:locale", "locale",
"string");

    googleOptions.SaveTokens = true;

    googleOptions.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens =
ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
                                    options.SignIn.RequireConfirmedAccount =
true)
```

```
.AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

var app = builder.Build();

// Remaining code removed for brevity.
```

Establish the authentication scope

Specify the list of permissions to retrieve from the provider by specifying the Scope. Authentication scopes for common external providers appear in the following table.

Expand table

Provider	Scope
Facebook	`https://www.facebook.com/dialog/oauth`
Google	`profile`, `email`, `openid`
Microsoft	`https://login.microsoftonline.com/common/oauth2/v2.0/authorize`
Twitter	`https://api.twitter.com/oauth/authenticate`

In the sample app, Google's `profile`, `email`, and `openid` scopes are automatically added by the framework when AddGoogle is called on the AuthenticationBuilder. If the app requires additional scopes, add them to the options. In the following example, the Google `https://www.googleapis.com/auth/user.birthday.read` scope is added to retrieve a user's birthday:

C#

```
options.Scope.Add("https://www.googleapis.com/auth/user.birthday.read");
```

Map user data keys and create claims

In the provider's options, specify a MapJsonKey or MapJsonSubKey for each key or subkey in the external provider's JSON user data for the app identity to read on sign in. For more information on claim types, see ClaimTypes.

The sample app creates locale (`urn:google:locale`) and picture (`urn:google:picture`) claims from the `locale` and `picture` keys in Google user data:

```
```

C#

```
builder.Services.AddAuthentication().AddGoogle(googleOptions =>
{
    googleOptions.ClientId =
configuration["Authentication:Google:ClientId"];
    googleOptions.ClientSecret =
configuration["Authentication:Google:ClientSecret"];

    googleOptions.ClaimActions.MapJsonKey("urn:google:picture", "picture",
"url");
    googleOptions.ClaimActions.MapJsonKey("urn:google:locale", "locale",
"string");

    googleOptions.SaveTokens = true;

    googleOptions.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens =
ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

In `Microsoft.AspNetCore.Identity.UI.Pages.Account.Internal.ExternalLoginModel.OnPostConfirmationAsync`, an IdentityUser (`ApplicationUser`) is signed into the app with SignInAsync. During the sign in process, the UserManager<TUser> can store an `ApplicationUser` claims for user data available from the Principal.

In the sample app, `OnPostConfirmationAsync` (`Account/ExternalLogin.cshtml.cs`) establishes the locale (`urn:google:locale`) and picture (`urn:google:picture`) claims for the signed in `ApplicationUser`, including a claim for GivenName:

C#

```
public async Task<IActionResult> OnPostConfirmationAsync(string returnUrl =
null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    // Get the information about the user from the external login provider
```

```
    var info = await _signInManager.GetExternalLoginInfoAsync();
    if (info == null)
    {
        ErrorMessage = "Error loading external login information during
confirmation.";
        return RedirectToPage("./Login", new { ReturnUrl = returnUrl });
    }

    if (ModelState.IsValid)
    {
        var user = CreateUser();

        await _userStore.SetUserNameAsync(user, Input.Email,
CancellationToken.None);
        await _emailStore.SetEmailAsync(user, Input.Email,
CancellationToken.None);

        var result = await _userManager.CreateAsync(user);
        if (result.Succeeded)
        {
            result = await _userManager.AddLoginAsync(user, info);
            if (result.Succeeded)
            {
                _logger.LogInformation("User created an account using {Name}
provider.", info.LoginProvider);

                // If they exist, add claims to the user for:
                //    Given (first) name
                //    Locale
                //    Picture
                if (info.Principal.HasClaim(c => c.Type ==
ClaimTypes.GivenName))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst(ClaimTypes.GivenName));
                }

                if (info.Principal.HasClaim(c => c.Type ==
"urn:google:locale"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:locale"));
                }

                if (info.Principal.HasClaim(c => c.Type ==
"urn:google:picture"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:picture"));
                }

                // Include the access token in the properties
                // using Microsoft.AspNetCore.Authentication;
                var props = new AuthenticationProperties();
                props.StoreTokens(info.AuthenticationTokens);
```

```
                props.IsPersistent = false;

                var userId = await _userManager.GetUserIdAsync(user);
                var code = await
_userManager.GenerateEmailConfirmationTokenAsync(user);
                code =
WebEncoders.Base64UrlEncode(Encoding.UTF8.GetBytes(code));
                var callbackUrl = Url.Page(
                    "/Account/ConfirmEmail",
                    pageHandler: null,
                    values: new { area = "Identity", userId = userId, code =
code },
                    protocol: Request.Scheme);

                await _emailSender.SendEmailAsync(Input.Email, "Confirm your
email",
                    $"Please confirm your account by <a
href='{HtmlEncoder.Default.Encode(callbackUrl)}'>clicking here</a>.");

                // If account confirmation is required, we need to show the
link if we don't have a real email sender
                if (_userManager.Options.SignIn.RequireConfirmedAccount)
                {
                    return RedirectToPage("./RegisterConfirmation", new {
Email = Input.Email });
                }

                await _signInManager.SignInAsync(user, props,
info.LoginProvider);
                return LocalRedirect(returnUrl);
            }
        }
        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }

    ProviderDisplayName = info.ProviderDisplayName;
    ReturnUrl = returnUrl;
    return Page();
}
```

By default, a user's claims are stored in the authentication cookie. If the authentication cookie is too large, it can cause the app to fail because:

- The browser detects that the cookie header is too long.
- The overall size of the request is too large.

If a large amount of user data is required for processing user requests:

- Limit the number and size of user claims for request processing to only what the app requires.
- Use a custom ITicketStore for the Cookie Authentication Middleware's SessionStore to store identity across requests. Preserve large quantities of identity information on the server while only sending a small session identifier key to the client.

Save the access token

SaveTokens defines whether access and refresh tokens should be stored in the AuthenticationProperties after a successful authorization. `SaveTokens` is set to `false` by default to reduce the size of the final authentication cookie.

The sample app sets the value of `SaveTokens` to `true` in GoogleOptions:

C#

```
builder.Services.AddAuthentication().AddGoogle(googleOptions =>
{
    googleOptions.ClientId =
configuration["Authentication:Google:ClientId"];
    googleOptions.ClientSecret =
configuration["Authentication:Google:ClientSecret"];

    googleOptions.ClaimActions.MapJsonKey("urn:google:picture", "picture",
"url");
    googleOptions.ClaimActions.MapJsonKey("urn:google:locale", "locale",
"string");

    googleOptions.SaveTokens = true;

    googleOptions.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens =
ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

When `OnPostConfirmationAsync` executes, store the access token (ExternalLoginInfo.AuthenticationTokens) from the external provider in the `ApplicationUser`'s `AuthenticationProperties`.

The sample app saves the access token in `OnPostConfirmationAsync` (new user registration) and `OnGetCallbackAsync` (previously registered user) in `Account/ExternalLogin.cshtml.cs`:

C#

```
public async Task<IActionResult> OnPostConfirmationAsync(string returnUrl =
null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    // Get the information about the user from the external login provider
    var info = await _signInManager.GetExternalLoginInfoAsync();
    if (info == null)
    {
        ErrorMessage = "Error loading external login information during
confirmation.";
        return RedirectToPage("./Login", new { ReturnUrl = returnUrl });
    }

    if (ModelState.IsValid)
    {
        var user = CreateUser();

        await _userStore.SetUserNameAsync(user, Input.Email,
CancellationToken.None);
        await _emailStore.SetEmailAsync(user, Input.Email,
CancellationToken.None);

        var result = await _userManager.CreateAsync(user);
        if (result.Succeeded)
        {
            result = await _userManager.AddLoginAsync(user, info);
            if (result.Succeeded)
            {
                _logger.LogInformation("User created an account using {Name}
provider.", info.LoginProvider);

                // If they exist, add claims to the user for:
                //    Given (first) name
                //    Locale
                //    Picture
                if (info.Principal.HasClaim(c => c.Type ==
ClaimTypes.GivenName))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst(ClaimTypes.GivenName));
                }
```

```
                if (info.Principal.HasClaim(c => c.Type ==
"urn:google:locale"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:locale"));
                }

                if (info.Principal.HasClaim(c => c.Type ==
"urn:google:picture"))
                {
                    await _userManager.AddClaimAsync(user,
                        info.Principal.FindFirst("urn:google:picture"));
                }

                // Include the access token in the properties
                // using Microsoft.AspNetCore.Authentication;
                var props = new AuthenticationProperties();
                props.StoreTokens(info.AuthenticationTokens);
                props.IsPersistent = false;

                var userId = await _userManager.GetUserIdAsync(user);
                var code = await
_userManager.GenerateEmailConfirmationTokenAsync(user);
                code =
WebEncoders.Base64UrlEncode(Encoding.UTF8.GetBytes(code));
                var callbackUrl = Url.Page(
                    "/Account/ConfirmEmail",
                    pageHandler: null,
                    values: new { area = "Identity", userId = userId, code =
code },
                    protocol: Request.Scheme);

                await _emailSender.SendEmailAsync(Input.Email, "Confirm your
email",
                    $"Please confirm your account by <a
href='{HtmlEncoder.Default.Encode(callbackUrl)}'>clicking here</a>.");

                // If account confirmation is required, we need to show the
link if we don't have a real email sender
                if (_userManager.Options.SignIn.RequireConfirmedAccount)
                {
                    return RedirectToPage("./RegisterConfirmation", new {
Email = Input.Email });
                }

                await _signInManager.SignInAsync(user, props,
info.LoginProvider);
                return LocalRedirect(returnUrl);
            }
        }
        foreach (var error in result.Errors)
        {
            ModelState.AddModelError(string.Empty, error.Description);
        }
    }
```

```
    ProviderDisplayName = info.ProviderDisplayName;
    ReturnUrl = returnUrl;
    return Page();
}
```

> **Note**
>
> For information on passing tokens to the Razor components of a server-side Blazor app, see **Server-side ASP.NET Core Blazor additional security scenarios**.

How to add additional custom tokens

To demonstrate how to add a custom token, which is stored as part of `SaveTokens`, the sample app adds an AuthenticationToken with the current DateTime for an AuthenticationToken.Name of `TicketCreated`:

C#

```
builder.Services.AddAuthentication().AddGoogle(googleOptions =>
{
    googleOptions.ClientId =
configuration["Authentication:Google:ClientId"];
    googleOptions.ClientSecret =
configuration["Authentication:Google:ClientSecret"];

    googleOptions.ClaimActions.MapJsonKey("urn:google:picture", "picture",
"url");
    googleOptions.ClaimActions.MapJsonKey("urn:google:locale", "locale",
"string");

    googleOptions.SaveTokens = true;
```

```
    googleOptions.Events.OnCreatingTicket = ctx =>
    {
        List<AuthenticationToken> tokens =
ctx.Properties.GetTokens().ToList();

        tokens.Add(new AuthenticationToken()
        {
            Name = "TicketCreated",
            Value = DateTime.UtcNow.ToString()
        });

        ctx.Properties.StoreTokens(tokens);

        return Task.CompletedTask;
    };
});
```

Create and add claims

The framework provides common actions and extension methods for creating and adding claims to the collection. For more information, see the ClaimActionCollectionMapExtensions and ClaimActionCollectionUniqueExtensions.

Users can define custom actions by deriving from ClaimAction and implementing the abstract Run method.

For more information, see Microsoft.AspNetCore.Authentication.OAuth.Claims.

Add and update user claims

Claims are copied from external providers to the user database on first registration, not on sign in. If additional claims are enabled in an app after a user registers to use the app, call SignInManager.RefreshSignInAsync on a user to force the generation of a new authentication cookie.

In the Development environment working with test user accounts, delete and recreate the user account. For production systems, new claims added to the app can be backfilled into user accounts. After scaffolding the ExternalLogin page into the app at `Areas/Pages/Identity/Account/Manage`, add the following code to the `ExternalLoginModel` in the `ExternalLogin.cshtml.cs` file.

Add a dictionary of added claims. Use the dictionary keys to hold the claim types, and use the values to hold a default value. Add the following line to the top of the class. The following example assumes that one claim is added for the user's Google picture with a generic headshot image as the default value:

C#

```
private readonly IReadOnlyDictionary<string, string> _claimsToSync =
     new Dictionary<string, string>()
     {
             { "urn:google:picture", "https://localhost:5001/headshot.png"
},
     };
```

Replace the default code of the `OnGetCallbackAsync` method with the following code. The code loops through the claims dictionary. Claims are added (backfilled) or updated for each user. When claims are added or updated, the user sign-in is refreshed using the SignInManager<TUser>, preserving the existing authentication properties (`AuthenticationProperties`).

C#

```
private readonly IReadOnlyDictionary<string, string> _claimsToSync =
     new Dictionary<string, string>()
     {
             { "urn:google:picture", "https://localhost:5001/headshot.png"
},
     };

public async Task<IActionResult> OnGetCallbackAsync(string returnUrl = null,
string remoteError = null)
{
    returnUrl = returnUrl ?? Url.Content("~/");
    if (remoteError != null)
    {
        ErrorMessage = $"Error from external provider: {remoteError}";
        return RedirectToPage("./Login", new { ReturnUrl = returnUrl });
    }
    var info = await _signInManager.GetExternalLoginInfoAsync();
    if (info == null)
    {
        ErrorMessage = "Error loading external login information.";
        return RedirectToPage("./Login", new { ReturnUrl = returnUrl });
    }

    // Sign in the user with this external login provider if the user
already has a login.
    var result = await
_signInManager.ExternalLoginSignInAsync(info.LoginProvider,
info.ProviderKey, isPersistent: false, bypassTwoFactor: true);
    if (result.Succeeded)
    {
        _logger.LogInformation("{Name} logged in with {LoginProvider}
provider.", info.Principal.Identity.Name, info.LoginProvider);
```

```
        if (_claimsToSync.Count > 0)
        {
            var user = await
_userManager.FindByLoginAsync(info.LoginProvider,
                info.ProviderKey);
            var userClaims = await _userManager.GetClaimsAsync(user);
            bool refreshSignIn = false;

            foreach (var addedClaim in _claimsToSync)
            {
                var userClaim = userClaims
                    .FirstOrDefault(c => c.Type == addedClaim.Key);

                if (info.Principal.HasClaim(c => c.Type == addedClaim.Key))
                {
                    var externalClaim =
info.Principal.FindFirst(addedClaim.Key);

                    if (userClaim == null)
                    {
                        await _userManager.AddClaimAsync(user,
                            new Claim(addedClaim.Key, externalClaim.Value));
                        refreshSignIn = true;
                    }
                    else if (userClaim.Value != externalClaim.Value)
                    {
                        await _userManager
                            .ReplaceClaimAsync(user, userClaim,
externalClaim);
                        refreshSignIn = true;
                    }
                }
                else if (userClaim == null)
                {
                    // Fill with a default value
                    await _userManager.AddClaimAsync(user, new
Claim(addedClaim.Key,
                        addedClaim.Value));
                    refreshSignIn = true;
                }
            }

            if (refreshSignIn)
            {
                await _signInManager.RefreshSignInAsync(user);
            }
        }

        return LocalRedirect(returnUrl);
    }
    if (result.IsLockedOut)
    {
        return RedirectToPage("./Lockout");
    }
    else
```

```
    {
        // If the user does not have an account, then ask the user to create
an account.
        ReturnUrl = returnUrl;
        ProviderDisplayName = info.ProviderDisplayName;
        if (info.Principal.HasClaim(c => c.Type == ClaimTypes.Email))
        {
            Input = new InputModel
            {
                Email = info.Principal.FindFirstValue(ClaimTypes.Email)
            };
        }
        return Page();
    }
}
```

A similar approach is taken when claims change while a user is signed in but a backfill step isn't required. To update a user's claims, call the following on the user:

- UserManager.ReplaceClaimAsync on the user for claims stored in the identity database.
- SignInManager.RefreshSignInAsync on the user to force the generation of a new authentication cookie.

Remove claim actions and claims

ClaimActionCollection.Remove(String) removes all claim actions for the given ClaimType from the collection.
ClaimActionCollectionMapExtensions.DeleteClaim(ClaimActionCollection, String) deletes a claim of the given ClaimType from the identity. DeleteClaim is primarily used with OpenID Connect (OIDC) to remove protocol-generated claims.

Forward request information with a proxy or load balancer

If the app is deployed behind a proxy server or load balancer, some of the original request information might be forwarded to the app in request headers. This information usually includes the secure request scheme (`https`), host, and client IP address. Apps don't automatically read these request headers to discover and use the original request information.

The scheme is used in link generation that affects the authentication flow with external providers. Losing the secure scheme (`https`) results in the app generating incorrect insecure redirect URLs.

Use Forwarded Headers Middleware to make the original request information available to the app for request processing.

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Articles based on ASP.NET Core projects created with individual user accounts

Article • 05/31/2024

ASP.NET Core Identity is included in project templates in Visual Studio with the "Individual User Accounts" option.

The authentication templates are available in .NET CLI with `-au Individual`:

```
dotnet new mvc -au Individual
dotnet new webapp -au Individual
```

See this GitHub issue for web API authentication.

No Authentication

Authentication is specified in the .NET CLI with the `-au` option. In Visual Studio, the **Change Authentication** dialog is available for new web applications. The default for new web apps in Visual Studio is **No Authentication**.

Projects created with no authentication:

- Don't contain web pages and UI to sign in and sign out.
- Don't contain authentication code.

Windows Authentication

Windows Authentication is specified for new web apps in the .NET CLI with the `-au Windows` option. In Visual Studio, the **Change Authentication** dialog provides the **Windows Authentication** options.

If Windows Authentication is selected, the app is configured to use the Windows Authentication IIS module. Windows Authentication is intended for Intranet web sites.

dotnet new webapp authentication options

The following table shows the authentication options available for new web apps:

Microsoft Entra ID with ASP.NET Core

Article • 08/30/2023

These tutorials and samples demonstrate authentication in ASP.NET Core using Microsoft identity platform and Microsoft Entra ID. For additional tutorials and samples using ASP.NET Core with Azure AD, see Microsoft identity platform.

Application Scenarios

- Quickstart: Add sign-in with Microsoft to an ASP.NET Core web app
- Web app that signs in users
- Web app that calls web APIs
- Protected web API
- Web API that calls other web APIs
- Web app that signs in users with Azure AD B2C

Samples

- Enable your ASP.NET Core app to sign-in users and call web APIs using Microsoft identity platform for developers

Microsoft identity platform documentation

Use the Microsoft identity platform and our open-source authentication libraries to sign in users with Microsoft Entra accounts, Microsoft personal accounts, and social accounts like Facebook and Google. Protect your web APIs and access protected APIs like Microsoft Graph to work with your users' and organization's data.

OVERVIEW
What is the Microsoft identity platform?

CONCEPT
Authentication and authorization basics

CONCEPT
App types and authentication flows

SAMPLE
Code samples

WHAT'S NEW
What's new in docs

CONCEPT
OAuth 2.0 and OpenID Connect (OIDC)

CONCEPT
Migrate apps to MSAL

QUICKSTART
Register an application

Authentication and authorization for any app

Focus on documentation for the app you're building or extending with identity and access management (IAM) support by selecting its type.

Single-page app (SPA)

Web app

Web API

A web app whose code is downloaded and run in the browser itself.

A traditional, or "classic," web app whose code runs on a server, returning page data for the browser to render.

A RESTful web service accessed by apps or other web APIs, typically to work with data served by the API.

Desktop app

Apps with a user interface (UI) whose code runs on a user's desktop, laptop, or notebook computer.

Mobile app

Apps with a UI whose code runs on a user's phone, tablet, or other mobile device.

Background service, daemon, or script

An app or script without a UI that performs non-interactive tasks like server-to-server communication or scheduled...

Get started

Quick access to guidance on adding core IAM features to your apps and best practices for keeping your apps secure and available.

Sign in users

- Single-page web app (SPA)
- Web app
- Desktop app
- Mobile app

Protect a web API

- Configure an app to expose a web API
- Build a protected web API
- Call an API from a non-interactive app or script

Test and deploy apps

- Build a test environment
- Run integration tests

Build for security and resilience

- Build Zero Trust-ready apps
- Prevent an over-privileged app
- Build auth resilience into your apps

Microsoft authentication libraries

The open-source Microsoft Authentication Library (MSAL) is built and supported by Microsoft. We recommend MSAL for any app that uses the Microsoft identity platform for authentication and authorization.

Authentication and authorization in Azure App Service and Azure Functions

Article • 09/27/2024

> **Note**
>
> Starting June 1, 2024, all newly created App Service apps will have the option to generate a unique default hostname using the naming convention `<app-name>-<random-hash>.<region>.azurewebsites.net`. Existing app names will remain unchanged.
>
> Example: `myapp-ds27dh7271aah175.westus-01.azurewebsites.net`
>
> For further details, refer to Unique Default Hostname for App Service Resource.

Azure App Service provides built-in authentication and authorization capabilities (sometimes referred to as "Easy Auth"), so you can sign in users and access data by writing minimal or no code in your web app, RESTful API, and mobile back end, and also Azure Functions. This article describes how App Service helps simplify authentication and authorization for your app.

Why use the built-in authentication?

You're not required to use this feature for authentication and authorization. You can use the bundled security features in your web framework of choice, or you can write your own utilities. However, you will need to ensure that your solution stays up to date with the latest security, protocol, and browser updates.

Implementing a secure solution for authentication (signing-in users) and authorization (providing access to secure data) can take significant effort. You must make sure to follow industry best practices and standards, and keep your implementation up to date. The built-in authentication feature for App Service and Azure Functions can save you time and effort by providing out-of-the-box authentication with federated identity providers, allowing you to focus on the rest of your application.

- Azure App Service allows you to integrate a variety of auth capabilities into your web app or API without implementing them yourself.
- It’s built directly into the platform and doesn’t require any particular language, SDK, security expertise, or even any code to utilize.

- You can integrate with multiple login providers. For example, Microsoft Entra, Facebook, Google, X.

Your app might need to support more complex scenarios such as Visual Studio integration or incremental consent. There are several different authentication solutions available to support these scenarios. To learn more, read Identity scenarios.

Identity providers

App Service uses federated identity, in which a third-party identity provider manages the user identities and authentication flow for you. The following identity providers are available by default:

Expand table

Provider	Sign-in endpoint	How-To guidance
Microsoft Entra	`/.auth/login/aad`	App Service Microsoft Entra platform login
Facebook	`/.auth/login/facebook`	App Service Facebook login
Google	`/.auth/login/google`	App Service Google login
X	`/.auth/login/x`	App Service X login
GitHub	`/.auth/login/github`	App Service GitHub login
Sign in with Apple	`/.auth/login/apple`	App Service Sign in With Apple login (Preview)
Any OpenID Connect provider	`/.auth/login/<providerName>`	App Service OpenID Connect login

When you configure this feature with one of these providers, its sign-in endpoint is available for user authentication and for validation of authentication tokens from the provider. You can provide your users with any number of these sign-in options.

Considerations for using built-in authentication

Enabling this feature will cause all requests to your application to be automatically redirected to HTTPS, regardless of the App Service configuration setting to enforce HTTPS. You can disable this with the `requireHttps` setting in the V2 configuration. However, we do recommend sticking with HTTPS, and you should ensure no security tokens ever get transmitted over non-secure HTTP connections.

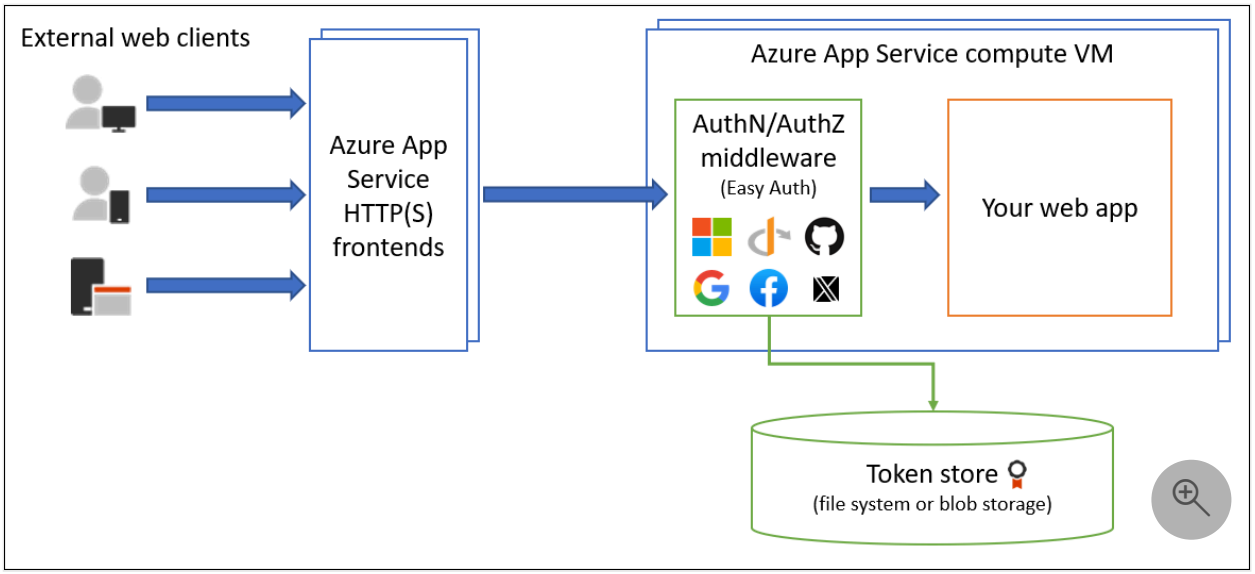
App Service can be used for authentication with or without restricting access to your site content and APIs. Access restrictions can be set in the **Authentication** > **Authentication settings** section of your web app. To restrict app access only to authenticated users, set **Action to take when request is not authenticated** to log in with one of the configured identity providers. To authenticate but not restrict access, set **Action to take when request is not authenticated** to "Allow anonymous requests (no action)."

> **Important**
>
> You should give each app registration its own permission and consent. Avoid permission sharing between environments by using separate app registrations for separate deployment slots. When testing new code, this practice can help prevent issues from affecting the production app.

How it works

Feature architecture

Authentication flow



Authorization behavior

Token store

Logging and tracing

Feature architecture

The authentication and authorization middleware component is a feature of the platform that runs on the same VM as your application. When it's enabled, every incoming HTTP request passes through it before being handled by your application.

The platform middleware handles several things for your app:

- Authenticates users and clients with the specified identity provider(s)
- Validates, stores, and refreshes OAuth tokens issued by the configured identity provider(s)
- Manages the authenticated session
- Injects identity information into HTTP request headers

The module runs separately from your application code and can be configured using Azure Resource Manager settings or using a configuration file. No SDKs, specific programming languages, or changes to your application code are required.

Feature architecture on Windows (non-container deployment)

The authentication and authorization module runs as a native IIS module in the same sandbox as your application. When it's enabled, every incoming HTTP request passes through it before being handled by your application.

Feature architecture on Linux and containers

The authentication and authorization module runs in a separate container, isolated from your application code. Using what's known as the Ambassador pattern, it interacts with the incoming traffic to perform similar functionality as on Windows. Because it does not run in-process, no direct integration with specific language frameworks is possible; however, the relevant information that your app needs is passed through using request headers as explained below.

Authentication flow

The authentication flow is the same for all providers, but differs depending on whether you want to sign in with the provider's SDK:

- Without provider SDK: The application delegates federated sign-in to App Service. This is typically the case with browser apps, which can present the provider's login page to the user. The server code manages the sign-in process, so it is also called *server-directed flow* or *server flow*. This case applies to browser apps and mobile apps that use an embedded browser for authentication.
- With provider SDK: The application signs users in to the provider manually and then submits the authentication token to App Service for validation. This is typically the case with browser-less apps, which can't present the provider's sign-in page to the user. The application code manages the sign-in process, so it is also called *client-directed flow* or *client flow*. This case applies to REST APIs, Azure Functions, and JavaScript browser clients, as well as browser apps that need more flexibility in the sign-in process. It also applies to native mobile apps that sign users in using the provider's SDK.

Calls from a trusted browser app in App Service to another REST API in App Service or Azure Functions can be authenticated using the server-directed flow. For more information, see Customize sign-ins and sign-outs.

The table below shows the steps of the authentication flow.

Expand table

Step	Without provider SDK	With provider SDK
1. Sign user in	Redirects client to `/.auth/login/<provider>`.	Client code signs user in directly with provider's SDK and receives an authentication token. For information, see the provider's documentation.
2. Post-authentication	Provider redirects client to `/.auth/login/<provider>/callback`.	Client code posts token from provider to `/.auth/login/<provider>` for validation.
3. Establish authenticated session	App Service adds authenticated cookie to response.	App Service returns its own authentication token to client code.
4. Serve authenticated content	Client includes authentication cookie in subsequent requests (automatically handled by browser).	Client code presents authentication token in `X-ZUMO-AUTH` header.

For client browsers, App Service can automatically direct all unauthenticated users to `/.auth/login/<provider>`. You can also present users with one or more `/.auth/login/<provider>` links to sign in to your app using their provider of choice.

Authorization behavior

> **Important**
>
> By default, this feature only provides authentication, not authorization. Your application may still need to make authorization decisions, in addition to any checks you configure here.

In the Azure portal, you can configure App Service with a number of behaviors when incoming request is not authenticated. The following headings describe the options.

Restrict access

- **Allow unauthenticated requests** This option defers authorization of unauthenticated traffic to your application code. For authenticated requests, App Service also passes along authentication information in the HTTP headers.

  This option provides more flexibility in handling anonymous requests. For example, it lets you present multiple sign-in providers to your users. However, you must write code.

- **Require authentication** This option will reject any unauthenticated traffic to your application. Specific action to take is specified in the **Unauthenticated requests** section.

  With this option, you don't need to write any authentication code in your app. Finer authorization, such as role-specific authorization, can be handled by inspecting the user's claims (see Access user claims).

  > **Caution**
  >
  > Restricting access in this way applies to all calls to your app, which may not be desirable for apps wanting a publicly available home page, as in many single-page applications.

  > **Note**

> When using the Microsoft identity provider for users in your organization, the default behavior is that any user in your Microsoft Entra tenant can request a token for your application. You can configure the application in Microsoft Entra if you want to restrict access to your app to a defined set of users. App Service also offers some basic built-in authorization checks which can help with some validations. To learn more about authorization in Microsoft Entra, see Microsoft Entra authorization basics.

Unauthenticated requests

- **HTTP 302 Found redirect: recommended for websites** Redirects action to one of the configured identity providers. In these cases, a browser client is redirected to `/.auth/login/<provider>` for the provider you choose.
- **HTTP 401 Unauthorized: recommended for APIs** If the anonymous request comes from a native mobile app, the returned response is an `HTTP 401 Unauthorized`. You can also configure the rejection to be an `HTTP 401 Unauthorized` for all requests.
- **HTTP 403 Forbidden** Configures the rejection to be an `HTTP 403 Forbidden` for all requests.
- **HTTP 404 Not found** Configures the rejection to be an `HTTP 404 Not found` for all requests.

Token store

App Service provides a built-in token store, which is a repository of tokens that are associated with the users of your web apps, APIs, or native mobile apps. When you enable authentication with any provider, this token store is immediately available to your app. If your application code needs to access data from these providers on the user's behalf, such as:

- post to the authenticated user's Facebook timeline
- read the user's corporate data using the Microsoft Graph API

You typically must write code to collect, store, and refresh these tokens in your application. With the token store, you just retrieve the tokens when you need them and tell App Service to refresh them when they become invalid.

The ID tokens, access tokens, and refresh tokens are cached for the authenticated session, and they're accessible only by the associated user.

If you don't need to work with tokens in your app, you can disable the token store in your app's **Authentication / Authorization** page.

Logging and tracing

If you enable application logging, you will see authentication and authorization traces directly in your log files. If you see an authentication error that you didn't expect, you can conveniently find all the details by looking in your existing application logs. If you enable failed request tracing, you can see exactly what role the authentication and authorization module may have played in a failed request. In the trace logs, look for references to a module named `EasyAuthModule_32/64`.

Cross-site request forgery mitigation

App Service authentication mitigates CSRF by inspecting client requests for the following conditions:

- It's a POST request that authenticated using a session cookie.
- The request came from a known browser (as determined by the HTTP `User-Agent` header).
- The HTTP `Origin` or HTTP `Referer` header is missing or is not in the configured list of approved external domains for redirection.
- The HTTP `Origin` header is missing or is not in the configured list of CORS origins.

When a request fulfills all these conditions, App Service authentication automatically rejects it. You can workaround this mitigation logic by adding your external domain to the redirect list to **Authentication** > **Edit authentication settings** > **Allowed external redirect URLs**.

Considerations when using Azure Front Door

When using Azure App Service with authentication behind Azure Front Door or other reverse proxies, a few additional things have to be taken into consideration.

- Disable Front Door caching for the authentication workflow.

- Use the Front Door endpoint for redirects.

  App Service is usually not accessible directly when exposed via Azure Front Door. This can be prevented, for example, by exposing App Service via Private Link in Azure Front Door Premium. To prevent the authentication workflow to redirect traffic back to App Service directly, it is important to configure the application to redirect back to `https://<front-door-endpoint>/.auth/login/<provider>/callback`.

- Ensure that App Service is using the right redirect URI

In some configurations, the App Service is using the App Service FQDN as the redirect URI instead of the Front Door FQDN. This will lead to an issue when the client is being redirected to App Service instead of Front Door. To change that, the `forwardProxy` setting needs to be set to `Standard` to make App Service respect the `X-Forwarded-Host` header set by Azure Front Door.

Other reverse proxies like Azure Application Gateway or 3rd-party products might use different headers and need a different forwardProxy setting.

This configuration cannot be done via the Azure portal today and needs to be done via `az rest`:

Export settings

`az rest --uri /subscriptions/REPLACE-ME-SUBSCRIPTIONID/resourceGroups/REPLACE-ME-RESOURCEGROUP/providers/Microsoft.Web/sites/REPLACE-ME-APPNAME/config/authsettingsV2?api-version=2020-09-01 --method get > auth.json`

Update settings

Search for

```JSON
"httpSettings": {
  "forwardProxy": {
    "convention": "Standard"
  }
}
```

and ensure that `convention` is set to `Standard` to respect the `X-Forwarded-Host` header used by Azure Front Door.

Import settings

`az rest --uri /subscriptions/REPLACE-ME-SUBSCRIPTIONID/resourceGroups/REPLACE-ME-RESOURCEGROUP/providers/Microsoft.Web/sites/REPLACE-ME-APPNAME/config/authsettingsV2?api-version=2020-09-01 --method put --body @auth.json`

Web app that signs in users: App registration

Article • 03/25/2024

This article explains the app registration steps for a web app that signs in users.

To register your application, you can use:

- The web app quickstarts. In addition to being a great first experience with creating an application, quickstarts in the Azure portal contain a button named **Make this change for me**. You can use this button to set the properties you need, even for an existing app. Adapt the values of these properties to your own case. In particular, the web API URL for your app is probably going to be different from the proposed default, which will also affect the sign-out URI.
- The Azure portal to register your application manually.
- PowerShell and command-line tools.

Register an app by using the quickstarts

You can use the following link to bootstrap the creation of your web application:

Register an application

Register an app by using the Azure portal

> **Tip**
>
> Steps in this article might vary slightly based on the portal you start from.

> **Note**
>
> The portal to use is different depending on whether your application runs in the Microsoft Azure public cloud or in a national or sovereign cloud. For more information, see National clouds.

1. Sign in to the Microsoft Entra admin center.
2. If you have access to multiple tenants, use the **Settings** icon in the top menu to switch to the tenant in which you want to register the application from the

Directories + subscriptions menu.

3. Browse to **Identity** > **Applications** > **App registrations**, select **New registration**.

ASP.NET Core

1. When the **Register an application** page appears, enter your application's registration information:
   a. Enter a **Name** for your application, for example `AspNetCore-WebApp`. Users of your app might see this name, and you can change it later.
   b. Choose the supported account types for your application. (See Supported account types.)
   c. For **Redirect URI**, add the type of application and the URI destination that will accept returned token responses after successful authentication. For example, enter `https://localhost:44321`.
   d. Select **Register**.
2. Under **Manage**, select **Authentication** and then add the following information:
   a. In the **Web** section, add `https://localhost:44321/signin-oidc` as a **Redirect URI**.
   b. In **Front-channel logout URL**, enter `https://localhost:44321/signout-oidc`.
   c. Select **Save**.

Register an app by using PowerShell

You can also register an application with Microsoft Graph PowerShell, using the New-MgApplication.

Here's an idea of the code. For a fully functioning code, see this sample

PowerShell

```
# Connect to the Microsoft Graph API, non-interactive is not supported for
the moment (Oct 2021)
Write-Host "Connecting to Microsoft Graph"
if ($tenantId -eq "") {
   Connect-MgGraph -Scopes "User.Read.All Organization.Read.All
Application.ReadWrite.All" -Environment $azureEnvironmentName
}
else {
   Connect-MgGraph -TenantId $tenantId -Scopes "User.Read.All
Organization.Read.All Application.ReadWrite.All" -Environment
$azureEnvironmentName
}
```

```
$context = Get-MgContext
$tenantId = $context.TenantId

# Get the user running the script
$currentUserPrincipalName = $context.Account
$user = Get-MgUser -Filter "UserPrincipalName eq '$($context.Account)'"

# get the tenant we signed in to
$Tenant = Get-MgOrganization
$tenantName = $Tenant.DisplayName

$verifiedDomain = $Tenant.VerifiedDomains | where {$_.Isdefault -eq $true}
$verifiedDomainName = $verifiedDomain.Name
$tenantId = $Tenant.Id

Write-Host ("Connected to Tenant {0} ({1}) as account '{2}'. Domain is
'{3}'" -f  $Tenant.DisplayName, $Tenant.Id, $currentUserPrincipalName,
$verifiedDomainName)

# Create the webApp AAD application
Write-Host "Creating the AAD application (WebApp)"
# create the application
$webAppAadApplication = New-MgApplication -DisplayName "WebApp" `
                                                    -Web `
                                                    @{ `
                                                          RedirectUris =
"https://localhost:44321/", "https://localhost:44321/signin-oidc"; `
                                                          HomePageUrl =
"https://localhost:44321/"; `
                                                          LogoutUrl =
"https://localhost:44321/signout-oidc"; `
                                                       } `
                                                       -SignInAudience
AzureADandPersonalMicrosoftAccount `
                                                    #end of command

$currentAppId = $webAppAadApplication.AppId
$currentAppObjectId = $webAppAadApplication.Id

$tenantName = (Get-MgApplication -ApplicationId
$currentAppObjectId).PublisherDomain
#Update-MgApplication -ApplicationId $currentAppObjectId -IdentifierUris
@("https://$tenantName/WebApp")

# create the service principal of the newly created application
$webAppServicePrincipal = New-MgServicePrincipal -AppId $currentAppId -Tags
{WindowsAzureActiveDirectoryIntegratedApp}

# add the user running the script as an app owner if needed
$owner = Get-MgApplicationOwner -ApplicationId $currentAppObjectId
if ($owner -eq $null)
{
   New-MgApplicationOwnerByRef -ApplicationId $currentAppObjectId  -
BodyParameter = @{"@odata.id" =
"https://graph.microsoft.com/v1.0/directoryObjects/$user.ObjectId"}
```

```
    Write-Host "'$($user.UserPrincipalName)' added as an application owner to
app '$($webAppServicePrincipal.DisplayName)'"
}
Write-Host "Done creating the webApp application (WebApp)"
```

A web app that calls web APIs: App registration

Article • 10/23/2023

A web app that calls web APIs has the same registration as a web app that signs users in. So, follow the instructions in A web app that signs in users: App registration.

However, because the web app now also calls web APIs, it becomes a confidential client application. That's why some extra registration is required. The app must share client credentials, or *secrets*, with the Microsoft identity platform.

Add a client secret or certificate

As with any confidential client application, you need to add a secret or certificate to act as that application's *credentials* so it can authenticate as itself, without user interaction.

You can add credentials to your client app's registration by using the Azure portal or by using a command-line tool like PowerShell.

Add client credentials by using the Azure portal

To add credentials to your confidential client application's app registration, follow the steps in Quickstart: Register an application with the Microsoft identity platform for the type of credential you want to add:

- Add a client secret
- Add a certificate

Add client credentials by using PowerShell

Alternatively, you can add credentials when you register your application with the Microsoft identity platform by using PowerShell.

The active-directory-dotnetcore-daemon-v2 code sample on GitHub shows how to add an application secret or certificate when registering an application:

- For details on how to add a **client secret** with PowerShell, see AppCreationScripts/Configure.ps1.
- For details on how to add a **certificate** with PowerShell, see AppCreationScripts-withCert/Configure.ps1.

API permissions

Web apps call APIs on behalf of the signed-in user. To do that, they must request *delegated permissions*. For details, see Add permissions to access your web API.

Next steps

Protected web API: App registration

Article • 05/28/2024

This article explains how to register an application for a protected web API.

For the common steps to register an app, see Quickstart: Register an application with the Microsoft identity platform.

Accepted token version

The Microsoft identity platform can issue v1.0 tokens and v2.0 tokens. For more information about these tokens, refer to Access tokens.

The token version your API may accept depends on your **Supported account types** selection when you create your web API application registration in the Azure portal.

- If the value of **Supported account types** is **Accounts in any organizational directory and personal Microsoft accounts (such as Skype, Xbox, Outlook.com)**, the accepted token version must be v2.0.
- Otherwise, the accepted token version can be v1.0.

After you create the application, you can determine or change the accepted token version by following these steps:

1. In the Microsoft Entra admin center, select your app and then select **Manifest**.
2. Find the property **accessTokenAcceptedVersion** in the manifest.
3. The value specifies to Microsoft Entra which token version the web API accepts.

    - If the value is 2, the web API accepts v2.0 tokens.
    - If the value is **null**, the web API accepts v1.0 tokens.

4. If you changed the token version, select **Save**.

The web API specifies which token version it accepts. When a client requests a token for your web API from the Microsoft identity platform, the client gets a token that indicates which token version the web API accepts.

No redirect URI

Web APIs don't need to register a redirect URI because no user is interactively signed in.

Exposed API

Other settings specific to web APIs are the exposed API and the exposed scopes or app roles.

Scopes and the Application ID URI

Scopes usually have the form `resourceURI/scopeName`. For Microsoft Graph, the scopes have shortcuts. For example, `User.Read` is a shortcut for `https://graph.microsoft.com/user.read`.

During app registration, define these parameters:

- The resource URI
- One or more scopes
- One or more app roles

By default, the application registration portal recommends that you use the resource URI `api://{clientId}`. This URI is unique but not human readable. If you change the URI, make sure the new value is unique. The application registration portal will ensure that you use a configured publisher domain.

To client applications, scopes show up as *delegated permissions* and app roles show up as *application permissions* for your web API.

Scopes also appear on the consent window that's presented to users of your app. Therefore, provide the corresponding strings that describe the scope:

- As seen by a user.
- As seen by a tenant admin, who can grant admin consent.

App roles cannot be consented to by a user (as they're used by an application that calls the web API on behalf of itself). A tenant administrator will need to consent to client applications of your web API exposing app roles. See Admin consent for details.

Expose delegated permissions (scopes)

To expose delegated permissions, or *scopes*, follow the steps in Configure an application to expose a web API.

If you're following along with the web API scenario described in this set of articles, use these settings:

- **Application ID URI**: Accept the proposed application ID URI (*api://<clientId>*) (if prompted)
- **Scope name**: *access_as_user*
- **Who can consent**: *Admins and users*
- **Admin consent display name**: *Access TodoListService as a user*
- **Admin consent description**: *Accesses the TodoListService web API as a user*
- **User consent display name**: *Access TodoListService as a user*
- **User consent description**: *Accesses the TodoListService web API as a user*
- **State**: *Enabled*

> **Tip**
>
> For the **Application ID URI**, you have the option to set it to the physical authority of the API, for example `https://graph.microsoft.com`. This can be useful if the URL of the API that needs to be called is known.

If your web API is called by a service or daemon app

Expose *application permissions* instead of delegated permissions if your API should be accessed by daemons, services, or other non-interactive (by a human) applications. Because daemon- and service-type applications run unattended and authenticate with their own identity, there is no user to "delegate" their permission.

Expose application permissions (app roles)

To expose application permissions, follow the steps in Add app roles to your app.

In the **Create app role** pane under **Allowed member types**, select **Applications**. Or, add the role by using the **Application manifest editor** as described in the article.

Restrict access tokens to specific clients apps

App roles are the mechanism an application developer uses to expose their app's permissions. Your web API's code should check for app roles in the access tokens it receives from callers.

To add another layer of security, a Microsoft Entra tenant administrator can configure their tenant so the Microsoft identity platform issues security tokens *only* to the client apps they've approved for API access.

To increase security by restricting token issuance only to client apps that have been assigned app roles:

1. In the Microsoft Entra admin center, select your app under **Identity** > **Applications** > **App registrations**.
2. On the application's **Overview** page, in **Essentials**, find and select its **Managed application in local directory** link to navigate to its **Enterprise Application Overview** page.
3. Under **Manage**, select **Properties**.
4. Set **Assignment required?** to **Yes**.
5. Select **Save**.

Microsoft Entra ID will now check for app role assignments of client applications that request access tokens for your web API. If a client app hasn't been assigned any app roles, Microsoft Entra ID returns an error message to the client similar to `_invalid_client: AADSTS501051: Application \<application name\> isn't assigned to a role for the \<web API\>_`.

> ⚠ **Warning**
>
> **DO NOT use AADSTS error codes** or their message strings as literals in your application's code. The "AADSTS" error codes and the error message strings returned by Microsoft Entra ID are *not immutable*, and may be changed by Microsoft at any time and without your knowledge. If you make branching decisions in your code based on the values of either the AADSTS codes or their message strings, you put your application's functionality and stability at risk.

Next step

The next article in this series is App code configuration.

A web API that calls web APIs: App registration

Article • 10/23/2023

A web API that calls downstream web APIs has the same registration as a protected web API. Follow the instructions in Protected web API: App registration.

Because the web app now calls web APIs, it becomes a confidential client application. That's why extra registration information is required: the app needs to share secrets (client credentials) with the Microsoft identity platform.

Add a client secret or certificate

As with any confidential client application, you need to add a secret or certificate to act as that application's *credentials* so it can authenticate as itself, without user interaction.

You can add credentials to your client app's registration by using the Azure portal or by using a command-line tool like PowerShell.

Add client credentials by using the Azure portal

To add credentials to your confidential client application's app registration, follow the steps in Quickstart: Register an application with the Microsoft identity platform for the type of credential you want to add:

- Add a client secret
- Add a certificate

Add client credentials by using PowerShell

Alternatively, you can add credentials when you register your application with the Microsoft identity platform by using PowerShell.

The active-directory-dotnetcore-daemon-v2 code sample on GitHub shows how to add an application secret or certificate when registering an application:

- For details on how to add a **client secret** with PowerShell, see AppCreationScripts/Configure.ps1.
- For details on how to add a **certificate** with PowerShell, see AppCreationScripts-withCert/Configure.ps1.

API permissions

Web apps call APIs on behalf of users for whom the bearer token was received. The web apps need to request delegated permissions. For more information, see Add permissions to access your web API.

Cloud authentication with Azure Active Directory B2C in ASP.NET Core

Article • 10/25/2024

By Damien Bod

Azure Active Directory B2C (Azure AD B2C) is a cloud identity management solution for web and mobile apps. The service provides authentication for apps hosted in the cloud and on-premises. Authentication types include individual accounts, social network accounts, and federated enterprise accounts. Additionally, Azure AD B2C can provide multi-factor authentication with minimal configuration.

> **Tip**
>
> Microsoft Entra ID, Microsoft Entra External ID and Azure AD B2C are separate product offerings. An Entra ID tenant generally represents an organization, while an Azure AD B2C tenant or a Microsoft Entra External ID tenant can represent a collection of identities to be used with relying party applications. To learn more, see **Azure AD B2C: Frequently asked questions (FAQ)**.

> **Tip**
>
> **Microsoft Entra External ID for customers** is Microsoft's new customer identity and access management (CIAM) solution.

In this tutorial, you'll learn how to configure an ASP.NET Core app for authentication with Azure AD B2C.

Prerequisites

- An Azure account with an active subscription. Create an account for free.
- .NET SDK. Install the latest .NET SDK for your platform.

Preparation

1. Create an Azure Active Directory B2C tenant.

2. Create a new ASP.NET Core Razor pages app:

.NET CLI

```
dotnet new razor -o azure-ad-b2c
```

The previous command creates a Razor pages app in a directory named *azure-ad-b2c*.

> **Tip**
>
> You may prefer to use Visual Studio to create your app.

3. Create a web app registration in the tenant. For **Redirect URI**, use `https://localhost:5001/signin-oidc`. Replace `5001` with the port used by your app when using Visual Studio generated ports.

Modify the app

1. Add the `Microsoft.Identity.Web` and `Microsoft.Identity.Web.UI` packages to the project. If you're using Visual Studio, you can use NuGet Package Manager.

.NET CLI

```
dotnet add package Microsoft.Identity.Web
dotnet add package Microsoft.Identity.Web.UI
```

In the preceding:

- `Microsoft.Identity.Web` includes the basic set of dependencies for authenticating with the Microsoft identity platform.
- `Microsoft.Identity.Web.UI` includes UI functionality encapsulated in an area named `MicrosoftIdentity`.

2. Add an `AzureADB2C` object to `appsettings.json`.

> **Note**
>
> When using Azure B2C user flows, you need to set the **Instance** and the PolicyId of the type of flow.

JSON

```
{
  "AzureADB2C": {
    "Instance": "https://--your-domain--.b2clogin.com",
    "Domain": "[Enter the domain of your B2C tenant, e.g.
contoso.onmicrosoft.com]",
    "TenantId": "[Enter 'common', or 'organizations' or the Tenant Id
(Obtained from the Azure portal. Select 'Endpoints' from the 'App
registrations' blade and use the GUID in any of the URLs), e.g.
da41245a5-11b3-996c-00a8-4d99re19f292]",
    "ClientId": "[Enter the Client Id (Application ID obtained from the
Azure portal), e.g. ba74781c2-53c2-442a-97c2-3d60re42f403]",
    // Use either a secret or a certificate. ClientCertificates are
recommended.
    "ClientSecret": "[Copy the client secret added to the app from the
Azure portal]",
    "ClientCertificates": [
    ],
    // the following is required to handle Continuous Access Evaluation
challenges
    "ClientCapabilities": [ "cp1" ],
    "CallbackPath": "/signin-oidc",
    // Add your policy here
    "SignUpSignInPolicyId": "B2C_1_signup_signin",
    "SignedOutCallbackPath": "/signout-callback-oidc"
  },
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

- For **Domain**, use the domain of your Azure AD B2C tenant.
- For **ClientId**, use the **Application (client) ID** from the app registration you created in your tenant.
- For **Instance**, use the domain of your Azure AD B2C tenant.
- For **SignUpSignInPolicyId**, use the user flow policy defined in the Azure B2C tenant
- Use either the **ClientSecret** or the **ClientCertificates** configuration. ClientCertificates are recommended.
- Leave all other values as they are.

3. In *Pages/Shared*, create a file named `_LoginPartial.cshtml`. Include the following code:

```
razor
```

```
@using System.Security.Principal

<ul class="navbar-nav">
@if (User.Identity?.IsAuthenticated == true)
{
        <span class="navbar-text text-dark">Hello @User.Identity?.Name!
</span>
        <li class="nav-item">
            <a class="nav-link text-dark" asp-area="MicrosoftIdentity"
asp-controller="Account" asp-action="SignOut">Sign out</a>
        </li>
}
else
{
        <li class="nav-item">
            <a class="nav-link text-dark" asp-area="MicrosoftIdentity"
asp-controller="Account" asp-action="SignIn">Sign in</a>
        </li>
}
</ul>
```

The preceding code:

- Checks if the user is authenticated.
- Renders a **Sign out** or **Sign in** link as appropriate.
  - The link points to an action method on the `Account` controller in the `MicrosoftIdentity` area.

4. In *Pages/Shared/_Layout.cshtml*, add the highlighted line within the `<header>` element:

razor

```
<header>
    <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-
light bg-white border-bottom box-shadow mb-3">
        <div class="container">
            <a class="navbar-brand" asp-area="" asp-
page="/Index">azure_ad_b2c</a>
            <button class="navbar-toggler" type="button" data-bs-
toggle="collapse" data-bs-target=".navbar-collapse" aria-
controls="navbarSupportedContent"
                    aria-expanded="false" aria-label="Toggle
navigation">
                <span class="navbar-toggler-icon"></span>
            </button>
            <div class="navbar-collapse collapse d-sm-inline-flex
justify-content-between">
                <ul class="navbar-nav flex-grow-1">
                    <li class="nav-item">
```

```
                        <a class="nav-link text-dark" asp-area="" asp-
page="/Index">Home</a>
                    </li>
                    <li class="nav-item">
                        <a class="nav-link text-dark" asp-area="" asp-
page="/Privacy">Privacy</a>
                    </li>
                </ul>
                <partial name="_LoginPartial" />
            </div>
        </div>
    </nav>
</header>
```

Adding `<partial name="_LoginPartial" />` renders the `_LoginPartial.cshtml` partial view in every page request that uses this layout.

5. In *Program.cs*, make the following changes:

   a. Add the following `using` directives:

   C#

   ```
   using Microsoft.Identity.Web;
   using Microsoft.Identity.Web.UI;
   using Microsoft.AspNetCore.Authentication.OpenIdConnect;
   ```

   The preceding code resolves references used in the next steps.

   b. Update the `builder.Services` lines with the following code:

   C#

   ```
   builder.Services.AddAuthentication(OpenIdConnectDefaults.Authenticat
   ionScheme)

   .AddMicrosoftIdentityWebApp(builder.Configuration.GetSection("AzureA
   DB2C"));

   builder.Services.AddAuthorization(options =>
   {
       // By default, all incoming requests will be authorized
   according to
       // the default policy
       options.FallbackPolicy = options.DefaultPolicy;
   });
   builder.Services.AddRazorPages(options => {
       options.Conventions.AllowAnonymousToPage("/Index");
   })
   ```

```
.AddMvcOptions(options => { })
.AddMicrosoftIdentityUI();
```

In the preceding code:

- Calls to the `AddAuthentication` and `AddMicrosoftIdentityWebApp` methods configure the app to use Open ID Connect, specifically configured for the Microsoft identity platform.
- `AddAuthorization` initializes ASP.NET Core authorization.
- The `AddRazorPages` call configures the app so anonymous browsers can view the Index page. All other requests require authentication.
- `AddMvcOptions` and `AddMicrosoftIdentityUI` add the required UI components for redirecting to/from Azure AD B2C.

c. Update the highlighted line to the `Configure` method:

C#

```
app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();
```

The preceding code enables authentication in ASP.NET Core.

Run the app

> **Note**
>
> Use the profile which matches the Azure App registration **Redirect URIs**

1. Run the app.

.NET CLI

```
dotnet run --launch-profile https
```

2. Browse to the app's secure endpoint, for example, `https://localhost:5001/`.

- The Index page renders with no authentication challenge.
- The header includes a **Sign in** link because you're not authenticated.

3. Select the **Privacy** link.

    - The browser is redirected to your tenant's configured authentication method.
    - After signing in, the header displays a welcome message and a **Sign out** link.

Next steps

In this tutorial, you learned how to configure an ASP.NET Core app for authentication with Azure AD B2C.

Now that the ASP.NET Core app is configured to use Azure AD B2C for authentication, the Authorize attribute can be used to secure your app. Continue developing your app by learning to:

- Customize the Azure AD B2C user interface.
- Configure password complexity requirements.
- Enable multi-factor authentication.
- Configure additional identity providers, such as Microsoft, Facebook, Google, Amazon, Twitter, and others.
- Use the Microsoft Graph API to retrieve additional user information, such as group membership, from the Azure AD B2C tenant.
- How to secure a Web API built with ASP.NET Core using the Azure AD B2C .
- Tutorial: Grant access to an ASP.NET web API using Azure Active Directory B2C.

Enable authentication in your own web API by using Azure AD B2C

Article • 01/11/2024

To authorize access to a web API, you can serve only requests that include a valid access token that Azure Active Directory B2C (Azure AD B2C) issues. This article shows you how to enable Azure AD B2C authorization to your web API. After you complete the steps in this article, only users who obtain a valid access token will be authorized to call your web API endpoints.

Prerequisites

Before you begin, read one of the following articles, which discuss how to configure authentication for apps that call web APIs. Then, follow the steps in this article to replace the sample web API with your own web API.

- Configure authentication in a sample ASP.NET Core application
- Configure authentication in a sample single-page application (SPA)

Overview

Token-based authentication ensures that requests to a web API includes a valid access token.

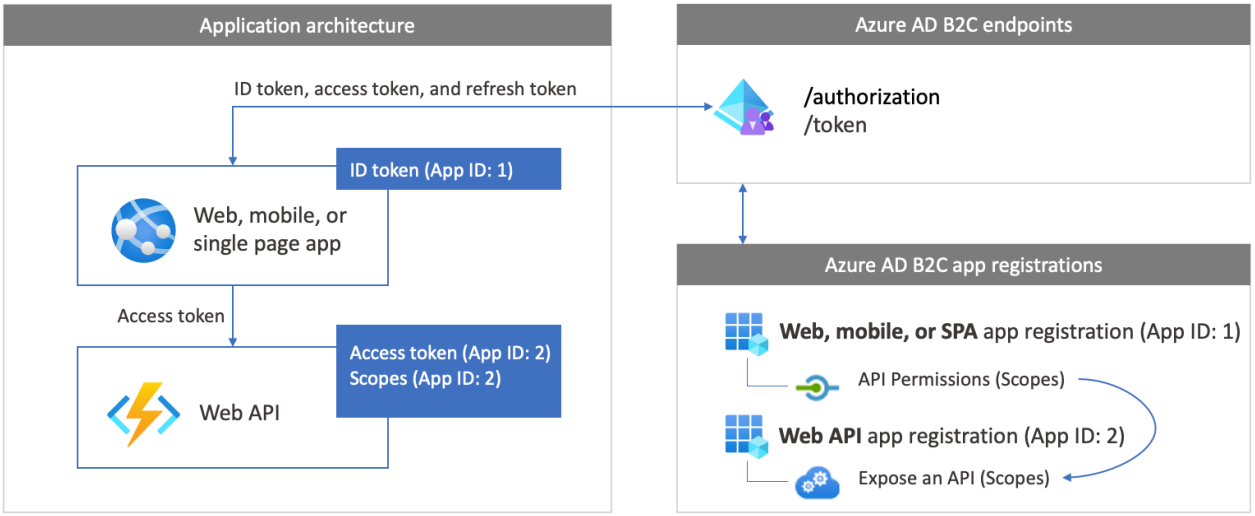
The app completes the following steps:

1. It authenticates users with Azure AD B2C.
2. It acquires an access token with the required permissions (scopes) for the web API endpoint.
3. It passes the access token as a bearer token in the authentication header of the HTTP request by using this format:

   ```HTTP
   Authorization: Bearer <access token>
   ```

The web API completes the following steps:

1. It reads the bearer token from the authorization header in the HTTP request.



2. It validates the token.
3. It validates the permissions (scopes) in the token.
4. It reads the claims that are encoded in the token (optional).
5. It responds to the HTTP request.

App registration overview

To enable your app to sign in with Azure AD B2C and call a web API, you need to register two applications in the Azure AD B2C directory.

- The *web, mobile, or SPA application* registration enables your app to sign in with Azure AD B2C. The app registration process generates an *Application ID*, also known as the *client ID*, which uniquely identifies your application (for example, *App ID: 1*).
- The *web API* registration enables your app to call a protected web API. The registration exposes the web API permissions (scopes). The app registration process generates an *Application ID*, which uniquely identifies your web API (for example, *App ID: 2*). Grant your app (App ID: 1) permissions to the web API scopes (App ID: 2).

The application registrations and the application architecture are described in the following diagram:

Prepare your development environment

In the next sections, you create a new web API project. Select your programming language, ASP.NET Core or Node.js. Make sure you have a computer that's running either of the following software:

ASP.NET Core

- Visual Studio Code
- C# for Visual Studio Code (latest version)
- .NET 5.0 SDK

Step 1: Create a protected web API

Create a new web API project. First, select the programming language you want to use, **ASP.NET Core** or **Node.js**.

ASP.NET Core

Use the dotnet new command. The `dotnet new` command creates a new folder named *TodoList* with the web API project assets. Open the directory, and then open Visual Studio Code.

.NET CLI

```
dotnet new webapi -o TodoList
cd TodoList
code .
```

When you're prompted to "add required assets to the project," select **Yes**.

Step 2: Install the dependencies

Add the authentication library to your web API project. The authentication library parses the HTTP authentication header, validates the token, and extracts claims. For more information, review the documentation for the library.

ASP.NET Core

To add the authentication library, install the package by running the following command:

.NET CLI

```
dotnet add package Microsoft.Identity.Web
```

Step 3: Initiate the authentication library

Add the necessary code to initiate the authentication library.

ASP.NET Core

Open *Startup.cs* and then, at the beginning of the class, add the following `using` declarations:

C#

```
using Microsoft.AspNetCore.Authentication.JwtBearer;
using Microsoft.Identity.Web;
```

Find the `ConfigureServices(IServiceCollection services)` function. Then, before the `services.AddControllers();` line of code, add the following code snippet:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    // Adds Microsoft Identity platform (Azure AD B2C) support to
protect this Api
    services.AddAuthentication(JwtBearerDefaults.AuthenticationScheme)
            .AddMicrosoftIdentityWebApi(options =>
    {
        Configuration.Bind("AzureAdB2C", options);

        options.TokenValidationParameters.NameClaimType = "name";
    },
    options => { Configuration.Bind("AzureAdB2C", options); });
    // End of the Microsoft Identity platform block

    services.AddControllers();
}
```

Find the `Configure` function. Then, immediately after the `app.UseRouting();` line of code, add the following code snippet:

C#

```
app.UseAuthentication();
```

After the change, your code should look like the following snippet:

C#

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.UseHttpsRedirection();

    app.UseRouting();

    // Add the following line
    app.UseAuthentication();
    // End of the block you add

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

Step 4: Add the endpoints

Add two endpoints to your web API:

- Anonymous `/public` endpoint. This endpoint returns the current date and time. Use it to debug your web API with anonymous calls.
- Protected `/hello` endpoint. This endpoint returns the value of the `name` claim within the access token.

To add the anonymous endpoint:

ASP.NET Core

Under the */Controllers* folder, add a *PublicController.cs* file, and then add it to the following code snippet:

C#

```
using System;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;

namespace TodoList.Controllers
{
    [ApiController]
    [Route("[controller]")]
    public class PublicController : ControllerBase
    {
        private readonly ILogger<PublicController> _logger;

        public PublicController(ILogger<PublicController> logger)
        {
            _logger = logger;
        }

        [HttpGet]
        public ActionResult Get()
        {
            return Ok( new {date = DateTime.UtcNow.ToString()});
        }
    }
}
```

To add the protected endpoint:

ASP.NET Core

Under the */Controllers* folder, add a *HelloController.cs* file, and then add it to the following code:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using Microsoft.Identity.Web.Resource;

namespace TodoList.Controllers
{
    [Authorize]
    [RequiredScope("tasks.read")]
    [ApiController]
    [Route("[controller]")]
    public class HelloController : ControllerBase
    {
```

```
        private readonly ILogger<HelloController> _logger;
        private readonly IHttpContextAccessor _contextAccessor;

        public HelloController(ILogger<HelloController> logger,
IHttpContextAccessor contextAccessor)
        {
            _logger = logger;
            _contextAccessor = contextAccessor;
        }

        [HttpGet]
        public ActionResult Get()
        {
            return Ok( new { name = User.Identity.Name});
        }
    }
}
```

The `HelloController` controller is decorated with the AuthorizeAttribute, which limits access to authenticated users only.

The controller is also decorated with the `[RequiredScope("tasks.read")]`. The RequiredScopeAttribute verifies that the web API is called with the right scopes, `tasks.read`.

Step 5: Configure the web server

In a development environment, set the web API to listen on incoming HTTP or HTTPS requests port number. In this example, use HTTP port 6000 and HTTPS port 6001. The base URI of the web API will be `http://localhost:6000` for HTTP and `https://localhost:6001` for HTTPS.

ASP.NET Core

Add the following JSON snippet to the *appsettings.json* file.

JSON

```
"Kestrel": {
    "EndPoints": {
      "Http": {
        "Url": "http://localhost:6000"
      },
      "Https": {
         "Url": "https://localhost:6001"
      }
```

```
    }
  }
```

Step 6: Configure the web API

Add configurations to a configuration file. The file contains information about your Azure AD B2C identity provider. The web API app uses this information to validate the access token that the web app passes as a bearer token.

ASP.NET Core

Under the project root folder, open the *appsettings.json* file, and then add the following settings:

JSON

```
{
  "AzureAdB2C": {
    "Instance": "https://contoso.b2clogin.com",
    "Domain": "contoso.onmicrosoft.com",
    "ClientId": "<web-api-app-application-id>",
    "SignedOutCallbackPath": "/signout/<your-sign-up-in-policy>",
    "SignUpSignInPolicyId": "<your-sign-up-in-policy>"
  },
  // More settings here
}
```

In the *appsettings.json* file, update the following properties:

Expand table

Section	Key	Value
AzureAdB2C	Instance	The first part of your Azure AD B2C tenant name (for example, `https://contoso.b2clogin.com`).
AzureAdB2C	Domain	Your Azure AD B2C tenant full tenant name (for example, `contoso.onmicrosoft.com`).
AzureAdB2C	ClientId	The web API application ID. In the preceding diagram, it's the application with *App ID: 2*. To learn how to get your web API application registration ID, see Prerequisites.
AzureAdB2C	SignUpSignInPolicyId	The user flows, or custom policy. To learn how to get

Section	Key	Value
		your user flow or policy, see Prerequisites.

Step 7: Run and test the web API

Finally, run the web API with your Azure AD B2C environment settings.

ASP.NET Core

In the command shell, start the web app by running the following command:

```bush
 dotnet run
```

You should see the following output, which means that your app is up and running and ready to receive requests.

```
Now listening on: http://localhost:6000
```

To stop the program, in the command shell, select Ctrl+C. You can rerun the app by using the `node app.js` command.

> **Tip**
>
> Alternatively, to run the `dotnet run` command, you can use the Visual Studio Code debugger. Visual Studio Code's built-in debugger helps accelerate your edit, compile, and debug loop.

Open a browser and go to `http://localhost:6000/public`. In the browser window, you should see the following text displayed, along with the current date and time.

Step 8: Call the web API from your app

Try to call the protected web API endpoint without an access token. Open a browser and go to `http://localhost:6000/hello`. The API will return an unauthorized HTTP error

message, confirming that web API is protected with a bearer token.

Continue to configure your app to call the web API. For guidance, see the Prerequisites section.

Watch this video to learn about some best practices when you integrate Azure AD B2C with an API.

Use cookie authentication without ASP.NET Core Identity

Article • 04/25/2024

By Rick Anderson

ASP.NET Core Identity is a complete, full-featured authentication provider for creating and maintaining logins. However, a cookie-based authentication provider without ASP.NET Core Identity can be used. For more information, see Introduction to Identity on ASP.NET Core.

View or download sample code (how to download)

For demonstration purposes in the sample app, the user account for the hypothetical user, Maria Rodriguez, is hardcoded into the app. Use the **Email** address `maria.rodriguez@contoso.com` and any password to sign in the user. The user is authenticated in the `AuthenticateUser` method in the `Pages/Account/Login.cshtml.cs` file. In a real-world example, the user would be authenticated against a datastore.

Add cookie authentication

- Add the Authentication Middleware services with the AddAuthentication and AddCookie methods.
- Call UseAuthentication and UseAuthorization to set the `HttpContext.User` property and run the Authorization Middleware for requests. `UseAuthentication` and `UseAuthorization` must be called before `Map` methods such as MapRazorPages and MapDefaultControllerRoute

C#

```
using Microsoft.AspNetCore.Authentication.Cookies;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddAuthentication(CookieAuthenticationDefaults.Authenticati
onScheme)
    .AddCookie();

builder.Services.AddHttpContextAccessor();
```

```
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();
app.MapDefaultControllerRoute();

app.Run();
```

AuthenticationScheme passed to `AddAuthentication` sets the default authentication scheme for the app. `AuthenticationScheme` is useful when there are multiple instances of cookie authentication and the app needs to authorize with a specific scheme. Setting the `AuthenticationScheme` to CookieAuthenticationDefaults.AuthenticationScheme provides a value of `"Cookies"` for the scheme. Any string value can be used that distinguishes the scheme.

The app's authentication scheme is different from the app's cookie authentication scheme. When a cookie authentication scheme isn't provided to AddCookie, it uses CookieAuthenticationDefaults.AuthenticationScheme. The CookieAuthenticationDefaults.AuthenticationScheme GitHub Source shows it's set to `"Cookies"`.

The authentication cookie's IsEssential property is set to `true` by default. Authentication cookies are allowed when a site visitor hasn't consented to data collection. For more information, see General Data Protection Regulation (GDPR) support in ASP.NET Core.

The CookieAuthenticationOptions class is used to configure the authentication provider options.

Configure CookieAuthenticationOptions in the AddCookie method:

C#

```
using Microsoft.AspNetCore.Authentication.Cookies;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
```

```
builder.Services.AddControllersWithViews();

builder.Services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        options.ExpireTimeSpan = TimeSpan.FromMinutes(20);
        options.SlidingExpiration = true;
        options.AccessDeniedPath = "/Forbidden/";
    });

builder.Services.AddSingleton<IHttpContextAccessor, HttpContextAccessor>();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();
app.MapDefaultControllerRoute();

app.Run();
```

Cookie Policy Middleware

The Cookie Policy Middleware (GitHub Source) UseCookiePolicy enables cookie policy capabilities. Middleware is processed in the order it's added:

```
C#

app.UseCookiePolicy(cookiePolicyOptions);
```

Use CookiePolicyOptions provided to the Cookie Policy Middleware to control global characteristics of cookie processing and hook into cookie processing handlers when cookies are appended or deleted.

The default MinimumSameSitePolicy value is `SameSiteMode.Lax` to permit OAuth2 authentication. To strictly enforce a same-site policy of `SameSiteMode.Strict`, set the `MinimumSameSitePolicy`. Although this setting breaks OAuth2 and other cross-origin

authentication schemes, it elevates the level of cookie security for other types of apps that don't rely on cross-origin request processing.

```
C#

var cookiePolicyOptions = new CookiePolicyOptions
{
    MinimumSameSitePolicy = SameSiteMode.Strict,
};
```

The Cookie Policy Middleware setting for `MinimumSameSitePolicy` can affect the setting of `Cookie.SameSite` in `CookieAuthenticationOptions` settings according to the matrix below.

Expand table

MinimumSameSitePolicy	Cookie.SameSite	Resultant Cookie.SameSite setting
SameSiteMode.None	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict
SameSiteMode.Lax	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict	SameSiteMode.Lax SameSiteMode.Lax SameSiteMode.Strict
SameSiteMode.Strict	SameSiteMode.None SameSiteMode.Lax SameSiteMode.Strict	SameSiteMode.Strict SameSiteMode.Strict SameSiteMode.Strict

Create an authentication cookie

To create a cookie holding user information, construct a ClaimsPrincipal. The user information is serialized and stored in the cookie.

Create a ClaimsIdentity with any required Claims and call SignInAsync to sign in the user. `Login.cshtml.cs` in the sample app contains the following code:

```
C#

public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    ReturnUrl = returnUrl;

    if (ModelState.IsValid)
    {
```

```
        // Use Input.Email and Input.Password to authenticate the user
        // with your custom authentication logic.
        //
        // For demonstration purposes, the sample validates the user
        // on the email address maria.rodriguez@contoso.com with
        // any password that passes model validation.

        var user = await AuthenticateUser(Input.Email, Input.Password);

        if (user == null)
        {
            ModelState.AddModelError(string.Empty, "Invalid login
attempt.");
            return Page();
        }

        var claims = new List<Claim>
        {
            new Claim(ClaimTypes.Name, user.Email),
            new Claim("FullName", user.FullName),
            new Claim(ClaimTypes.Role, "Administrator"),
        };

        var claimsIdentity = new ClaimsIdentity(
            claims, CookieAuthenticationDefaults.AuthenticationScheme);

        var authProperties = new AuthenticationProperties
        {
            //AllowRefresh = <bool>,
            // Refreshing the authentication session should be allowed.

            //ExpiresUtc = DateTimeOffset.UtcNow.AddMinutes(10),
            // The time at which the authentication ticket expires. A
            // value set here overrides the ExpireTimeSpan option of
            // CookieAuthenticationOptions set with AddCookie.

            //IsPersistent = true,
            // Whether the authentication session is persisted across
            // multiple requests. When used with cookies, controls
            // whether the cookie's lifetime is absolute (matching the
            // lifetime of the authentication ticket) or session-based.

            //IssuedUtc = <DateTimeOffset>,
            // The time at which the authentication ticket was issued.

            //RedirectUri = <string>
            // The full path or absolute URI to be used as an http
            // redirect response value.
        };

        await HttpContext.SignInAsync(
            CookieAuthenticationDefaults.AuthenticationScheme,
            new ClaimsPrincipal(claimsIdentity),
            authProperties);
```

```
            _logger.LogInformation("User {Email} logged in at {Time}.",
                user.Email, DateTime.UtcNow);

            return LocalRedirect(Url.GetLocalUrl(returnUrl));
        }

        // Something failed. Redisplay the form.
        return Page();
    }
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

`SignInAsync` creates an encrypted cookie and adds it to the current response. If `AuthenticationScheme` isn't specified, the default scheme is used.

RedirectUri is only used on a few specific paths by default, for example, the login path and logout paths. For more information see the CookieAuthenticationHandler source.

ASP.NET Core's Data Protection system is used for encryption. For an app hosted on multiple machines, load balancing across apps, or using a web farm, configure data protection to use the same key ring and app identifier.

Sign out

To sign out the current user and delete their cookie, call SignOutAsync:

C#

```
public async Task OnGetAsync(string returnUrl = null)
{
    if (!string.IsNullOrEmpty(ErrorMessage))
    {
        ModelState.AddModelError(string.Empty, ErrorMessage);
    }

    // Clear the existing external cookie
    await HttpContext.SignOutAsync(
        CookieAuthenticationDefaults.AuthenticationScheme);

    ReturnUrl = returnUrl;
}
```

If `CookieAuthenticationDefaults.AuthenticationScheme` or "Cookies" isn't used as the scheme, supply the scheme used when configuring the authentication provider. Otherwise, the default scheme is used. For example, if "ContosoCookie" is used as the scheme, supply the scheme used when configuring the authentication provider.

When the browser closes it automatically deletes session based cookies (non-persistent cookies), but no cookies are cleared when an individual tab is closed. The server is not notified of tab or browser close events.

React to back-end changes

Once a cookie is created, the cookie is the single source of identity. If a user account is disabled in back-end systems:

- The app's cookie authentication system continues to process requests based on the authentication cookie.
- The user remains signed into the app as long as the authentication cookie is valid.

The ValidatePrincipal event can be used to intercept and override validation of the cookie identity. Validating the cookie on every request mitigates the risk of revoked users accessing the app.

One approach to cookie validation is based on keeping track of when the user database changes. If the database hasn't been changed since the user's cookie was issued, there's no need to re-authenticate the user if their cookie is still valid. In the sample app, the database is implemented in `IUserRepository` and stores a `LastChanged` value. When a user is updated in the database, the `LastChanged` value is set to the current time.

In order to invalidate a cookie when the database changes based on the `LastChanged` value, create the cookie with a `LastChanged` claim containing the current `LastChanged` value from the database:

C#

```
var claims = new List<Claim>
{
    new Claim(ClaimTypes.Name, user.Email),
    new Claim("LastChanged", {Database Value})
};

var claimsIdentity = new ClaimsIdentity(
    claims,
    CookieAuthenticationDefaults.AuthenticationScheme);

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity));
```

To implement an override for the `ValidatePrincipal` event, write a method with the following signature in a class that derives from CookieAuthenticationEvents:

C#

```
ValidatePrincipal(CookieValidatePrincipalContext)
```

The following is an example implementation of `CookieAuthenticationEvents`:

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.Cookies;

public class CustomCookieAuthenticationEvents : CookieAuthenticationEvents
{
    private readonly IUserRepository _userRepository;

    public CustomCookieAuthenticationEvents(IUserRepository userRepository)
    {
        _userRepository = userRepository;
    }

    public override async Task
ValidatePrincipal(CookieValidatePrincipalContext context)
    {
        var userPrincipal = context.Principal;

        // Look for the LastChanged claim.
        var lastChanged = (from c in userPrincipal.Claims
                           where c.Type == "LastChanged"
                           select c.Value).FirstOrDefault();

        if (string.IsNullOrEmpty(lastChanged) ||
            !_userRepository.ValidateLastChanged(lastChanged))
        {
            context.RejectPrincipal();

            await context.HttpContext.SignOutAsync(
                CookieAuthenticationDefaults.AuthenticationScheme);
        }
    }
}
```

Register the events instance during cookie service registration. Provide a scoped service registration for your `CustomCookieAuthenticationEvents` class:

C#

```
using Microsoft.AspNetCore.Authentication.Cookies;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
```

```
builder.Services.AddControllersWithViews();

builder.Services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        options.EventsType = typeof(CustomCookieAuthenticationEvents);
    });

builder.Services.AddScoped<CustomCookieAuthenticationEvents>();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();
app.MapDefaultControllerRoute();

app.Run();
```

Consider a situation in which the user's name is updated—a decision that doesn't affect security in any way. If you want to non-destructively update the user principal, call `context.ReplacePrincipal` and set the `context.ShouldRenew` property to `true`.

> ⚠ **Warning**
>
> The approach described here is triggered on every request. Validating authentication cookies for all users on every request can result in a large performance penalty for the app.

Persistent cookies

You may want the cookie to persist across browser sessions. This persistence should only be enabled with explicit user consent with a "Remember Me" checkbox on sign in or a similar mechanism.

The following code snippet creates an identity and corresponding cookie that survives through browser closures. Any sliding expiration settings previously configured are honored. If the cookie expires while the browser is closed, the browser clears the cookie once it's restarted.

Set IsPersistent to `true` in AuthenticationProperties:

```
C#

// using Microsoft.AspNetCore.Authentication;

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity),
    new AuthenticationProperties
    {
        IsPersistent = true
    });
```

Absolute cookie expiration

An absolute expiration time can be set with ExpiresUtc. To create a persistent cookie, `IsPersistent` must also be set. Otherwise, the cookie is created with a session-based lifetime and could expire either before or after the authentication ticket that it holds. When `ExpiresUtc` is set, it overrides the value of the ExpireTimeSpan option of CookieAuthenticationOptions, if set.

The following code snippet creates an identity and corresponding cookie that lasts for 20 minutes. This ignores any sliding expiration settings previously configured.

```
C#

// using Microsoft.AspNetCore.Authentication;

await HttpContext.SignInAsync(
    CookieAuthenticationDefaults.AuthenticationScheme,
    new ClaimsPrincipal(claimsIdentity),
    new AuthenticationProperties
    {
        IsPersistent = true,
        ExpiresUtc = DateTime.UtcNow.AddMinutes(20)
    });
```

Configure certificate authentication in ASP.NET Core

Article • 09/10/2024

`Microsoft.AspNetCore.Authentication.Certificate` contains an implementation similar to Certificate Authentication for ASP.NET Core. Certificate authentication happens at the TLS level, long before it ever gets to ASP.NET Core. More accurately, this is an authentication handler that validates the certificate and then gives you an event where you can resolve that certificate to a `ClaimsPrincipal`.

You ***must*** configure your server for certificate authentication, be it IIS, Kestrel, Azure Web Apps, or whatever else you're using.

Proxy and load balancer scenarios

Certificate authentication is a stateful scenario primarily used where a proxy or load balancer doesn't handle traffic between clients and servers. If a proxy or load balancer is used, certificate authentication only works if the proxy or load balancer:

- Handles the authentication.
- Passes the user authentication information to the app (for example, in a request header), which acts on the authentication information.

An alternative to certificate authentication in environments where proxies and load balancers are used is Active Directory Federated Services (ADFS) with OpenID Connect (OIDC).

Get started

Acquire an HTTPS certificate, apply it, and configure your server to require certificates.

In the web app:

- Add a reference to the Microsoft.AspNetCore.Authentication.Certificate NuGet package.
- In `Program.cs`, call `builder.Services.AddAuthentication(CertificateAuthenticationDefaults.AuthenticationScheme).AddCertificate(...);`. Provide a delegate for `OnCertificateValidated` to do any supplementary validation on the client

certificate sent with requests. Turn that information into a `ClaimsPrincipal` and set it on the `context.Principal` property.

If authentication fails, this handler returns a `403 (Forbidden)` response rather a `401 (Unauthorized)`, as you might expect. The reasoning is that the authentication should happen during the initial TLS connection. By the time it reaches the handler, it's too late. There's no way to upgrade the connection from an anonymous connection to one with a certificate.

`UseAuthentication` is required to set `HttpContext.User` to a `ClaimsPrincipal` created from the certificate. For example:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication(
        CertificateAuthenticationDefaults.AuthenticationScheme)
    .AddCertificate();

var app = builder.Build();

app.UseAuthentication();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The preceding example demonstrates the default way to add certificate authentication. The handler constructs a user principal using the common certificate properties.

Configure certificate validation

The `CertificateAuthenticationOptions` handler has some built-in validations that are the minimum validations you should perform on a certificate. Each of these settings is enabled by default.

AllowedCertificateTypes = Chained, SelfSigned, or All (Chained | SelfSigned)

Default value: `CertificateTypes.Chained`

This check validates that only the appropriate certificate type is allowed. If the app is using self-signed certificates, this option needs to be set to `CertificateTypes.All` or

`CertificateTypes.SelfSigned`.

ChainTrustValidationMode

Default value: X509ChainTrustMode.System

The certificate presented by the client must chain to a trusted root certificate. This check controls which trust store contains these root certificates.

By default, the handler uses the system trust store. If the presented client certificate needs to chain to a root certificate which doesn't appear in the system trust store, this option can be set to X509ChainTrustMode.CustomRootTrust to make the handler use the `CustomTrustStore`.

CustomTrustStore

Default value: Empty X509Certificate2Collection

If the handler's ChainTrustValidationMode property is set to `X509ChainTrustMode.CustomRootTrust`, this X509Certificate2Collection contains every certificate which will be used to validate the client certificate up to a trusted root, including the trusted root.

When the client presents a certificate which is part of a multi-level certificate chain, `CustomTrustStore` must contain every issuing certificate in the chain.

ValidateCertificateUse

Default value: `true`

This check validates that the certificate presented by the client has the Client Authentication extended key use (EKU), or no EKUs at all. As the specifications say, if no EKU is specified, then all EKUs are deemed valid.

ValidateValidityPeriod

Default value: `true`

This check validates that the certificate is within its validity period. On each request, the handler ensures that a certificate that was valid when it was presented hasn't expired during its current session.

RevocationFlag

Default value: `X509RevocationFlag.ExcludeRoot`

A flag that specifies which certificates in the chain are checked for revocation.

Revocation checks are only performed when the certificate is chained to a root certificate.

RevocationMode

Default value: `X509RevocationMode.Online`

A flag that specifies how revocation checks are performed.

Specifying an online check can result in a long delay while the certificate authority is contacted.

Revocation checks are only performed when the certificate is chained to a root certificate.

Can I configure my app to require a certificate only on certain paths?

This isn't possible. Remember the certificate exchange is done at the start of the HTTPS conversation, it's done by the server before the first request is received on that connection so it's not possible to scope based on any request fields.

Handler events

The handler has two events:

- `OnAuthenticationFailed`: Called if an exception happens during authentication and allows you to react.
- `OnCertificateValidated`: Called after the certificate has been validated, passed validation and a default principal has been created. This event allows you to perform your own validation and augment or replace the principal. For examples include:
    - Determining if the certificate is known to your services.
    - Constructing your own principal. Consider the following example:

C#

```
builder.Services.AddAuthentication(
        CertificateAuthenticationDefaults.AuthenticationScheme)
    .AddCertificate(options =>
    {
        options.Events = new CertificateAuthenticationEvents
        {
            OnCertificateValidated = context =>
            {
                var claims = new[]
                {
                    new Claim(
                        ClaimTypes.NameIdentifier,
                        context.ClientCertificate.Subject,
                        ClaimValueTypes.String,
context.Options.ClaimsIssuer),
                    new Claim(
                        ClaimTypes.Name,
                        context.ClientCertificate.Subject,
                        ClaimValueTypes.String,
context.Options.ClaimsIssuer)
                };

                context.Principal = new ClaimsPrincipal(
                    new ClaimsIdentity(claims,
context.Scheme.Name));
                context.Success();

                return Task.CompletedTask;
            }
        };
    });
```

If you find the inbound certificate doesn't meet your extra validation, call `context.Fail("failure reason")` with a failure reason.

For better functionality, call a service registered in dependency injection that connects to a database or other type of user store. Access the service by using the context passed into the delegate. Consider the following example:

C#

```
builder.Services.AddAuthentication(
        CertificateAuthenticationDefaults.AuthenticationScheme)
    .AddCertificate(options =>
    {
        options.Events = new CertificateAuthenticationEvents
        {
            OnCertificateValidated = context =>
            {
```

```
                var validationService = context.HttpContext.RequestServices
                    .GetRequiredService<ICertificateValidationService>();

                if
(validationService.ValidateCertificate(context.ClientCertificate))
                {
                    var claims = new[]
                    {
                        new Claim(
                            ClaimTypes.NameIdentifier,
                            context.ClientCertificate.Subject,
                            ClaimValueTypes.String,
context.Options.ClaimsIssuer),
                        new Claim(
                            ClaimTypes.Name,
                            context.ClientCertificate.Subject,
                            ClaimValueTypes.String,
context.Options.ClaimsIssuer)
                    };

                    context.Principal = new ClaimsPrincipal(
                        new ClaimsIdentity(claims, context.Scheme.Name));
                    context.Success();
                }

                return Task.CompletedTask;
            }
        };
    });
```

Conceptually, the validation of the certificate is an authorization concern. Adding a check on, for example, an issuer or thumbprint in an authorization policy, rather than inside `OnCertificateValidated`, is perfectly acceptable.

Configure your server to require certificates

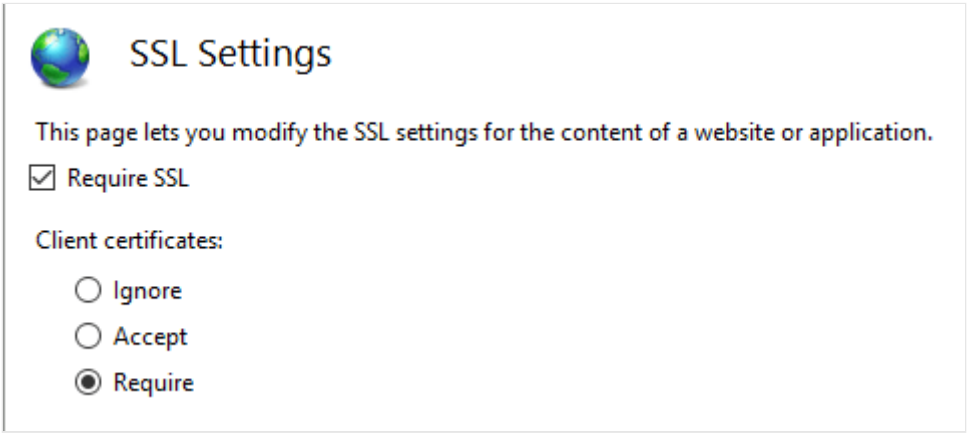
Kestrel

In `Program.cs`, configure Kestrel as follows:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.Configure<KestrelServerOptions>(options =>
{
    options.ConfigureHttpsDefaults(options =>
        options.ClientCertificateMode =
```



```
ClientCertificateMode.RequireCertificate);
});
```

> ⓘ Note
>
> Endpoints created by calling Listen **before** calling ConfigureHttpsDefaults won't have the defaults applied.

IIS

Complete the following steps in IIS Manager:

1. Select your site from the **Connections** tab.
2. Double-click the **SSL Settings** option in the **Features View** window.
3. Check the **Require SSL** checkbox, and select the **Require** radio button in the **Client certificates** section.

Azure and custom web proxies

See the host and deploy documentation for how to configure the certificate forwarding middleware.

Use certificate authentication in Azure Web Apps

No forwarding configuration is required for Azure. Forwarding configuration is set up by the Certificate Forwarding Middleware.

> ⓘ Note
>
> Certificate Forwarding Middleware is required for this scenario.

For more information, see Use a TLS/SSL certificate in your code in Azure App Service (Azure documentation).

Use certificate authentication in custom web proxies

The `AddCertificateForwarding` method is used to specify:

- The client header name.
- How the certificate is to be loaded (using the `HeaderConverter` property).

In custom web proxies, the certificate is passed as a custom request header, for example `X-SSL-CERT`. To use it, configure certificate forwarding in `Program.cs`:

C#

```
builder.Services.AddCertificateForwarding(options =>
{
    options.CertificateHeader = "X-SSL-CERT";

    options.HeaderConverter = headerValue =>
    {
        X509Certificate2? clientCertificate = null;

        if (!string.IsNullOrWhiteSpace(headerValue))
        {
            clientCertificate = new
X509Certificate2(StringToByteArray(headerValue));
        }

        return clientCertificate!;

        static byte[] StringToByteArray(string hex)
        {
            var numberChars = hex.Length;
            var bytes = new byte[numberChars / 2];

            for (int i = 0; i < numberChars; i += 2)
            {
                bytes[i / 2] = Convert.ToByte(hex.Substring(i, 2), 16);
            }

            return bytes;
        }
    };
});
```

If the app is reverse proxied by NGINX with the configuration `proxy_set_header ssl-client-cert $ssl_client_escaped_cert` or deployed on Kubernetes using NGINX Ingress,

the client certificate is passed to the app in URL-encoded form. To use the certificate, decode it as follows:

C#

```
builder.Services.AddCertificateForwarding(options =>
{
    options.CertificateHeader = "ssl-client-cert";

    options.HeaderConverter = (headerValue) =>
    {
        X509Certificate2? clientCertificate = null;

        if (!string.IsNullOrWhiteSpace(headerValue))
        {
            clientCertificate = X509Certificate2.CreateFromPem(
                WebUtility.UrlDecode(headerValue));
        }

        return clientCertificate!;
    };
});
```

Add the middleware in `Program.cs`. `UseCertificateForwarding` is called before the calls to `UseAuthentication` and `UseAuthorization`:

C#

```
var app = builder.Build();

app.UseCertificateForwarding();

app.UseAuthentication();
app.UseAuthorization();
```

A separate class can be used to implement validation logic. Because the same self-signed certificate is used in this example, ensure that only your certificate can be used. Validate that the thumbprints of both the client certificate and the server certificate match, otherwise any certificate can be used and will be enough to authenticate. This would be used inside the `AddCertificate` method. You could also validate the subject or the issuer here if you're using intermediate or child certificates.

C#

```
using System.Security.Cryptography.X509Certificates;

namespace CertAuthSample.Snippets;
```

```
public class SampleCertificateValidationService :
ICertificateValidationService
{
    public bool ValidateCertificate(X509Certificate2 clientCertificate)
    {
        // Don't hardcode passwords in production code.
        // Use a certificate thumbprint or Azure Key Vault.
        var expectedCertificate = new X509Certificate2(
            Path.Combine("/path/to/pfx"), "1234");

        return clientCertificate.Thumbprint ==
expectedCertificate.Thumbprint;
    }
}
```

Implement an HttpClient using a certificate and IHttpClientFactory

In the following example, a client certificate is added to a `HttpClientHandler` using the `ClientCertificates` property from the handler. This handler can then be used in a named instance of an `HttpClient` using the ConfigurePrimaryHttpMessageHandler method. This is setup in `Program.cs`:

C#

```
var clientCertificate =
    new X509Certificate2(
      Path.Combine(_environment.ContentRootPath, "sts_dev_cert.pfx"),
"1234");

builder.Services.AddHttpClient("namedClient", c =>
{
}).ConfigurePrimaryHttpMessageHandler(() =>
{
    var handler = new HttpClientHandler();
    handler.ClientCertificates.Add(clientCertificate);
    return handler;
});
```

The `IHttpClientFactory` can then be used to get the named instance with the handler and the certificate. The `CreateClient` method with the name of the client defined in `Program.cs` is used to get the instance. The HTTP request can be sent using the client as required:

C#

```
public class SampleHttpService
{
    private readonly IHttpClientFactory _httpClientFactory;
```

```
    public SampleHttpService(IHttpClientFactory httpClientFactory)
        => _httpClientFactory = httpClientFactory;

    public async Task<JsonDocument> GetAsync()
    {
        var httpClient = _httpClientFactory.CreateClient("namedClient");
        var httpResponseMessage = await
httpClient.GetAsync("https://example.com");

        if (httpResponseMessage.IsSuccessStatusCode)
        {
            return JsonDocument.Parse(
                await httpResponseMessage.Content.ReadAsStringAsync());
        }

        throw new ApplicationException($"Status code:
{httpResponseMessage.StatusCode}");
    }
}
```

If the correct certificate is sent to the server, the data is returned. If no certificate or the wrong certificate is sent, an HTTP 403 status code is returned.

Create certificates in PowerShell

Creating the certificates is the hardest part in setting up this flow. A root certificate can be created using the `New-SelfSignedCertificate` PowerShell cmdlet. When creating the certificate, use a strong password. It's important to add the `KeyUsageProperty` parameter and the `KeyUsage` parameter as shown.

Create root CA

PowerShell

```
New-SelfSignedCertificate -DnsName "root_ca_dev_damienbod.com",
"root_ca_dev_damienbod.com" -CertStoreLocation "cert:\LocalMachine\My" -
NotAfter (Get-Date).AddYears(20) -FriendlyName "root_ca_dev_damienbod.com" -
KeyUsageProperty All -KeyUsage CertSign, CRLSign, DigitalSignature

$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

Get-ChildItem -Path cert:\localMachine\my\"The thumbprint..." | Export-
PfxCertificate -FilePath C:\git\root_ca_dev_damienbod.pfx -Password $mypwd

Export-Certificate -Cert cert:\localMachine\my\"The thumbprint..." -FilePath
root_ca_dev_damienbod.crt
```

> **Note**
>
> The `-DnsName` parameter value must match the deployment target of the app. For example, "localhost" for development.

Install in the trusted root

The root certificate must be trusted on your host system. Only root certificates created by a certificate authority are trusted by default. For information on how to trust the root certificate on Windows, see the Windows documentation or the Import-Certificate PowerShell cmdlet.

Intermediate certificate

An intermediate certificate can now be created from the root certificate. This isn't required for all use cases, but you might need to create many certificates or need to activate or disable groups of certificates. The `TextExtension` parameter is required to set the path length in the basic constraints of the certificate.

The intermediate certificate can then be added to the trusted intermediate certificate in the Windows host system.

PowerShell

```
$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

$parentcert = ( Get-ChildItem -Path cert:\LocalMachine\My\"The thumbprint of
the root..." )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname
"intermediate_dev_damienbod.com" -Signer $parentcert -NotAfter (Get-
Date).AddYears(20) -FriendlyName "intermediate_dev_damienbod.com" -
KeyUsageProperty All -KeyUsage CertSign, CRLSign, DigitalSignature -
TextExtension @("2.5.29.19={text}CA=1&pathlength=1")

Get-ChildItem -Path cert:\localMachine\my\"The thumbprint..." | Export-
PfxCertificate -FilePath
C:\git\AspNetCoreCertificateAuth\Certs\intermediate_dev_damienbod.pfx -
Password $mypwd

Export-Certificate -Cert cert:\localMachine\my\"The thumbprint..." -FilePath
intermediate_dev_damienbod.crt
```

Create child certificate from intermediate certificate

A child certificate can be created from the intermediate certificate. This is the end entity and doesn't need to create more child certificates.

PowerShell

```
$parentcert = ( Get-ChildItem -Path cert:\LocalMachine\My\"The thumbprint
from the Intermediate certificate..." )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname
"child_a_dev_damienbod.com" -Signer $parentcert -NotAfter (Get-
Date).AddYears(20) -FriendlyName "child_a_dev_damienbod.com"

$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

Get-ChildItem -Path cert:\localMachine\my\"The thumbprint..." | Export-
PfxCertificate -FilePath
C:\git\AspNetCoreCertificateAuth\Certs\child_a_dev_damienbod.pfx -Password
$mypwd

Export-Certificate -Cert cert:\localMachine\my\"The thumbprint..." -FilePath
child_a_dev_damienbod.crt
```

Create child certificate from root certificate

A child certificate can also be created from the root certificate directly.

PowerShell

```
$rootcert = ( Get-ChildItem -Path cert:\LocalMachine\My\"The thumbprint from
the root cert..." )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname
"child_a_dev_damienbod.com" -Signer $rootcert -NotAfter (Get-
Date).AddYears(20) -FriendlyName "child_a_dev_damienbod.com"

$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

Get-ChildItem -Path cert:\localMachine\my\"The thumbprint..." | Export-
PfxCertificate -FilePath
C:\git\AspNetCoreCertificateAuth\Certs\child_a_dev_damienbod.pfx -Password
$mypwd

Export-Certificate -Cert cert:\localMachine\my\"The thumbprint..." -FilePath
child_a_dev_damienbod.crt
```

Example root - intermediate certificate - certificate

PowerShell

```
$mypwdroot = ConvertTo-SecureString -String "1234" -Force -AsPlainText
$mypwd = ConvertTo-SecureString -String "1234" -Force -AsPlainText

New-SelfSignedCertificate -DnsName "root_ca_dev_damienbod.com",
"root_ca_dev_damienbod.com" -CertStoreLocation "cert:\LocalMachine\My" -
NotAfter (Get-Date).AddYears(20) -FriendlyName "root_ca_dev_damienbod.com" -
KeyUsageProperty All -KeyUsage CertSign, CRLSign, DigitalSignature

Get-ChildItem -Path
cert:\localMachine\my\0C89639E4E2998A93E423F919B36D4009A0F9991 | Export-
PfxCertificate -FilePath C:\git\root_ca_dev_damienbod.pfx -Password
$mypwdroot

Export-Certificate -Cert
cert:\localMachine\my\0C89639E4E2998A93E423F919B36D4009A0F9991 -FilePath
root_ca_dev_damienbod.crt

$rootcert = ( Get-ChildItem -Path
cert:\LocalMachine\My\0C89639E4E2998A93E423F919B36D4009A0F9991 )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname
"child_a_dev_damienbod.com" -Signer $rootcert -NotAfter (Get-
Date).AddYears(20) -FriendlyName "child_a_dev_damienbod.com" -
KeyUsageProperty All -KeyUsage CertSign, CRLSign, DigitalSignature -
TextExtension @("2.5.29.19={text}CA=1&pathlength=1")

Get-ChildItem -Path
cert:\localMachine\my\BA9BF91ED35538A01375EFC212A2F46104B33A44 | Export-
PfxCertificate -FilePath
C:\git\AspNetCoreCertificateAuth\Certs\child_a_dev_damienbod.pfx -Password
$mypwd

Export-Certificate -Cert
cert:\localMachine\my\BA9BF91ED35538A01375EFC212A2F46104B33A44 -FilePath
child_a_dev_damienbod.crt

$parentcert = ( Get-ChildItem -Path
cert:\LocalMachine\My\BA9BF91ED35538A01375EFC212A2F46104B33A44 )

New-SelfSignedCertificate -certstorelocation cert:\localmachine\my -dnsname
"child_b_from_a_dev_damienbod.com" -Signer $parentcert -NotAfter (Get-
Date).AddYears(20) -FriendlyName "child_b_from_a_dev_damienbod.com"

Get-ChildItem -Path
cert:\localMachine\my\141594A0AE38CBBECED7AF680F7945CD51D8F28A | Export-
PfxCertificate -FilePath
C:\git\AspNetCoreCertificateAuth\Certs\child_b_from_a_dev_damienbod.pfx -
Password $mypwd

Export-Certificate -Cert
cert:\localMachine\my\141594A0AE38CBBECED7AF680F7945CD51D8F28A -FilePath
child_b_from_a_dev_damienbod.crt
```

When using the root, intermediate, or child certificates, the certificates can be validated using the Thumbprint or PublicKey as required:

C#

```
using System.Security.Cryptography.X509Certificates;

namespace CertAuthSample.Snippets;

public class SampleCertificateThumbprintsValidationService :
ICertificateValidationService
{
    private readonly string[] validThumbprints = new[]
    {
        "141594A0AE38CBBECED7AF680F7945CD51D8F28A",
        "0C89639E4E2998A93E423F919B36D4009A0F9991",
        "BA9BF91ED35538A01375EFC212A2F46104B33A44"
    };

    public bool ValidateCertificate(X509Certificate2 clientCertificate)
        => validThumbprints.Contains(clientCertificate.Thumbprint);
}
```

Certificate validation caching

ASP.NET Core 5.0 and later versions support the ability to enable caching of validation results. The caching dramatically improves performance of certificate authentication, as validation is an expensive operation.

By default, certificate authentication disables caching. To enable caching, call `AddCertificateCache` in `Program.cs`:

C#

```
builder.Services.AddAuthentication(
        CertificateAuthenticationDefaults.AuthenticationScheme)
    .AddCertificate()
    .AddCertificateCache(options =>
    {
        options.CacheSize = 1024;
        options.CacheEntryExpiration = TimeSpan.FromMinutes(2);
    });
```

The default caching implementation stores results in memory. You can provide your own cache by implementing `ICertificateValidationCache` and registering it with dependency injection. For example, `services.AddSingleton<ICertificateValidationCache, YourCache>()`.

Optional client certificates

This section provides information for apps that must protect a subset of the app with a certificate. For example, a Razor Page or controller in the app might require client certificates. This presents challenges as client certificates:

- Are a TLS feature, not an HTTP feature.
- Are negotiated per-connection and usually at the start of the connection before any HTTP data is available.

There are two approaches to implementing optional client certificates:

1. Using separate host names (SNI) and redirecting. While more work to configure, this is recommended because it works in most environments and protocols.
2. Renegotiation during an HTTP request. This has several limitations and is not recommended.

Separate Hosts (SNI)

At the start of the connection, only the Server Name Indication (SNI)† is known. Client certificates can be configured per host name so that one host requires them and another does not.

- Set up binding for the domain and subdomain:
  - For example, set up bindings on `contoso.com` and `myClient.contoso.com`. The `contoso.com` host doesn't require a client certificate but `myClient.contoso.com` does.
  - For more information, see:
    - Kestrel web server in ASP.NET Core:
      - ListenOptions.UseHttps
      - ClientCertificateMode
    - IIS
      - Hosting IIS
      - Configure security on IIS
    - HTTP.sys: Configure Windows Server

ASP.NET Core 5 and later adds more convenient support for redirecting to acquire optional client certificates. For more information, see the Optional certificates sample.

- For requests to the web app that require a client certificate and don't have one:
  - Redirect to the same page using the client certificate protected subdomain.

    - For example, redirect to `myClient.contoso.com/requestedPage`. Because the request to `myClient.contoso.com/requestedPage` is a different hostname than `contoso.com/requestedPage`, the client establishes a different connection and the client certificate is provided.
    - For more information, see Introduction to authorization in ASP.NET Core.

† Server Name Indication (SNI) is a TLS extension to include a virtual domain as a part of SSL negotiation. This effectively means the virtual domain name, or a hostname, can be used to identify the network end point.

Renegotiation

TLS renegotiation is a process by which the client and server can re-assess the encryption requirements for an individual connection, including requesting a client certificate if not previously provided. TLS renegotiation is a security risk and isn't recommended because:

- In HTTP/1.1 the server must first buffer or consume any HTTP data that is in flight such as POST request bodies to make sure the connection is clear for the renegotiation. Otherwise the renegotiation can stop responding or fail.
- HTTP/2 and HTTP/3 explicitly prohibit renegotiation.
- There are security risks associated with renegotiation. TLS 1.3 removed renegotiation of the whole connection and replaced it with a new extension for requesting only the client certificate after the start of the connection. This mechanism is exposed via the same APIs and is still subject to the prior constraints of buffering and HTTP protocol versions.

The implementation and configuration of this feature varies by server and framework version.

IIS

IIS manages the client certificate negotiation on your behalf. A subsection of the application can enable the `SslRequireCert` option to negotiate the client certificate for those requests. See Configuration in the IIS documentation for details.

IIS will automatically buffer any request body data up to a configured size limit before renegotiating. Requests that exceed the limit are rejected with a 413 response. This limit defaults to 48KB and is configurable by setting the uploadReadAheadSize.

HttpSys

HttpSys has two settings which control the client certificate negotiation and both should be set. The first is in netsh.exe under `http add sslcert clientcertnegotiation=enable/disable`. This flag indicates if the client certificate should be negotiated at the start of a connection and it should be set to `disable` for optional client certificates. See the netsh docs for details.

The other setting is ClientCertificateMethod. When set to `AllowRenegotation`, the client certificate can be renegotiated during a request.

NOTE The application should buffer or consume any request body data before attempting the renegotiation, otherwise the request may become unresponsive.

An application can first check the ClientCertificate property to see if the certificate is available. If it is not available, ensure the request body has been consumed before calling GetClientCertificateAsync to negotiate one. Note `GetClientCertificateAsync` can return a null certificate if the client declines to provide one.

NOTE The behavior of the `ClientCertificate` property changed in .NET 6. For more information, see this GitHub issue.

Kestrel

Kestrel controls client certificate negotiation with the ClientCertificateMode option.

ClientCertificateMode.DelayCertificate is new option available in .NET 6 or later. When set, an app can check the ClientCertificate property to see if the certificate is available. If it isn't available, ensure the request body has been consumed before calling GetClientCertificateAsync to negotiate one. Note `GetClientCertificateAsync` can return a null certificate if the client declines to provide one.

NOTE The application should buffer or consume any request body data before attempting the renegotiation, otherwise `GetClientCertificateAsync` may throw `InvalidOperationException: Client stream needs to be drained before renegotiation.`.

If you're programmatically configuring the TLS settings per SNI host name, call the UseHttps overload (.NET 6 or later) that takes TlsHandshakeCallbackOptions and controls client certificate renegotiation via TlsHandshakeCallbackContext.AllowDelayedClientCertificateNegotation.

Leave questions, comments, and other feedback on optional client certificates in this GitHub discussion issue.

Configure Windows Authentication in ASP.NET Core

Article • 09/12/2024

By Rick Anderson and Kirk Larkin

Windows Authentication (also known as Negotiate, Kerberos, or NTLM authentication) can be configured for ASP.NET Core apps hosted with IIS, Kestrel, or HTTP.sys.

Windows Authentication relies on the operating system to authenticate users of ASP.NET Core apps. Windows Authentication is used for servers that run on a corporate network using Active Directory domain identities or Windows accounts to identify users. Windows Authentication is best suited to intranet environments where users, client apps, and web servers belong to the same Windows domain.

> **Note**
>
> Windows Authentication isn't supported with HTTP/2. Authentication challenges can be sent on HTTP/2 responses, but the client must downgrade to HTTP/1.1 before authenticating.

Proxy and load balancer scenarios

Windows Authentication is a stateful scenario primarily used in an intranet, where a proxy or load balancer doesn't usually handle traffic between clients and servers. If a proxy or load balancer is used, Windows Authentication only works if the proxy or load balancer:

- Handles the authentication.
- Passes the user authentication information to the app (for example, in a request header), which acts on the authentication information.

An alternative to Windows Authentication in environments where proxies and load balancers are used is Active Directory Federated Services (ADFS) with OpenID Connect (OIDC).

IIS/IIS Express

Add the NuGet package Microsoft.AspNetCore.Authentication.Negotiate and authentication services by calling AddAuthentication in `Program.cs`:

C#

```
using Microsoft.AspNetCore.Authentication.Negotiate;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication(NegotiateDefaults.AuthenticationScheme)
    .AddNegotiate();

builder.Services.AddAuthorization(options =>
{
    options.FallbackPolicy = options.DefaultPolicy;
});
builder.Services.AddRazorPages();

var app = builder.Build();
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The preceding code was generated by the ASP.NET Core Razor Pages template with **Windows Authentication** specified.

Launch settings (debugger)

Configuration for launch settings only affects the `Properties/launchSettings.json` file for IIS Express and doesn't configure IIS for Windows Authentication. Server configuration is explained in the IIS section.

The **Web Application** templates available via Visual Studio or the .NET CLI can be configured to support Windows Authentication, which updates the `Properties/launchSettings.json` file automatically.

Visual Studio

New project

Create a new Razor Pages or MVC app. In the **Additional information** dialog, set the **Authentication type** to **Windows**.

Run the app. The username appears in the rendered app's user interface.

Existing project

The project's properties enable Windows Authentication and disable Anonymous Authentication. Open the launch profiles dialog:

1. In Solution Explorer, right click the project and select **Properties**.
2. Select the **Debug** > **General** tab and select **Open debug launch profiles UI**.
3. Clear the checkbox for **Enable Anonymous Authentication**.
4. Select the checkbox for **Enable Windows Authentication**.

Alternatively, the properties can be configured in the `iisSettings` node of the `launchSettings.json` file:

JSON

```
"iisSettings": {
    "windowsAuthentication": true,
    "anonymousAuthentication": false,
    "iisExpress": {
        "applicationUrl": "http://localhost:52171/",
        "sslPort": 44308
    }
}
```

IIS

IIS uses the ASP.NET Core Module to host ASP.NET Core apps. Windows Authentication is configured for IIS via the *web.config* file. The following sections show how to:

- Provide a local *web.config* file that activates Windows Authentication on the server when the app is deployed.
- Use the IIS Manager to configure the *web.config* file of an ASP.NET Core app that has already been deployed to the server.

If you haven't already done so, enable IIS to host ASP.NET Core apps. For more information, see Host ASP.NET Core on Windows with IIS.

Enable the IIS Role Service for Windows Authentication. For more information, see Enable Windows Authentication in IIS Role Services (see Step 2).

IIS Integration Middleware is configured to automatically authenticate requests by default. For more information, see Host ASP.NET Core on Windows with IIS: IIS options (AutomaticAuthentication).

The ASP.NET Core Module is configured to forward the Windows Authentication token to the app by default. For more information, see ASP.NET Core Module configuration reference: Attributes of the aspNetCore element.

Use **either** of the following approaches:

- **Before publishing and deploying the project,** add the following *web.config* file to the project root:

  XML

  ```
  <?xml version="1.0" encoding="utf-8"?>
  <configuration>
    <location path="." inheritInChildApplications="false">
      <system.webServer>
        <security>
          <authentication>
            <anonymousAuthentication enabled="false" />
            <windowsAuthentication enabled="true" />
          </authentication>
        </security>
      </system.webServer>
    </location>
  </configuration>
  ```

  When the project is published by the .NET Core SDK (without the `<IsTransformWebConfigDisabled>` property set to `true` in the project file), the published *web.config* file includes the `<location><system.webServer><security><authentication>` section. For more information on the `<IsTransformWebConfigDisabled>` property, see Host ASP.NET Core on Windows with IIS.

- **After publishing and deploying the project,** perform server-side configuration with the IIS Manager:

1. In IIS Manager, select the IIS site under the **Sites** node of the **Connections** sidebar.
2. Double-click **Authentication** in the **IIS** area.
3. Select **Anonymous Authentication**. Select **Disable** in the **Actions** sidebar.
4. Select **Windows Authentication**. Select **Enable** in the **Actions** sidebar.

When these actions are taken, IIS Manager modifies the app's *web.config* file. A `<system.webServer><security><authentication>` node is added with updated settings for `anonymousAuthentication` and `windowsAuthentication`:

XML

```
<system.webServer>
  <security>
    <authentication>
      <anonymousAuthentication enabled="false" />
      <windowsAuthentication enabled="true" />
    </authentication>
  </security>
</system.webServer>
```

The `<system.webServer>` section added to the *web.config* file by IIS Manager is outside of the app's `<location>` section added by the .NET Core SDK when the app is published. Because the section is added outside of the `<location>` node, the settings are inherited by any sub-apps to the current app. To prevent inheritance, move the added `<security>` section inside of the `<location><system.webServer>` section that the .NET Core SDK provided.

When IIS Manager is used to add the IIS configuration, it only affects the app's *web.config* file on the server. A subsequent deployment of the app may overwrite the settings on the server if the server's copy of *web.config* is replaced by the project's *web.config* file. Use **either** of the following approaches to manage the settings:

- Use IIS Manager to reset the settings in the *web.config* file after the file is overwritten on deployment.
- Add a *web.config file* to the app locally with the settings.

Kestrel

The Microsoft.AspNetCore.Authentication.Negotiate NuGet package can be used with Kestrel to support Windows Authentication using Negotiate and Kerberos on Windows, Linux, and macOS.

> **⚠ Warning**
>
> Credentials can be persisted across requests on a connection. *Negotiate authentication must not be used with proxies unless the proxy maintains a 1:1 connection affinity (a persistent connection) with Kestrel.*

> **ⓘ Note**
>
> The Negotiate handler detects if the underlying server supports Windows Authentication natively and if it is enabled. If the server supports Windows Authentication but it is disabled, an error is thrown asking you to enable the server implementation. When Windows Authentication is enabled in the server, the Negotiate handler transparently forwards authentication requests to it.

Authentication is enabled by the following highlighted code to `Program.cs`:

C#

```
using Microsoft.AspNetCore.Authentication.Negotiate;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication(NegotiateDefaults.AuthenticationScheme)
   .AddNegotiate();

builder.Services.AddAuthorization(options =>
{
    options.FallbackPolicy = options.DefaultPolicy;
});
builder.Services.AddRazorPages();

var app = builder.Build();
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();
app.MapRazorPages();
```

```
app.Run();
```

The preceding code was generated by the ASP.NET Core Razor Pages template with **Windows Authentication** specified. The following APIs are used in the preceding code:

- AddAuthentication
- AddNegotiate
- UseAuthentication

Kerberos authentication and role-based access control (RBAC)

Kerberos authentication on Linux or macOS doesn't provide any role information for an authenticated user. To add role and group information to a Kerberos user, the authentication handler must be configured to retrieve the roles from an LDAP domain. The most basic configuration only specifies an LDAP domain to query against and uses the authenticated user's context to query the LDAP domain:

C#

```
using Microsoft.AspNetCore.Authentication.Negotiate;
using System.Runtime.InteropServices;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication(NegotiateDefaults.AuthenticationScheme)
    .AddNegotiate(options =>
    {
        if (RuntimeInformation.IsOSPlatform(OSPlatform.Linux))
        {
            options.EnableLdap("contoso.com");
        }
    });
```

Some configurations may require specific credentials to query the LDAP domain. The credentials can be specified in the following highlighted options:

C#

```
using Microsoft.AspNetCore.Authentication.Negotiate;
using System.Runtime.InteropServices;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication(NegotiateDefaults.AuthenticationScheme)
        .AddNegotiate(options =>
```

```
        {
            if (RuntimeInformation.IsOSPlatform(OSPlatform.Linux))
            {
                options.EnableLdap(settings =>
                {
                    settings.Domain = "contoso.com";
                    settings.MachineAccountName = "machineName";
                    settings.MachineAccountPassword =
                                    builder.Configuration["Password"];
                });
            }
        });

builder.Services.AddRazorPages();
```

By default, the negotiate authentication handler resolves nested domains. In a large or complicated LDAP environment, resolving nested domains may result in a slow lookup or a lot of memory being used for each user. Nested domain resolution can be disabled using the `IgnoreNestedGroups` option.

Anonymous requests are allowed. Use ASP.NET Core Authorization to challenge anonymous requests for authentication.

Windows environment configuration

The Microsoft.AspNetCore.Authentication.Negotiate component performs User Mode authentication. Service Principal Names (SPNs) must be added to the user account running the service, not the machine account. Execute `setspn -S HTTP/myservername.mydomain.com myuser` in an administrative command shell.

Kerberos vs NTLM

The Negotiate package on Kestrel for ASP.NET Core attempts to use Kerberos, which is a more secure and peformant authentication scheme than NTLM:

C#

```
using Microsoft.AspNetCore.Authentication.Negotiate;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication(NegotiateDefaults.AuthenticationScheme)
   .AddNegotiate();

builder.Services.AddAuthorization(options =>
{
    options.FallbackPolicy = options.DefaultPolicy;
```

```
});
builder.Services.AddRazorPages();

var app = builder.Build();
```

NegotiateDefaults.AuthenticationScheme specifies Kerberos because it's the default.

IIS, IISExpress, and Kestrel support both Kerberos and NTLM.

Examining the WWW-Authenticate: header using IIS or IISExpress with a tool like Fiddler shows either `Negotiate` or NTLM.

Kestrel only shows `WWW-Authenticate: Negotiate`

The `WWW-Authenticate: Negotiate` header means that the server can use NTLM or Kerberos. Kestrel requires the Negotiate header prefix, it doesn't support directly specifying `NTLM` in the request or response auth headers. NTLM is supported in Kestrel, but it must be sent as `Negotiate`.

On Kestrel, to see if NTLM or Kerberos is used, Base64 decode the header and it shows either `NTLM` or `HTTP`. `HTTP` indicates Kerberos was used.

Linux and macOS environment configuration

Instructions for joining a Linux or macOS machine to a Windows domain are available in the Connect Azure Data Studio to your SQL Server using Windows authentication - Kerberos article. The instructions create a machine account for the Linux machine on the domain. SPNs must be added to that machine account.

> **Note**
>
> When following the guidance in the Connect Azure Data Studio to your SQL Server using Windows authentication - Kerberos article, replace `python-software-properties` with `python3-software-properties` if needed.

Once the Linux or macOS machine is joined to the domain, additional steps are required to provide a keytab file with the SPNs:

- On the domain controller, add new web service SPNs to the machine account:
  - `setspn -S HTTP/mywebservice.mydomain.com mymachine`
  - `setspn -S HTTP/mywebservice@MYDOMAIN.COM mymachine`
- Use ktpass to generate a keytab file:

    - `ktpass -princ HTTP/mywebservice.mydomain.com@MYDOMAIN.COM -pass myKeyTabFilePassword -mapuser MYDOMAIN\mymachine$ -pType KRB5_NT_PRINCIPAL -out c:\temp\mymachine.HTTP.keytab -crypto AES256-SHA1`
    - Some fields must be specified in uppercase as indicated.
- Copy the keytab file to the Linux or macOS machine.
- Select the keytab file via an environment variable: `export KRB5_KTNAME=/tmp/mymachine.HTTP.keytab`
- Invoke `klist` to show the SPNs currently available for use.

> ⓘ Note
>
> A keytab file contains domain access credentials and must be protected accordingly.

HTTP.sys

HTTP.sys supports Kernel Mode Windows Authentication using Negotiate, NTLM, or Basic authentication.

The following code adds authentication and configures the app's web host to use HTTP.sys with Windows Authentication:

C#

```
using Microsoft.AspNetCore.Server.HttpSys;
using System.Runtime.InteropServices;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication(HttpSysDefaults.AuthenticationScheme);

if (RuntimeInformation.IsOSPlatform(OSPlatform.Windows))
{
    builder.WebHost.UseHttpSys(options =>
        {
            options.Authentication.Schemes =
                AuthenticationSchemes.NTLM |
                AuthenticationSchemes.Negotiate;
            options.Authentication.AllowAnonymous = false;
        });
}
```

> ⓘ Note

HTTP.sys delegates to Kernel Mode authentication with the Kerberos authentication protocol. User Mode authentication isn't supported with Kerberos and HTTP.sys. The machine account must be used to decrypt the Kerberos token/ticket that's obtained from Active Directory and forwarded by the client to the server to authenticate the user. Register the Service Principal Name (SPN) for the host, not the user of the app.

> **Note**
>
> HTTP.sys isn't supported on Nano Server version 1709 or later. To use Windows Authentication and HTTP.sys with Nano Server, use a Server Core (microsoft/windowsservercore) container (see `https://hub.docker.com/_/microsoft-windows-servercore`). For more information on Server Core, see What is the Server Core installation option in Windows Server?.

Authorize users

The configuration state of anonymous access determines the way in which the [Authorize] and [AllowAnonymous] attributes are used in the app. The following two sections explain how to handle the disallowed and allowed configuration states of anonymous access.

Disallow anonymous access

When Windows Authentication is enabled and anonymous access is disabled, the [Authorize] and [AllowAnonymous] attributes have no effect. If an IIS site is configured to disallow anonymous access, the request never reaches the app. For this reason, the [AllowAnonymous] attribute isn't applicable.

Allow anonymous access

When both Windows Authentication and anonymous access are enabled, use the [Authorize] and [AllowAnonymous] attributes. The [Authorize] attribute allows you to secure endpoints of the app which require authentication. The [AllowAnonymous] attribute overrides the [Authorize] attribute in apps that allow anonymous access. For attribute usage details, see Simple authorization in ASP.NET Core.

> **Note**

By default, users who lack authorization to access a page are presented with an empty HTTP 403 response. The StatusCodePages Middleware can be configured to provide users with a better "Access Denied" experience.

Impersonation

ASP.NET Core doesn't implement impersonation. Apps run with the app's identity for all requests, using app pool or process identity. If the app should perform an action on behalf of a user, use WindowsIdentity.RunImpersonated or RunImpersonatedAsync in a terminal inline middleware in `Program.cs`. Run a single action in this context and then close the context.

C#

```
app.Run(async (context) =>
{
    try
    {
        var user = (WindowsIdentity)context.User.Identity!;

        await context.Response
            .WriteAsync($"User: {user.Name}\tState:
{user.ImpersonationLevel}\n");

        await WindowsIdentity.RunImpersonatedAsync(user.AccessToken, async
() =>
        {
            var impersonatedUser = WindowsIdentity.GetCurrent();
            var message =
                $"User: {impersonatedUser.Name}\t" +
                $"State: {impersonatedUser.ImpersonationLevel}";

            var bytes = Encoding.UTF8.GetBytes(message);
            await context.Response.Body.WriteAsync(bytes, 0, bytes.Length);
        });
    }
    catch (Exception e)
    {
        await context.Response.WriteAsync(e.ToString());
    }
});
```

While the Microsoft.AspNetCore.Authentication.Negotiate package enables authentication on Windows, Linux, and macOS, impersonation is only supported on Windows.

Claims transformations

When hosting with IIS, AuthenticateAsync isn't called internally to initialize a user. Therefore, an IClaimsTransformation implementation used to transform claims after every authentication isn't activated by default. For more information and a code example that activates claims transformations, see Differences between in-process and out-of-process hosting.

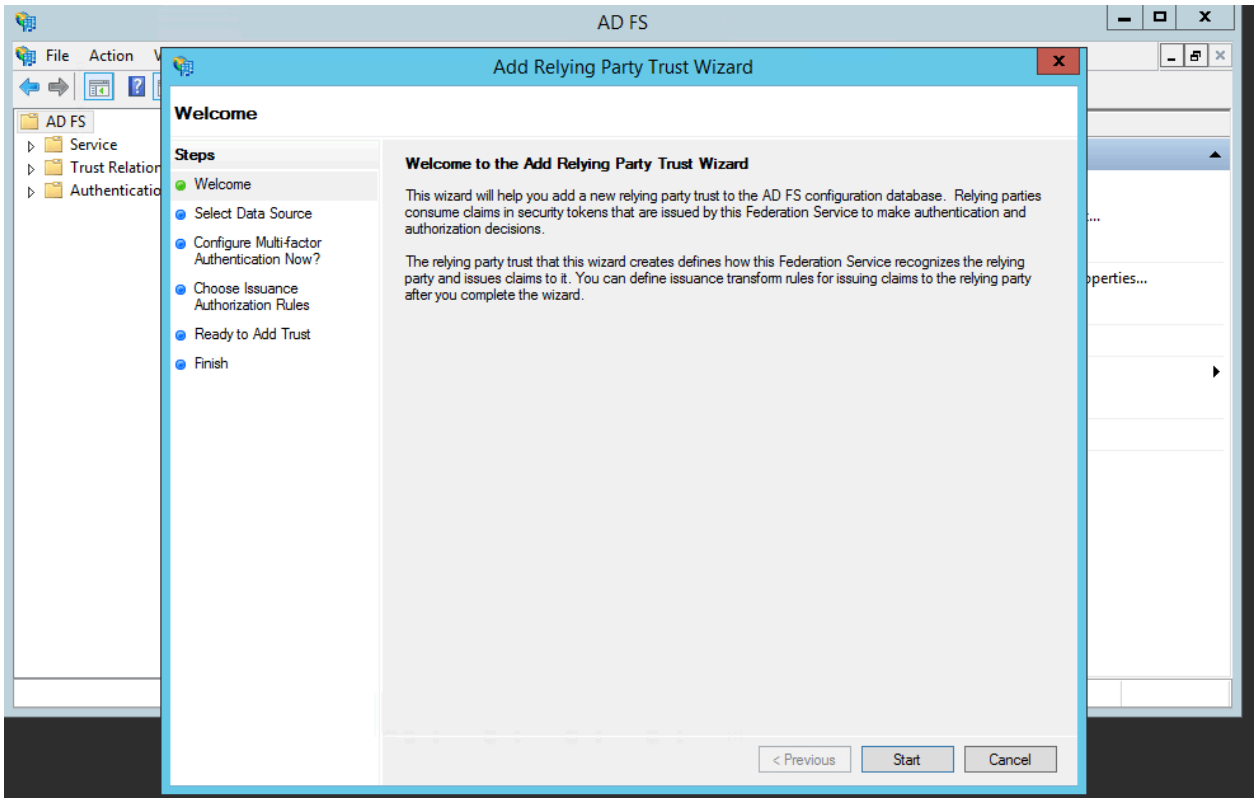
Authenticate users with WS-Federation in ASP.NET Core

Article • 06/18/2024

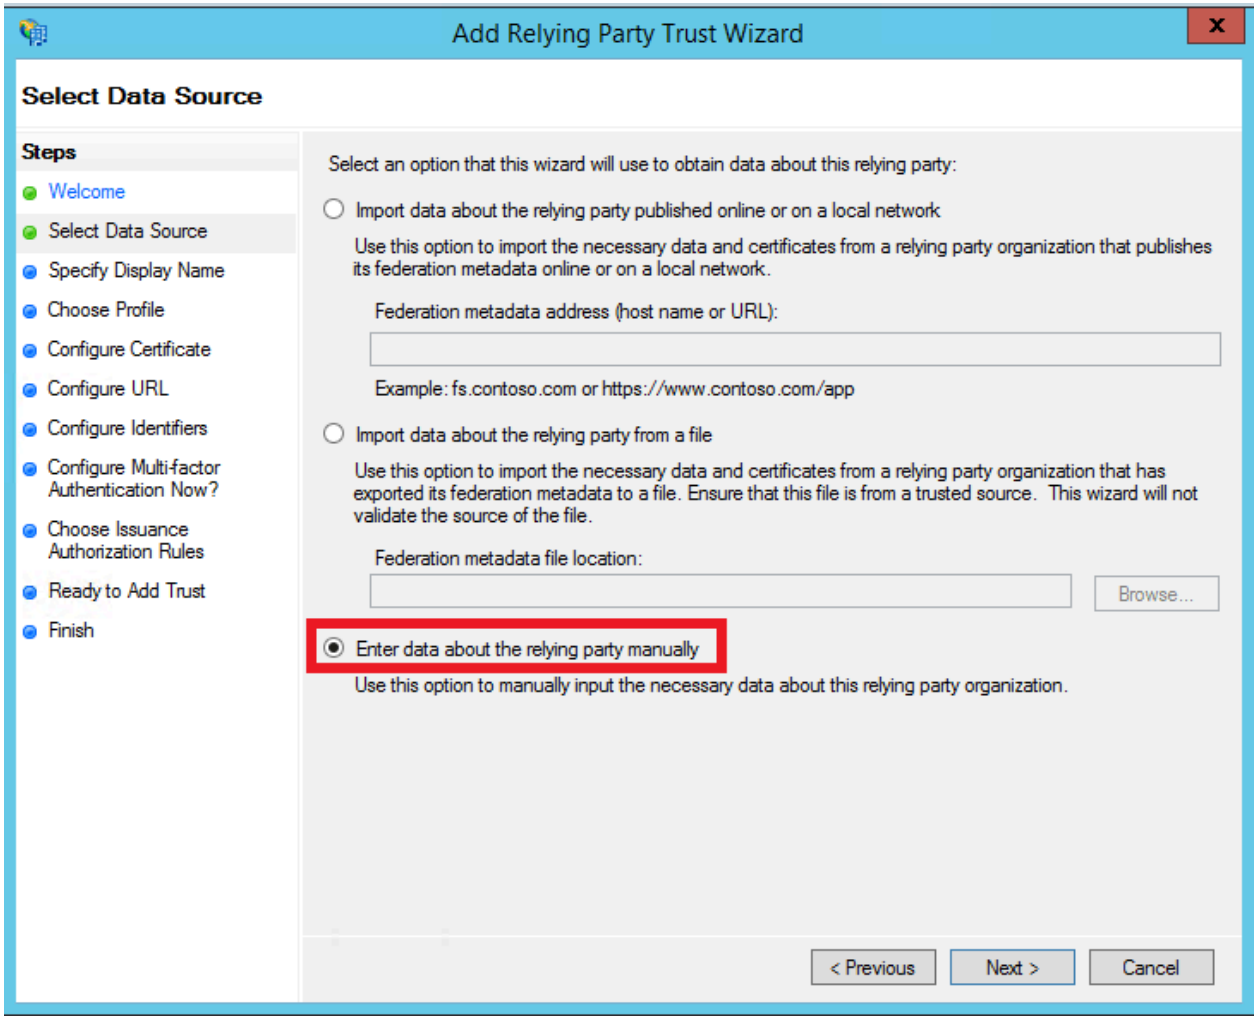
This tutorial demonstrates how to enable users to sign in with a WS-Federation authentication provider like Active Directory Federation Services (ADFS) or Microsoft Entra ID. It uses the ASP.NET Core sample app described in Facebook, Google, and external provider authentication.

For ASP.NET Core apps, WS-Federation support is provided by Microsoft.AspNetCore.Authentication.WsFederation. This component is ported from Microsoft.Owin.Security.WsFederation and shares many of that component's mechanics. However, the components differ in a couple of important ways.



By default, the new middleware:

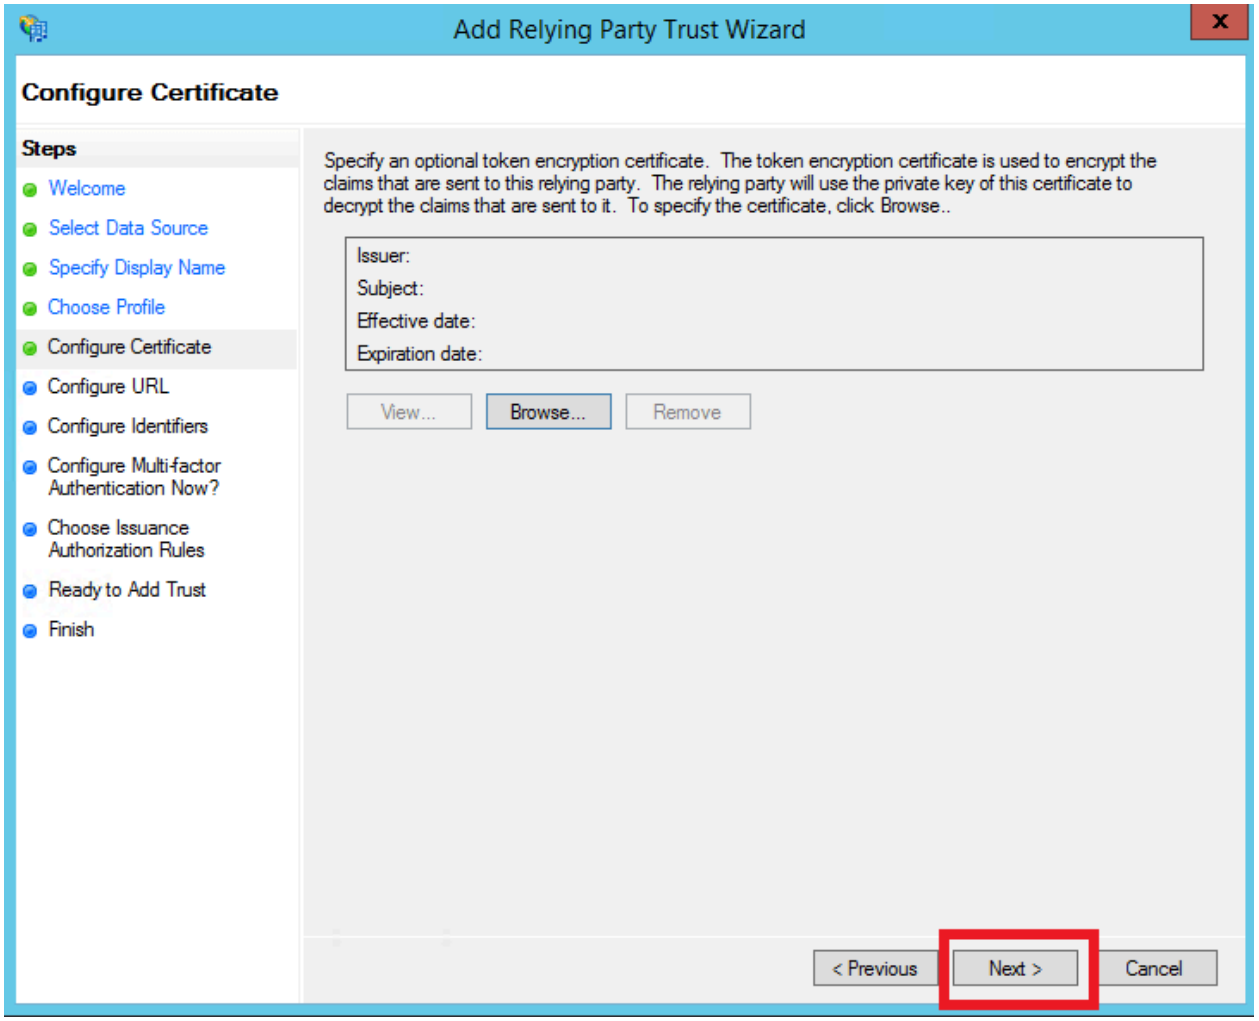
- Doesn't allow unsolicited logins. This feature of the WS-Federation protocol is vulnerable to XSRF attacks. However, it can be enabled with the `AllowUnsolicitedLogins` option.
- Doesn't check every form post for sign-in messages. Only requests to the `CallbackPath` are checked for sign-ins. `CallbackPath` defaults to `/signin-wsfed` but can be changed via the inherited RemoteAuthenticationOptions.CallbackPath property of the WsFederationOptions class. This path can be shared with other authentication providers by enabling the SkipUnrecognizedRequests option.



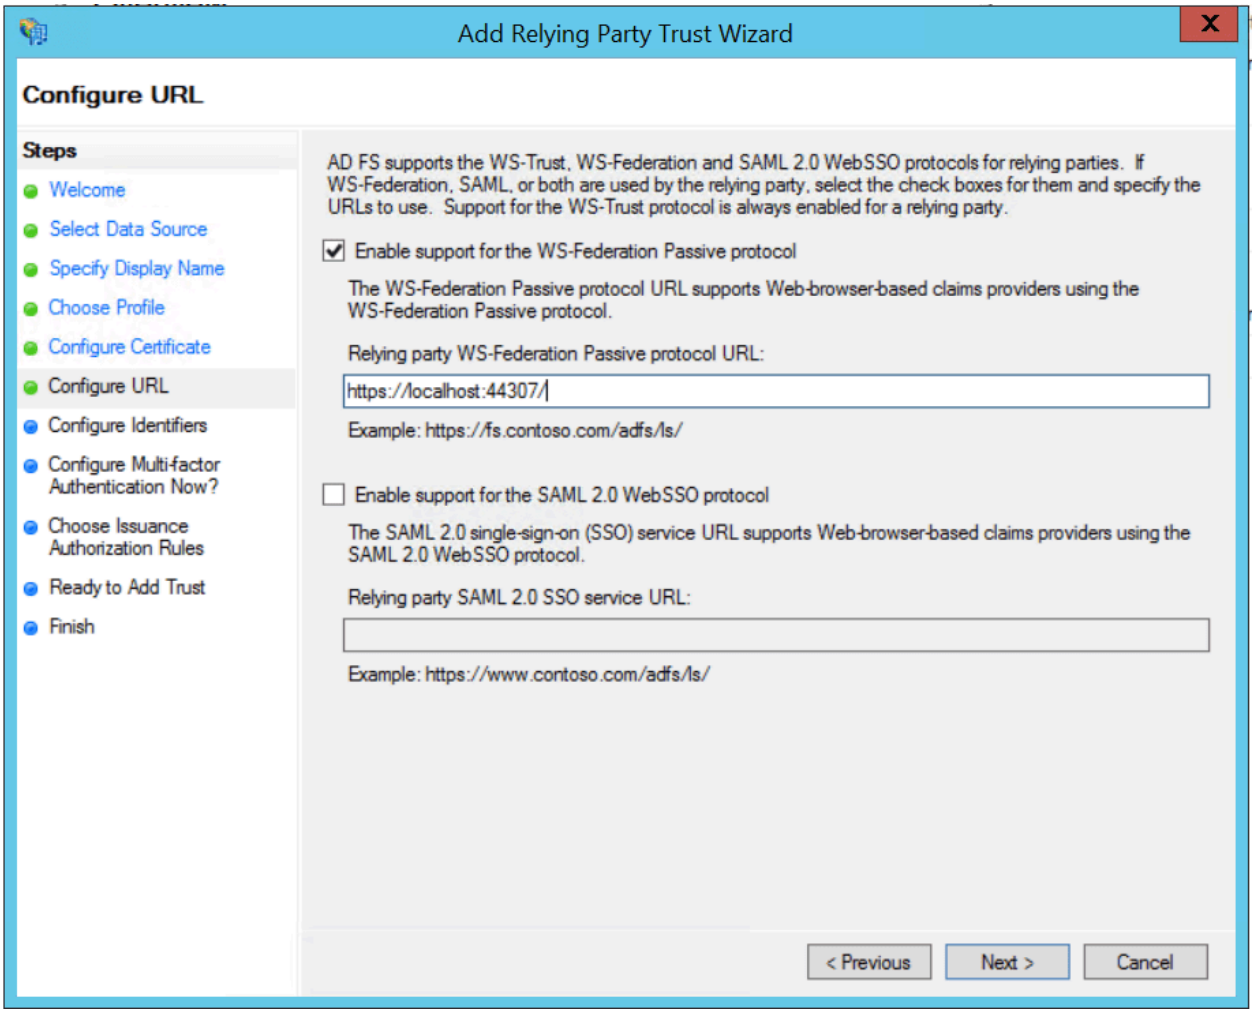
Register the app with Active Directory

Active Directory Federation Services

- Open the server's **Add Relying Party Trust Wizard** from the ADFS Management console:

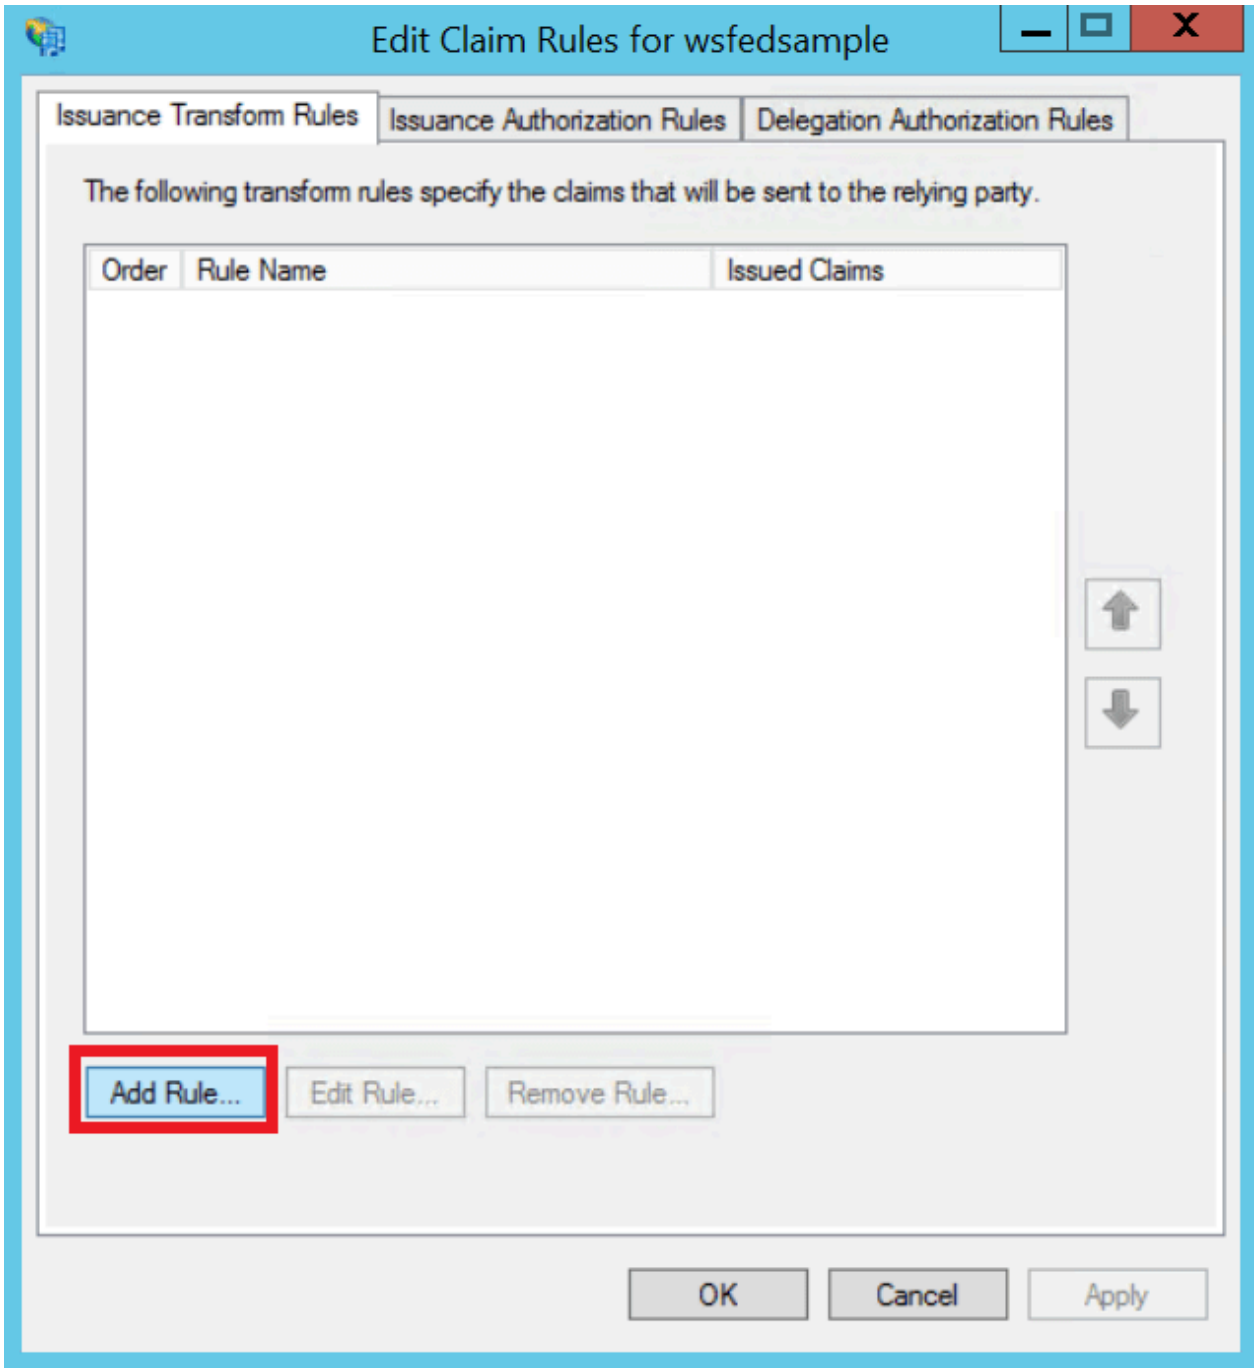


- Choose to enter data manually:

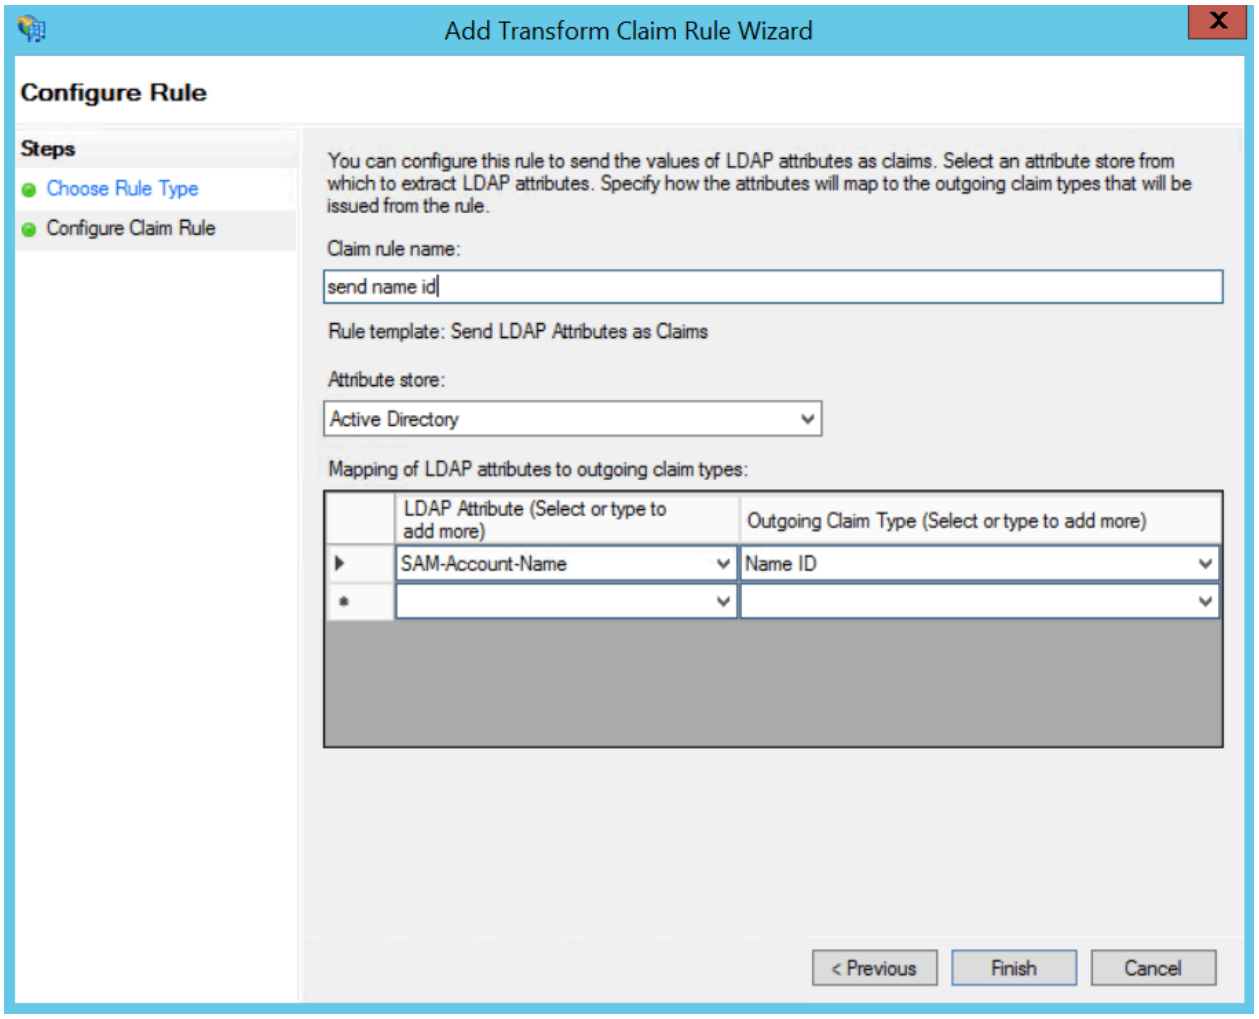


- Enter a display name for the relying party. The name isn't important to the ASP.NET Core app.

- Microsoft.AspNetCore.Authentication.WsFederation lacks support for token encryption, so don't configure a token encryption certificate:

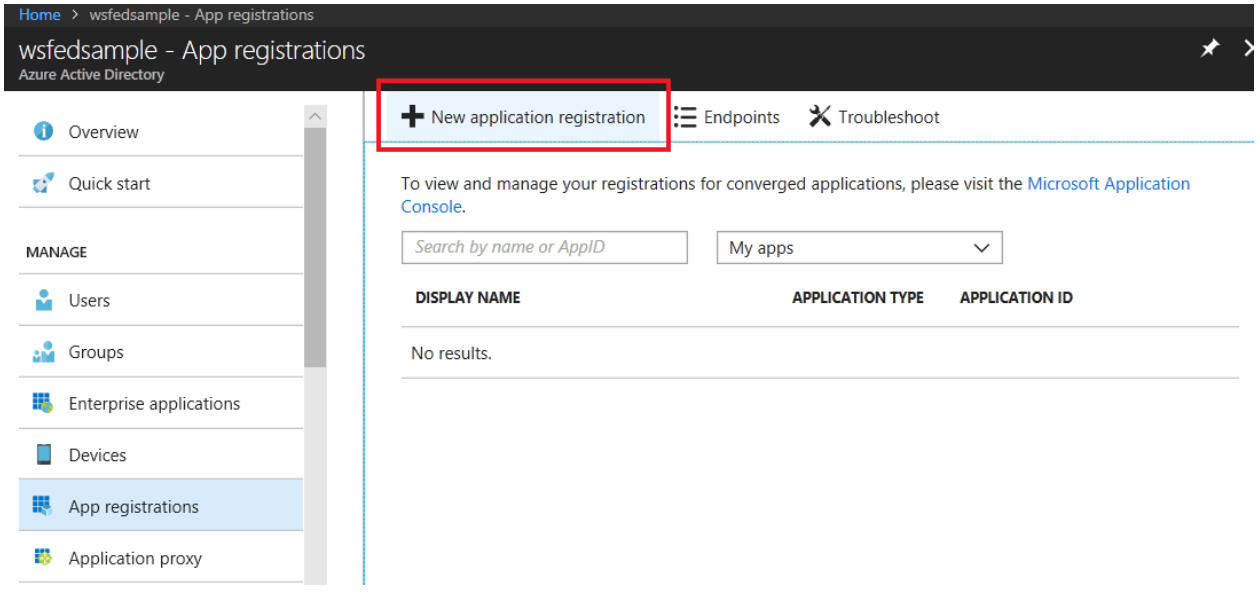


- Enable support for WS-Federation Passive protocol, using the app's URL. Verify the port is correct for the app:

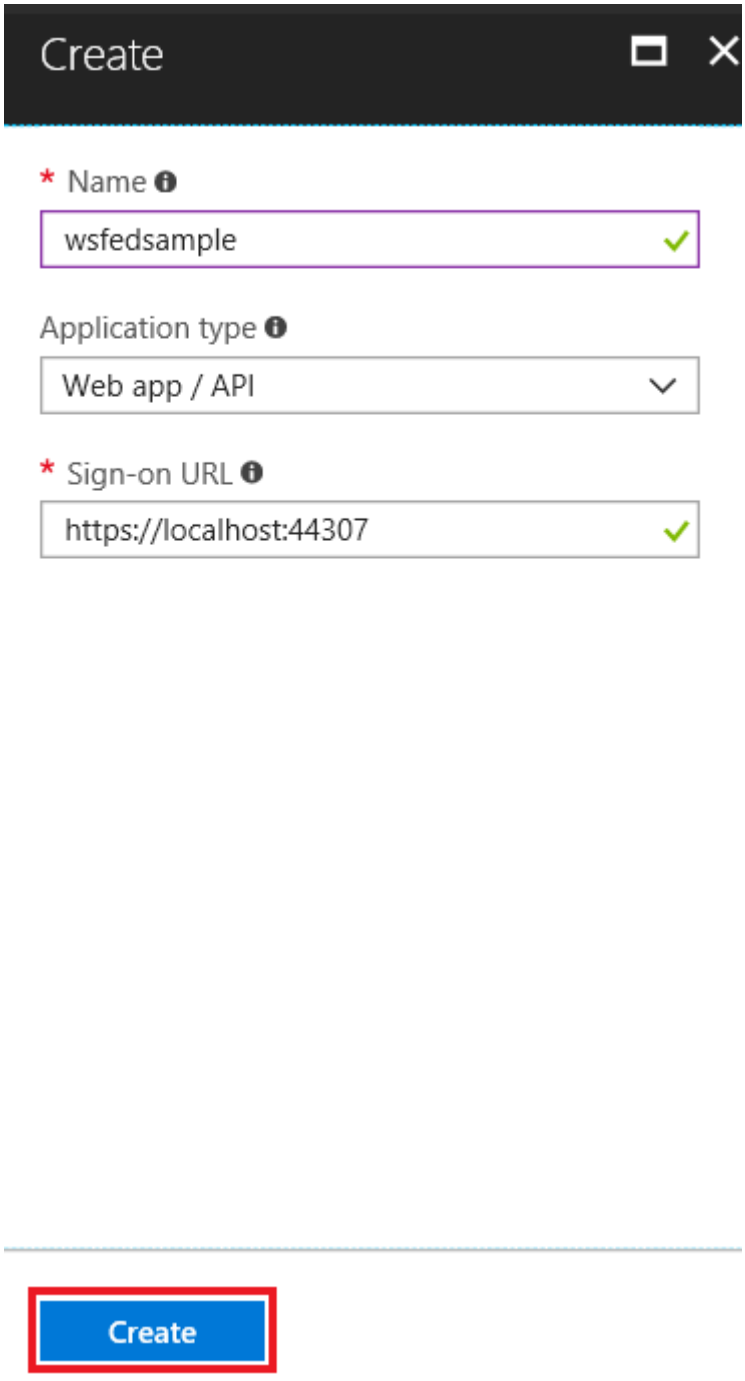


> ⓘ **Note**
>
> This must be an HTTPS URL. IIS Express can provide a self-signed certificate when hosting the app during development. Kestrel requires manual certificate configuration. See the Kestrel documentation for more details.

- Click **Next** through the rest of the wizard and **Close** at the end.
- ASP.NET Core Identity requires a **Name ID** claim. Add one from the **Edit Claim Rules** dialog:

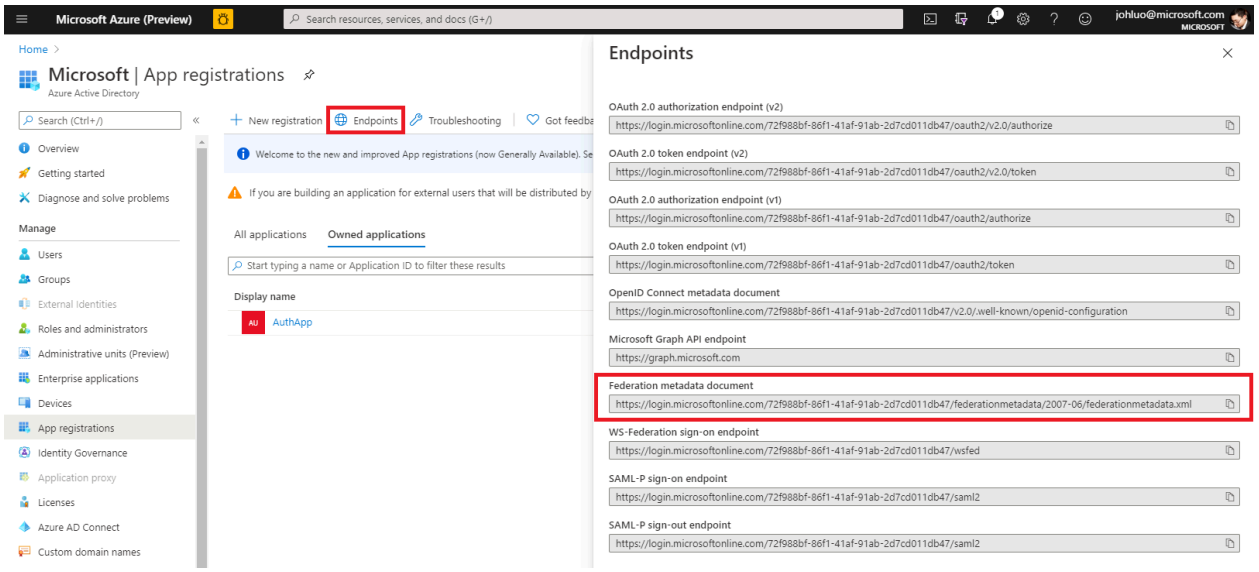


- In the **Add Transform Claim Rule Wizard**, leave the default **Send LDAP Attributes as Claims** template selected, and click **Next**. Add a rule mapping the **SAM-Account-Name** LDAP attribute to the **Name ID** outgoing claim:

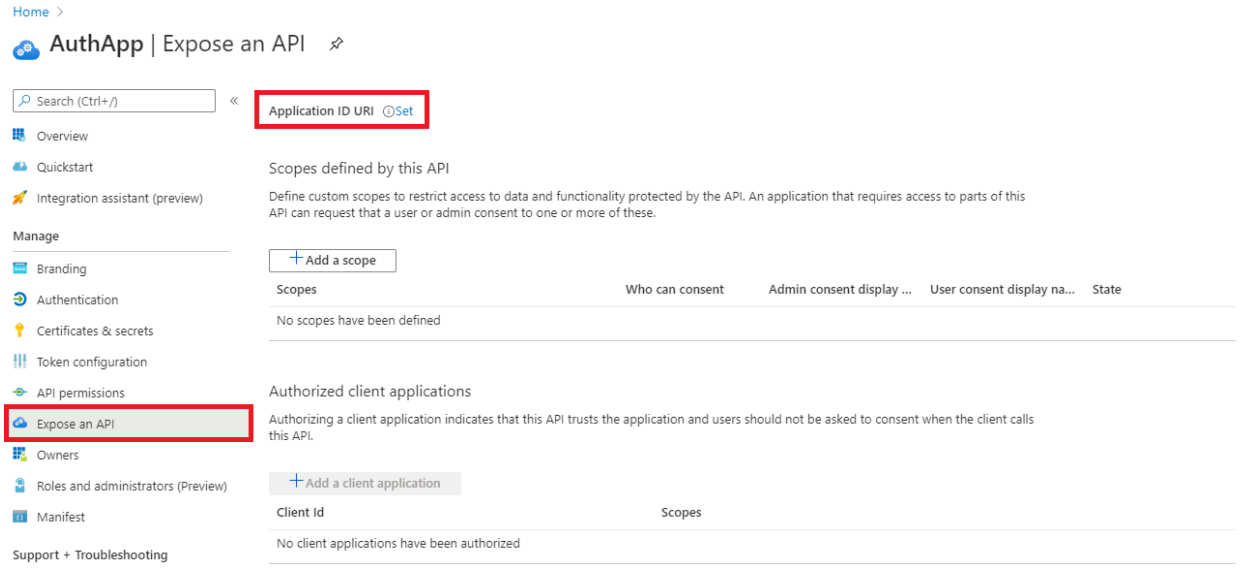


- Click **Finish** > **OK** in the **Edit Claim Rules** window.

Microsoft Entra ID



- Navigate to the Microsoft Entra ID tenant's app registrations blade. Click **New application registration**:



- Enter a name for the app registration. This isn't important to the ASP.NET Core app.
- Enter the URL the app listens on as the **Sign-on URL**:

- Click **Endpoints** and note the **Federation Metadata Document** URL. This is the WS-Federation middleware's `MetadataAddress`:

- Navigate to the new app registration. Click **Expose an API**. Click Application ID URI **Set** > **Save**. Make note of the **Application ID URI**. This is the WS-Federation middleware's `Wtrealm`:

Use WS-Federation without ASP.NET Core Identity

The WS-Federation middleware can be used without Identity. For example:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(sharedOptions =>
    {
        sharedOptions.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
        sharedOptions.DefaultChallengeScheme =
```

```
WsFederationDefaults.AuthenticationScheme;
    })
     .AddWsFederation(options =>
     {
         options.Wtrealm = Configuration["wsfed:realm"];
         options.MetadataAddress = Configuration["wsfed:metadata"];
     })
     .AddCookie();

    services.AddControllersWithViews();
    services.AddRazorPages();
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }
    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllerRoute(
            name: "default",
            pattern: "{controller=Home}/{action=Index}/{id?}");
        endpoints.MapRazorPages();
    });
}
```

Add WS-Federation as an external login provider for ASP.NET Core Identity

- Add a dependency on Microsoft.AspNetCore.Authentication.WsFederation to the project.
- Add WS-Federation to `Startup.ConfigureServices`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();

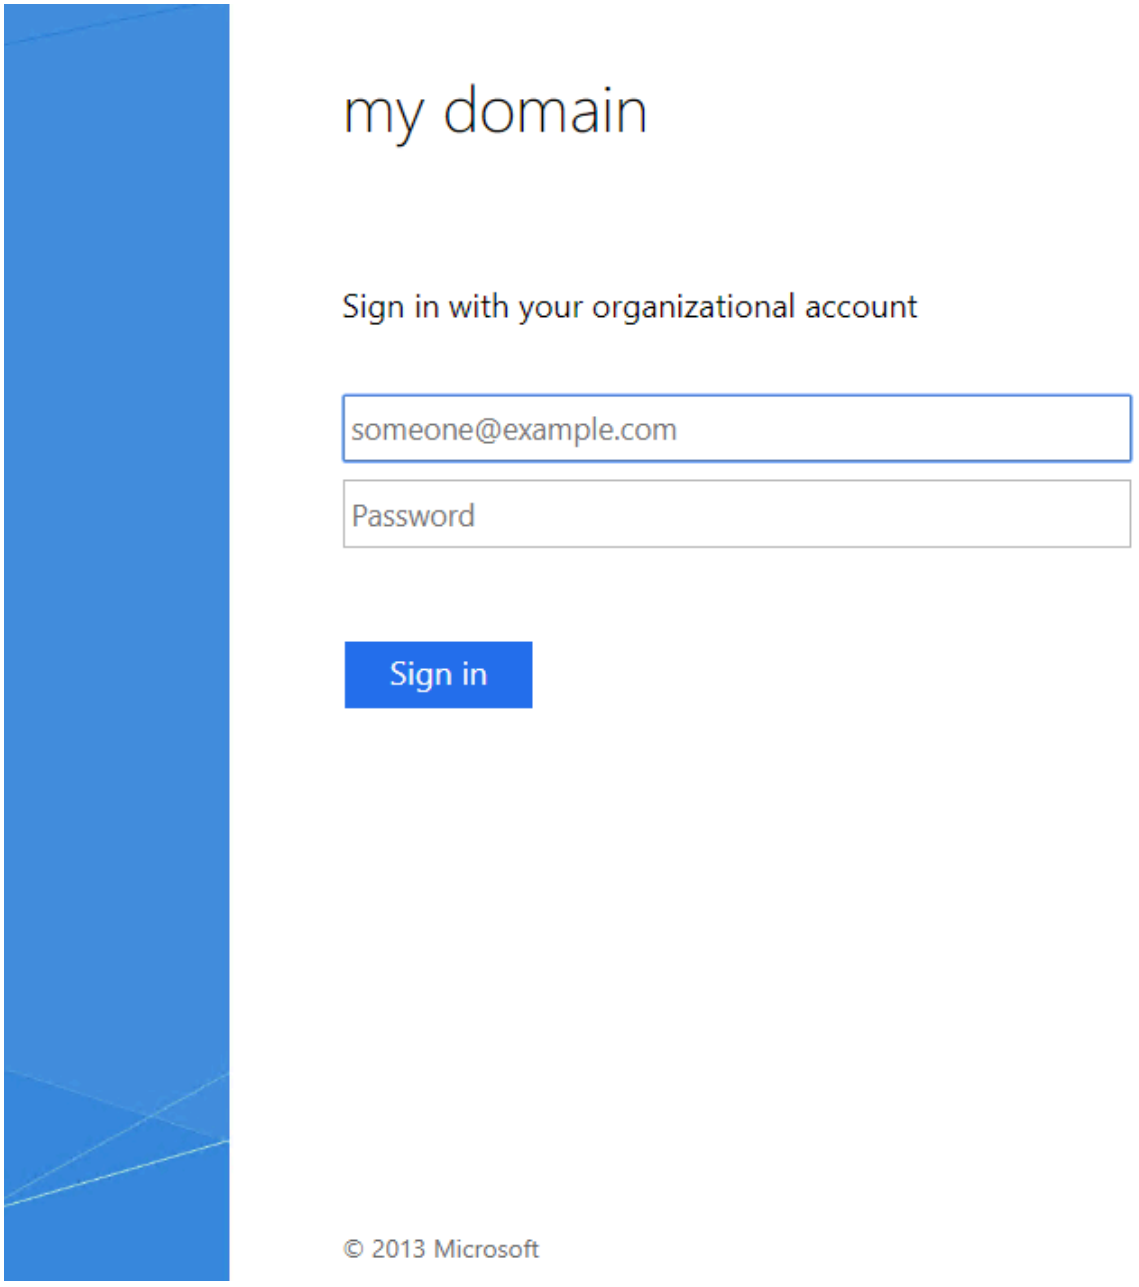
    services.AddAuthentication()
        .AddWsFederation(options =>
        {
            // MetadataAddress represents the Active Directory instance used
to authenticate users.
            options.MetadataAddress = "https://<ADFS FQDN or AAD
tenant>/FederationMetadata/2007-06/FederationMetadata.xml";

            // Wtrealm is the app's identifier in the Active Directory
instance.
            // For ADFS, use the relying party's identifier, its WS-
Federation Passive protocol URL:
            options.Wtrealm = "https://localhost:44307/";

            // For AAD, use the Application ID URI from the app
registration's Overview blade:
            options.Wtrealm = "api://bbd35166-7c13-49f3-8041-9551f2847b69";
        });

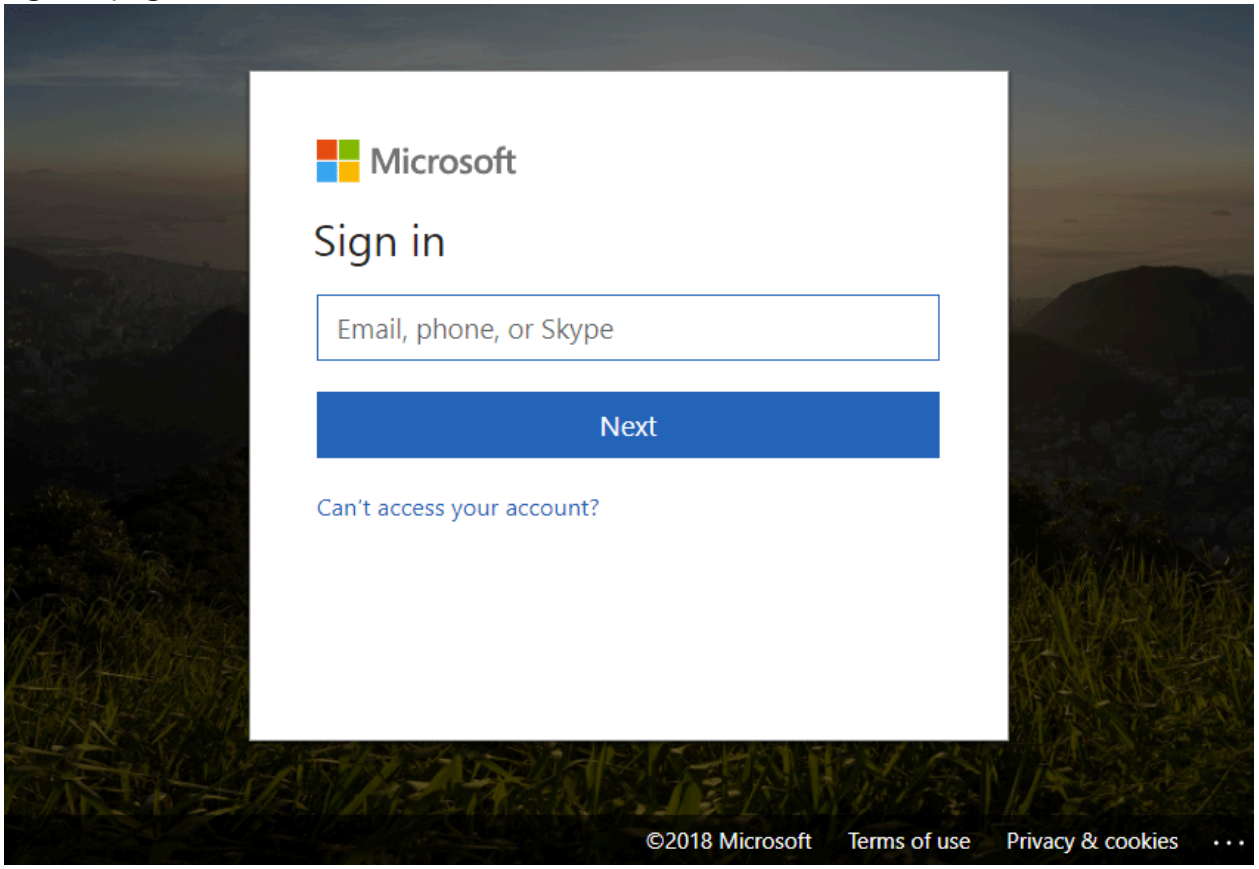
    services.AddControllersWithViews();
    services.AddRazorPages();
}
```

The AddAuthentication(IServiceCollection, String) overload sets the DefaultScheme property. The AddAuthentication(IServiceCollection, Action<AuthenticationOptions>) overload allows configuring authentication options, which can be used to set up default authentication schemes for different purposes. Subsequent calls to `AddAuthentication` override previously configured AuthenticationOptions properties.

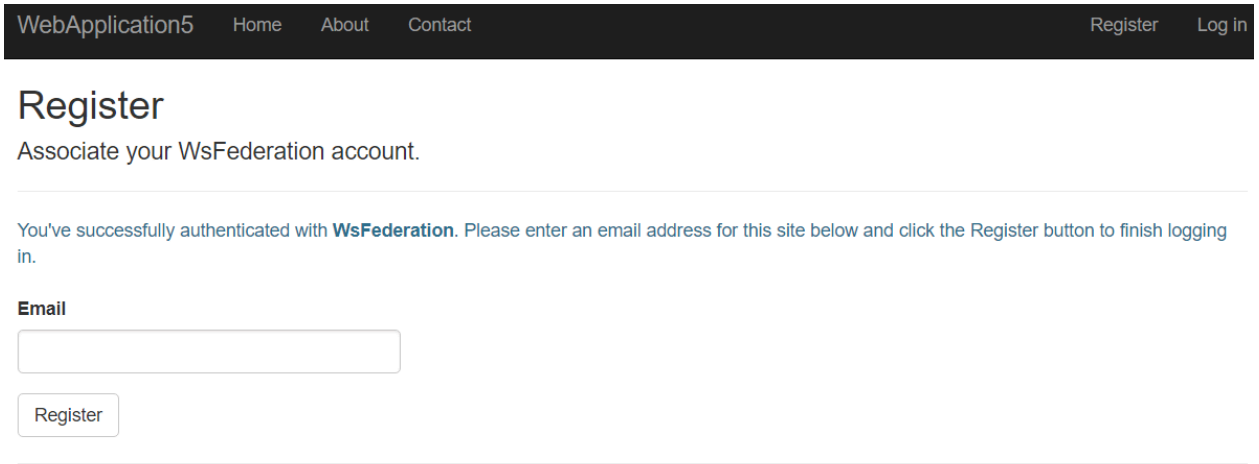


AuthenticationBuilder extension methods that register an authentication handler may only be called once per authentication scheme. Overloads exist that allow configuring the scheme properties, scheme name, and display name.

Log in with WS-Federation



Browse to the app and click the **Log in** link in the nav header. There's an option to log in with WsFederation:



With ADFS as the provider, the button redirects to an ADFS sign-in page:

With Microsoft Entra ID as the provider, the button redirects to a Microsoft Entra ID sign-in page:

A successful sign-in for a new user redirects to the app's user registration page:

Use social sign-in provider authentication without ASP.NET Core Identity

Article • 06/03/2022

By Kirk Larkin and Rick Anderson

Facebook and Google authentication in ASP.NET Core describes how to enable users to sign in using OAuth 2.0 with credentials from external authentication providers. The approach described in that article includes ASP.NET Core Identity as an authentication provider.

This sample demonstrates how to use an external authentication provider **without** ASP.NET Core Identity. This approach is useful for apps that don't require all of the features of ASP.NET Core Identity, but still require integration with a trusted external authentication provider.

This sample uses Google authentication for authenticating users. Using Google authentication shifts many of the complexities of managing the sign-in process to Google. To integrate with a different external authentication provider, see the following articles:

- Facebook authentication
- Microsoft authentication
- Twitter authentication
- Other providers

Configuration

In `Program.cs`, configure the app's authentication schemes with the AddAuthentication, AddCookie, and AddGoogle methods:

C#

```
using Microsoft.AspNetCore.Authentication.Cookies;
using Microsoft.AspNetCore.Authentication.Google;

var builder = WebApplication.CreateBuilder(args);

builder.Services
    .AddAuthentication(options =>
    {
```

```
        options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
        options.DefaultChallengeScheme =
GoogleDefaults.AuthenticationScheme;
    })
    .AddCookie()
    .AddGoogle(options =>
    {
        options.ClientId =
builder.Configuration["Authentication:Google:ClientId"];
        options.ClientSecret =
builder.Configuration["Authentication:Google:ClientSecret"];
    });

builder.Services.AddRazorPages();
```

The call to AddAuthentication sets the app's DefaultScheme. The `DefaultScheme` is the default scheme used by the following `HttpContext` authentication extension methods:

- AuthenticateAsync
- ChallengeAsync
- ForbidAsync
- SignInAsync
- SignOutAsync

Setting the app's `DefaultScheme` to CookieAuthenticationDefaults.AuthenticationScheme ("Cookies") configures the app to use Cookies as the default scheme for these extension methods. Setting the app's DefaultChallengeScheme to GoogleDefaults.AuthenticationScheme ("Google") configures the app to use Google as the default scheme for calls to `ChallengeAsync`. `DefaultChallengeScheme` overrides `DefaultScheme`. See AuthenticationOptions for more properties that override `DefaultScheme` when set.

In `Program.cs`, call UseAuthentication and UseAuthorization. This middleware combination sets the HttpContext.User property and runs the Authorization Middleware for requests:

C#

```
app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();
```

To learn more about authentication schemes, see Authentication Concepts. To learn more about cookie authentication, see Use cookie authentication without ASP.NET Core Identity.

Apply authorization

Test the app's authentication configuration by applying the [Authorize] attribute to a controller, action, or page. The following code limits access to the *Privacy* page to users that have been authenticated:

C#

```
[Authorize]
public class PrivacyModel : PageModel
{

}
```

Save the access token

SaveTokens defines whether access and refresh tokens should be stored in the AuthenticationProperties after a successful authorization. `SaveTokens` is set to `false` by default to reduce the size of the final authentication cookie.

To save access and refresh tokens after a successful authorization, set `SaveTokens` to `true` in `Program.cs`:

C#

```
builder.Services
    .AddAuthentication(options =>
    {
        options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
        options.DefaultChallengeScheme =
GoogleDefaults.AuthenticationScheme;
    })
    .AddCookie()
    .AddGoogle(options =>
    {
        options.ClientId =
builder.Configuration["Authentication:Google:ClientId"];
        options.ClientSecret =
builder.Configuration["Authentication:Google:ClientSecret"];
```

```
            options.SaveTokens = true;
        });
```

To retrieve a saved token, use GetTokenAsync. The following example retrieves the token named `access_token`:

```
C#

public async Task OnGetAsync()
{
    var accessToken = await HttpContext.GetTokenAsync(
        GoogleDefaults.AuthenticationScheme, "access_token");

    // ...
}
```

Sign out

To sign out the current user and delete their cookie, call SignOutAsync. The following code adds a `Logout` page handler to the *Index* page:

```
C#

public class IndexModel : PageModel
{
    public async Task<IActionResult> OnPostLogoutAsync()
    {
        // using Microsoft.AspNetCore.Authentication;
        await HttpContext.SignOutAsync();
        return RedirectToPage();
    }
}
```

Notice that the call to `SignOutAsync` doesn't specify an authentication scheme. The app uses the `DefaultScheme`, `CookieAuthenticationDefaults.AuthenticationScheme`, as a fallback.

Policy schemes in ASP.NET Core

Article • 06/03/2022

Authentication policy schemes make it easier to have a single logical authentication scheme potentially use multiple approaches. For example, a policy scheme might use Google authentication for challenges, and cookie authentication for everything else. Authentication policy schemes make it:

- Easy to forward any authentication action to another scheme.
- Forward dynamically based on the request.

All authentication schemes that use derived AuthenticationSchemeOptions and the associated AuthenticationHandler<TOptions>:

- Are automatically policy schemes in ASP.NET Core 2.1 and later.
- Can be enabled via configuring the scheme's options.

C#

```
public class AuthenticationSchemeOptions
{
    /// <summary>
    /// If set, this specifies a default scheme that authentication handlers
should
    /// forward all authentication operations to, by default. The default
forwarding
    /// logic checks in this order:
    /// 1. The most specific
ForwardAuthenticate/Challenge/Forbid/SignIn/SignOut
    /// 2. The ForwardDefaultSelector
    /// 3. ForwardDefault
    /// The first non null result is used as the target scheme to forward
to.
    /// </summary>
    public string ForwardDefault { get; set; }

    /// <summary>
    /// If set, this specifies the target scheme that this scheme should
forward
    /// AuthenticateAsync calls to. For example:
    /// Context.AuthenticateAsync("ThisScheme") =>
    ///
Context.AuthenticateAsync("ForwardAuthenticateValue");
    /// Set the target to the current scheme to disable forwarding and allow
    /// normal processing.
    /// </summary>
    public string ForwardAuthenticate { get; set; }

    /// <summary>
```

```
    /// If set, this specifies the target scheme that this scheme should
forward
    /// ChallengeAsync calls to. For example:
    /// Context.ChallengeAsync("ThisScheme") =>
    ///
Context.ChallengeAsync("ForwardChallengeValue");
    /// Set the target to the current scheme to disable forwarding and allow
normal
    /// processing.
    /// </summary>
    public string ForwardChallenge { get; set; }

    /// <summary>
    /// If set, this specifies the target scheme that this scheme should
forward
    /// ForbidAsync calls to.For example:
    /// Context.ForbidAsync("ThisScheme")
    ///                                =>
Context.ForbidAsync("ForwardForbidValue");
    /// Set the target to the current scheme to disable forwarding and allow
normal
    /// processing.
    /// </summary>
    public string ForwardForbid { get; set; }

    /// <summary>
    /// If set, this specifies the target scheme that this scheme should
forward
    /// SignInAsync calls to. For example:
    /// Context.SignInAsync("ThisScheme") =>
    ///
Context.SignInAsync("ForwardSignInValue");
    /// Set the target to the current scheme to disable forwarding and allow
normal
    /// processing.
    /// </summary>
    public string ForwardSignIn { get; set; }

    /// <summary>
    /// If set, this specifies the target scheme that this scheme should
forward
    /// SignOutAsync calls to. For example:
    /// Context.SignOutAsync("ThisScheme") =>
    ///
Context.SignOutAsync("ForwardSignOutValue");
    /// Set the target to the current scheme to disable forwarding and allow
normal
    /// processing.
    /// </summary>
    public string ForwardSignOut { get; set; }

    /// <summary>
    /// Used to select a default scheme for the current request that
authentication
    /// handlers should forward all authentication operations to by default.
```

```
The
    /// default forwarding checks in this order:
    /// 1. The most specific
ForwardAuthenticate/Challenge/Forbid/SignIn/SignOut
    /// 2. The ForwardDefaultSelector
    /// 3. ForwardDefault.
    /// The first non null result will be used as the target scheme to
forward to.
    /// </summary>
    public Func<HttpContext, string> ForwardDefaultSelector { get; set; }
}
```

Examples

The following example shows a higher level scheme that combines lower level schemes. Google authentication is used for challenges, and cookie authentication is used for everything else:

C#

```
public void ConfigureServices(IServiceCollection services)
{

services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme
)
       .AddCookie(options => options.ForwardChallenge = "Google")
       .AddGoogle(options => { });
}
```

The following example enables dynamic selection of schemes on a per request basis. That is, how to mix cookies and API authentication:

C#

```
public void ConfigureServices(IServiceCollection services)
{

services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme
)
        .AddCookie(options =>
        {
            // For example, can foward any requests that start with /api
            // to the api scheme.
            options.ForwardDefaultSelector = ctx =>
               ctx.Request.Path.StartsWithSegments("/api") ? "Api" : null;
        })
        .AddYourApiAuth("Api");
}
```

Manage JSON Web Tokens in development with dotnet user-jwts

Article • 09/27/2024

By Rick Anderson

The `dotnet user-jwts` command line tool can create and manage app specific local JSON Web Tokens (JWTs).

Synopsis

.NET CLI

```
dotnet user-jwts [<PROJECT>] [command]
dotnet user-jwts [command] -h|--help
```

Description

Creates and manages project specific local JSON Web Tokens.

Arguments

`PROJECT | SOLUTION`

The MSBuild project to apply a command on. If a project is not specified, MSBuild searches the current working directory for a file that has a file extension that ends in *proj* and uses that file.

Commands

Expand table

Command	Description
clear	Delete all issued JWTs for a project.
create	Issue a new JSON Web Token.
remove	Delete a given JWT.

Command	Description
key	Display or reset the signing key used to issue JWTs.
list	Lists the JWTs issued for the project.
print	Display the details of a given JWT.

Create

Usage: `dotnet user-jwts create [options]`

Expand table

Option	Description
-p | --project	The path of the project to operate on. Defaults to the project in the current directory.
--scheme	The scheme name to use for the generated token. Defaults to 'Bearer'.
-n | --name	The name of the user to create the JWT for. Defaults to the current environment user.
--audience	The audiences to create the JWT for. Defaults to the URLs configured in the project's launchSettings.json.
--issuer	The issuer of the JWT. Defaults to 'dotnet-user-jwts'.
--scope	A scope claim to add to the JWT. Specify once for each scope.
--role	A role claim to add to the JWT. Specify once for each role.
--claim	Claims to add to the JWT. Specify once for each claim in the format "name=value".
--not-before	The UTC date & time the JWT should not be valid before in the format 'yyyy-MM-dd [[HH:mm[[:ss]]]]'. Defaults to the date & time the JWT is created.
--expires-on	The UTC date & time the JWT should expire in the format 'yyyy-MM-dd [[[[HH:mm]]:ss]]'. Defaults to 6 months after the --not-before date. Do not use this option in conjunction with the --valid-for option.
--valid-for	The period the JWT should expire after. Specify using a number followed by duration type like 'd' for days, 'h' for hours, 'm' for minutes, and 's' for seconds, for example 365d'. Do not use this option in conjunction with the --expires-on option.
-o | --output	The format to use for displaying output from the command. Can be one of 'default', 'token', or 'json'.
-h | --help	Show help information

Examples

Run the following commands to create an empty web project and add the Microsoft.AspNetCore.Authentication.JwtBearer NuGet package:

.NET CLI

```
dotnet new web -o MyJWT
cd MyJWT
dotnet add package Microsoft.AspNetCore.Authentication.JwtBearer
```

Replace the contents of `Program.cs` with the following code:

C#

```
using System.Security.Claims;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization();
builder.Services.AddAuthentication("Bearer").AddJwtBearer();

var app = builder.Build();

app.UseAuthorization();

app.MapGet("/", () => "Hello, World!");
app.MapGet("/secret", (ClaimsPrincipal user) => $"Hello
{user.Identity?.Name}. My secret")
    .RequireAuthorization();

app.Run();
```

In the preceding code, a GET request to `/secret` returns an `401 Unauthorized` error. A production app might get the JWT from a Security token service (STS), perhaps in response to logging in via a set of credentials. For the purpose of working with the API during local development, the `dotnet user-jwts` command line tool can be used to create and manage app-specific local JWTs.

The `user-jwts` tool is similar in concept to the user-secrets tool, it can be used to manage values for the app that are only valid for the developer on the local machine. In fact, the user-jwts tool utilizes the `user-secrets` infrastructure to manage the key that the JWTs are signed with, ensuring it's stored safely in the user profile.

The `user-jwts` tool hides implementation details, such as where and how the values are stored. The tool can be used without knowing the implementation details. The values

are stored in a JSON file in the local machine's user profile folder:

Windows

File system path:

`%APPDATA%\Microsoft\UserSecrets\<secrets_GUID>\user-jwts.json`

Create a JWT

The following command creates a local JWT:

.NET CLI

```
dotnet user-jwts create
```

The preceding command creates a JWT and updates the project's `appsettings.Development.json` file with JSON similar to the following:

C#

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "Authentication": {
    "Schemes": {
      "Bearer": {
        "ValidAudiences": [
          "http://localhost:8401",
          "https://localhost:44308",
          "http://localhost:5182",
          "https://localhost:7076"
        ],
        "ValidIssuer": "dotnet-user-jwts"
      }
    }
  }
}
```

Copy the JWT and the `ID` created in the preceding command. Use a tool like Curl to test `/secret`:

.NET CLI

```
curl -i -H "Authorization: Bearer {token}" https://localhost:{port}/secret
```

Where `{token}` is the previously generated JWT.

Display JWT security information

The following command displays the JWT security information, including expiration, scopes, roles, token header and payload, and the compact token:

.NET CLI

```
dotnet user-jwts print {ID} --show-all
```

Create a token for a specific user and scope

See Create in this topic for supported create options.

The following command creates a JWT for a user named `MyTestUser`:

.NET CLI

```
dotnet user-jwts create --name MyTestUser --scope "myapi:secrets"
```

The preceding command has output similar to the following:

.NET CLI

```
New JWT saved with ID '43e0b748'.
Name: MyTestUser
Scopes: myapi:secrets

Token: eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.{Remaining token deleted}
```

The preceding token can be used to test the `/secret2` endpoint in the following code:

C#

```
using System.Security.Claims;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization();
```

```
builder.Services.AddAuthentication("Bearer").AddJwtBearer();

var app = builder.Build();

app.MapGet("/", () => "Hello, World!");
app.MapGet("/secret", (ClaimsPrincipal user) => $"Hello
{user.Identity?.Name}. My secret")
    .RequireAuthorization();
app.MapGet("/secret2", () => "This is a different secret!")
    .RequireAuthorization(p => p.RequireClaim("scope", "myapi:secrets"));

app.Run();
```

Mapping, customizing, and transforming claims in ASP.NET Core

Article • 08/16/2024

By Damien Bowden

Claims can be created from any user or identity data which can be issued using a trusted identity provider or ASP.NET Core identity. A claim is a name value pair that represents what the subject is, not what the subject can do. This article covers the following areas:

- How to configure and map claims using an OpenID Connect client
- Set the name and role claim
- Reset the claims namespaces
- Customize, extend the claims using TransformAsync

Mapping claims using OpenID Connect authentication

The profile claims can be returned in the `id_token`, which is returned after a successful authentication. The ASP.NET Core client app only requires the profile scope. When using the `id_token` for claims, no extra claims mapping is required.

C#

```
using Microsoft.AspNetCore.Authentication.Cookies;
using Microsoft.AspNetCore.Authentication.OpenIdConnect;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
```

```
builder.Services.AddAuthentication(options =>
{
    options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme =
OpenIdConnectDefaults.AuthenticationScheme;
})
   .AddCookie()
   .AddOpenIdConnect(options =>
   {
       options.SignInScheme = "Cookies";
       options.Authority = "-your-identity-provider-";
       options.RequireHttpsMetadata = true;
       options.ClientId = "-your-clientid-";
       options.ClientSecret = "-your-client-secret-from-user-secrets-or-
keyvault";
       options.ResponseType = "code";
       options.UsePkce = true;
       options.Scope.Add("profile");
       options.SaveTokens = true;
   });
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The preceding code requires the Microsoft.AspNetCore.Authentication.OpenIdConnect NuGet package.

Another way to get the user claims is to use the OpenID Connect User Info API. The ASP.NET Core client app uses the `GetClaimsFromUserInfoEndpoint` property to configure this. One important difference from the first settings, is that you must specify the claims you require using the `MapUniqueJsonKey` method, otherwise only the `name`, `given_name` and `email` standard claims will be available in the client app. The claims included in the `id_token` are mapped per default. This is the major difference to the first option. You must explicitly define some of the claims you require.

```
```

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.Cookies;
using Microsoft.AspNetCore.Authentication.OpenIdConnect;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddAuthentication(options =>
{
    options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme =
OpenIdConnectDefaults.AuthenticationScheme;
})
   .AddCookie()
   .AddOpenIdConnect(options =>
   {
       options.SignInScheme = "Cookies";
       options.Authority = "-your-identity-provider-";
       options.RequireHttpsMetadata = true;
       options.ClientId = "-your-clientid-";
       options.ClientSecret = "-client-secret-from-user-secrets-or-
keyvault";
       options.ResponseType = "code";
       options.UsePkce = true;
       options.Scope.Add("profile");
       options.SaveTokens = true;
       options.GetClaimsFromUserInfoEndpoint = true;
       options.ClaimActions.MapUniqueJsonKey("preferred_username",
                                             "preferred_username");
       options.ClaimActions.MapUniqueJsonKey("gender", "gender");
   });

var app = builder.Build();

// Code removed for brevity.
```

> **Note**
>
> The default Open ID Connect handler uses Pushed Authorization Requests (PAR) if the identity provider's discovery document advertises support for PAR. The identity provider's discovery document is usually found at `.well-known/openid-configuration`. If you cannot use PAR in the client configuration on the identity provider, PAR can be disabled by using the **PushedAuthorizationBehavior** option.

C#

```
builder.Services
    .AddAuthentication(options =>
    {
        options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
        options.DefaultChallengeScheme =
OpenIdConnectDefaults.AuthenticationScheme;
    })
    .AddCookie()
    .AddOpenIdConnect("oidc", oidcOptions =>
    {
        // Other provider-specific configuration goes here.

        // The default value is PushedAuthorizationBehavior.UseIfAvailable.

        // 'OpenIdConnectOptions' does not contain a definition for
'PushedAuthorizationBehavior'
        // and no accessible extension method 'PushedAuthorizationBehavior'
accepting a first argument
        // of type 'OpenIdConnectOptions' could be found
        oidcOptions.PushedAuthorizationBehavior =
PushedAuthorizationBehavior.Disable;
    });
```

To ensure that authentication only succeeds if PAR is used, use PushedAuthorizationBehavior.Require instead. This change also introduces a new OnPushAuthorization event to OpenIdConnectEvents which can be used to customize the pushed authorization request or handle it manually. See the API proposal for more details.

Name claim and role claim mapping

The **Name** claim and the **Role** claim are mapped to default properties in the ASP.NET Core HTTP context. Sometimes it is required to use different claims for the default properties, or the name claim and the role claim do not match the default values. The claims can be mapped using the **TokenValidationParameters** property and set to any claim as required. The values from the claims can be used directly in the HttpContext **User.Identity.Name** property and the roles.

If the `User.Identity.Name` has no value or the roles are missing, please check the values in the returned claims and set the `NameClaimType` and the `RoleClaimType` values. The returned claims from the client authentication can be viewed in the HTTP context.

```
C#
```

```
builder.Services.AddAuthentication(options =>
{
    options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme =
OpenIdConnectDefaults.AuthenticationScheme;
})
  .AddCookie()
  .AddOpenIdConnect(options =>
  {
        // Other options...
        options.TokenValidationParameters = new TokenValidationParameters
        {
           NameClaimType = "email"
           //, RoleClaimType = "role"
        };
  });
```

Claims namespaces, default namespaces

ASP.NET Core adds default namespaces to some known claims, which might not be required in the app. Optionally, disable these added namespaces and use the exact claims that the OpenID Connect server created.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

JsonWebTokenHandler.DefaultInboundClaimTypeMap.Clear();

builder.Services.AddAuthentication(options =>
{
    options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme =
OpenIdConnectDefaults.AuthenticationScheme;
})
   .AddCookie()
   .AddOpenIdConnect(options =>
   {
       options.SignInScheme = "Cookies";
       options.Authority = "-your-identity-provider-";
       options.RequireHttpsMetadata = true;
       options.ClientId = "-your-clientid-";
       options.ClientSecret = "-your-client-secret-from-user-secrets-or-
keyvault";
       options.ResponseType = "code";
       options.UsePkce = true;
```

```
        options.Scope.Add("profile");
        options.SaveTokens = true;
    });

var app = builder.Build();

// Code removed for brevity.
```

If you need to disable the namespaces per scheme and not globally, you can use the **MapInboundClaims = false** option.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddAuthentication(options =>
{
    options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme =
OpenIdConnectDefaults.AuthenticationScheme;
})
    .AddCookie()
    .AddOpenIdConnect(options =>
    {
        options.SignInScheme = "Cookies";
        options.Authority = "-your-identity-provider-";
        options.RequireHttpsMetadata = true;
        options.ClientId = "-your-clientid-";
        options.ClientSecret = "-your-client-secret-from-user-secrets-or-
keyvault";
        options.ResponseType = "code";
        options.UsePkce = true;
        options.MapInboundClaims = false;
        options.Scope.Add("profile");
        options.SaveTokens = true;
    });

var app = builder.Build();

// Code removed for brevity.
```

Extend or add custom claims using `IClaimsTransformation`

The IClaimsTransformation interface can be used to add extra claims to the ClaimsPrincipal class. The interface requires a single method TransformAsync. This

method might get called multiple times. Only add a new claim if it does not already exist in the `ClaimsPrincipal`. A `ClaimsIdentity` is created to add the new claims and this can be added to the `ClaimsPrincipal`.

C#

```
using Microsoft.AspNetCore.Authentication;
using System.Security.Claims;

public class MyClaimsTransformation : IClaimsTransformation
{
    public Task<ClaimsPrincipal> TransformAsync(ClaimsPrincipal principal)
    {
        ClaimsIdentity claimsIdentity = new ClaimsIdentity();
        var claimType = "myNewClaim";
        if (!principal.HasClaim(claim => claim.Type == claimType))
        {
            claimsIdentity.AddClaim(new Claim(claimType, "myClaimValue"));
        }

        principal.AddIdentity(claimsIdentity);
        return Task.FromResult(principal);
    }
}
```

The IClaimsTransformation interface and the `MyClaimsTransformation` class can be registered as a service:

C#

```
builder.Services.AddTransient<IClaimsTransformation, MyClaimsTransformation>
();
```

Map claims from external identity providers

Community OSS authentication options for ASP.NET Core

Article • 05/06/2024

This page shows community-provided open-source software (OSS) authentication options for ASP.NET Core. This page is periodically updated as new providers become available.

OSS authentication providers [.NET]

Expand table

Name	Description
Duende IdentityServer	IdentityServer is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core.
OpenIddict	OAuth 2.0/OpenID Connect server for ASP.NET Core and ASP.NET 4.x.
FIDO2 .NET Library, WebAuthn	FIDO2 .NET library for FIDO2 / WebAuthn Attestation and Assertion using .NET

OSS authentication provider clients [.NET]

Expand table

Name	Description
OpenIddict	OAuth 2.0/OpenID Connect client for ASP.NET Core, ASP.NET 4.x and Windows/Linux desktop apps with built-in integrations for 80+ services such as Auth0, Microsoft Entra ID, GitHub, Google, Twitter or Yahoo.
AspNet.Security.OAuth.Providers	A collection of security middleware for ASP.NET Core apps to support social authentication.
AspNet.Security.OpenId.Providers	A collection of security middleware for ASP.NET Core apps to support OpenID 2.0 authentication providers like Steam.

Other OSS authentication providers

Expand table

Name	Description
Gluu Server	Enterprise ready, open source software for identity, access management (IAM), and single sign-on (SSO). For more information, see the Gluu Product Documentation.
Keycloak	Open Source Identity and Access Management For Modern Applications and Services.
node-oidc-provider	OpenID Certified™ OAuth 2.0 Authorization Server implementation for Node.js.
Authentik	Authentik is an open-source Identity Provider focused on flexibility and versatility.

To add a provider, edit this page.

Identity management solutions for .NET web apps

Article • 10/18/2024

The following table provides an overview of various identity management solutions that can be used in ASP.NET Core apps. These solutions offer features and capabilities to manage user authentication, authorization, and user identity within an app. It includes options for apps that are:

- Container-based
- Self-hosted, where you manage the installation and infrastructure to support it.
- Managed, such as cloud-based services like Microsoft Entra

The following table lists both open source and commercial solutions in alphabetical order. Each line contains details such as license type, website, and documentation that is specific to ASP.NET Core integration. The table can help identify the identity management solutions that best align with your app's needs.

Many of the commercial licenses provide "community" or free options that may be available depending on your company size and app requirements.

Expand table

Name	Type	License Type	Documentation
ASP.NET Core Identity	Self host	OSS (MIT)	Secure a web app with ASP.NET Core Identity
Auth0	Managed	Commercial	Get started
Duende IdentityServer	Self host	Commercial	ASP.NET Identity integration
Keycloak	Container	OSS (Apache 2.0)	Keycloak securing apps documentation
Microsoft Entra ID	Managed	Commercial	Entra documentation
Okta	Managed	Commercial	Okta for ASP.NET Core
OpenIddict	Self host	OSS (Apache 2.0)	OpenIddict documentation

Is there a solution that should be added to this list? Do you have a correction, suggestion, or feedback? We welcome your contributions. Learn how to contribute.

Multi-factor authentication in ASP.NET Core

Article • 10/30/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Damien Bowden

View or download sample code (damienbod/AspNetCoreHybridFlowWithApi GitHub repository)

Multi-factor authentication (MFA) is a process in which a user is requested during a sign-in event for additional forms of identification. This prompt could be to enter a code from a cellphone, use a FIDO2 key, or to provide a fingerprint scan. When you require a second form of authentication, security is enhanced. The additional factor isn't easily obtained or duplicated by a cyberattacker.

This article covers the following areas:

- What is MFA and what MFA flows are recommended
- Configure MFA for administration pages using ASP.NET Core Identity
- Send MFA sign-in requirement to OpenID Connect server
- Force ASP.NET Core OpenID Connect client to require MFA

MFA, 2FA

MFA requires at least two or more types of proof for an identity like something you know, something you possess, or biometric validation for the user to authenticate.

Two-factor authentication (2FA) is like a subset of MFA, but the difference being that MFA can require two or more factors to prove the identity.

2FA is supported by default when using ASP.NET Core Identity. To enable or disable 2FA for a specific user, set the IdentityUser<TKey>.TwoFactorEnabled property. The ASP.NET Core Identity Default UI includes pages for configuring 2FA.

MFA TOTP (Time-based One-time Password Algorithm)

MFA using TOTP is supported by default when using ASP.NET Core Identity. This approach can be used together with any compliant authenticator app, including:

- Microsoft Authenticator
- Google Authenticator

For implementation details, see Enable QR Code generation for TOTP authenticator apps in ASP.NET Core.

To disable support for MFA TOTP, configure authentication using AddIdentity instead of AddDefaultIdentity. `AddDefaultIdentity` calls AddDefaultTokenProviders internally, which registers multiple token providers including one for MFA TOTP. To register only specific token providers, call AddTokenProvider for each required provider. For more information about available token providers, see the AddDefaultTokenProviders source on GitHub.

MFA passkeys/FIDO2 or passwordless

passkeys/FIDO2 is currently:

- The most secure way of achieving MFA.
- MFA that protects against phishing attacks. (As well as certificate authentication and Windows for business)

At present, ASP.NET Core doesn't support passkeys/FIDO2 directly. Passkeys/FIDO2 can be used for MFA or passwordless flows.

Microsoft Entra ID provides support for passkeys/FIDO2 and passwordless flows. For more information, see Passwordless authentication options.

Other forms of passwordless MFA do not or may not protect against phishing.

MFA SMS

MFA with SMS increases security massively compared with password authentication (single factor). However, using SMS as a second factor is no longer recommended. Too many known attack vectors exist for this type of implementation.

NIST guidelines

Configure MFA for administration pages using ASP.NET Core Identity

MFA could be forced on users to access sensitive pages within an ASP.NET Core Identity app. This could be useful for apps where different levels of access exist for the different identities. For example, users might be able to view the profile data using a password login, but an administrator would be required to use MFA to access the administrative pages.

Extend the login with an MFA claim

The demo code is setup using ASP.NET Core with Identity and Razor Pages. The `AddIdentity` method is used instead of `AddDefaultIdentity` one, so an `IUserClaimsPrincipalFactory` implementation can be used to add claims to the identity after a successful login.

> ⚠ **Warning**
>
> This article shows the use of connection strings. With a local database the user doesn't have to be authenticated, but in production, connection strings sometimes include a password to authenticate. A resource owner password credential (ROPC) is a security risk that should be avoided in production databases. Production apps should use the most secure authentication flow available. For more information on authentication for apps deployed to test or production environments, see Secure authentication flows.

C#

```
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlite(
        Configuration.GetConnectionString("DefaultConnection")));

builder.Services.AddIdentity<IdentityUser, IdentityRole>(options =>
        options.SignIn.RequireConfirmedAccount = false)
    .AddEntityFrameworkStores<ApplicationDbContext>()
    .AddDefaultTokenProviders();

builder.Services.AddSingleton<IEmailSender, EmailSender>();
builder.Services.AddScoped<IUserClaimsPrincipalFactory<IdentityUser>,
    AdditionalUserClaimsPrincipalFactory>();

builder.Services.AddAuthorization(options =>
    options.AddPolicy("TwoFactorEnabled", x => x.RequireClaim("amr",
"mfa")));
```

```
builder.Services.AddRazorPages();
```

The `AdditionalUserClaimsPrincipalFactory` class adds the `amr` claim to the user claims only after a successful login. The claim's value is read from the database. The claim is added here because the user should only access the higher protected view if the identity has logged in with MFA. If the database view is read from the database directly instead of using the claim, it's possible to access the view without MFA directly after activating the MFA.

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.Extensions.Options;
using System.Collections.Generic;
using System.Security.Claims;
using System.Threading.Tasks;

namespace IdentityStandaloneMfa
{
    public class AdditionalUserClaimsPrincipalFactory :
        UserClaimsPrincipalFactory<IdentityUser, IdentityRole>
    {
        public AdditionalUserClaimsPrincipalFactory(
            UserManager<IdentityUser> userManager,
            RoleManager<IdentityRole> roleManager,
            IOptions<IdentityOptions> optionsAccessor)
            : base(userManager, roleManager, optionsAccessor)
        {
        }

        public async override Task<ClaimsPrincipal> CreateAsync(IdentityUser
user)
        {
            var principal = await base.CreateAsync(user);
            var identity = (ClaimsIdentity)principal.Identity;

            var claims = new List<Claim>();

            if (user.TwoFactorEnabled)
            {
                claims.Add(new Claim("amr", "mfa"));
            }
            else
            {
                claims.Add(new Claim("amr", "pwd"));
            }

            identity.AddClaims(claims);
            return principal;
        }
```

```
    }
}
```

Because the Identity service setup changed in the `Startup` class, the layouts of the Identity need to be updated. Scaffold the Identity pages into the app. Define the layout in the `Identity/Account/Manage/_Layout.cshtml` file.

CSHTML

```
@{
    Layout = "/Pages/Shared/_Layout.cshtml";
}
```

Also assign the layout for all the manage pages from the Identity pages:

CSHTML

```
@{
    Layout = "_Layout.cshtml";
}
```

Validate the MFA requirement in the administration page

The administration Razor Page validates that the user has logged in using MFA. In the `OnGet` method, the identity is used to access the user claims. The `amr` claim is checked for the value `mfa`. If the identity is missing this claim or is `false`, the page redirects to the Enable MFA page. This is possible because the user has logged in already, but without MFA.

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace IdentityStandaloneMfa
{
    public class AdminModel : PageModel
    {
        public IActionResult OnGet()
        {
            var claimTwoFactorEnabled =
                User.Claims.FirstOrDefault(t => t.Type == "amr");
```

```
            if (claimTwoFactorEnabled != null &&
                "mfa".Equals(claimTwoFactorEnabled.Value))
            {
                // You logged in with MFA, do the administrative stuff
            }
            else
            {
                return Redirect(
                    "/Identity/Account/Manage/TwoFactorAuthentication");
            }

            return Page();
        }
    }
}
```

UI logic to toggle user login information

An authorization policy was added at startup. The policy requires the `amr` claim with the value `mfa`.

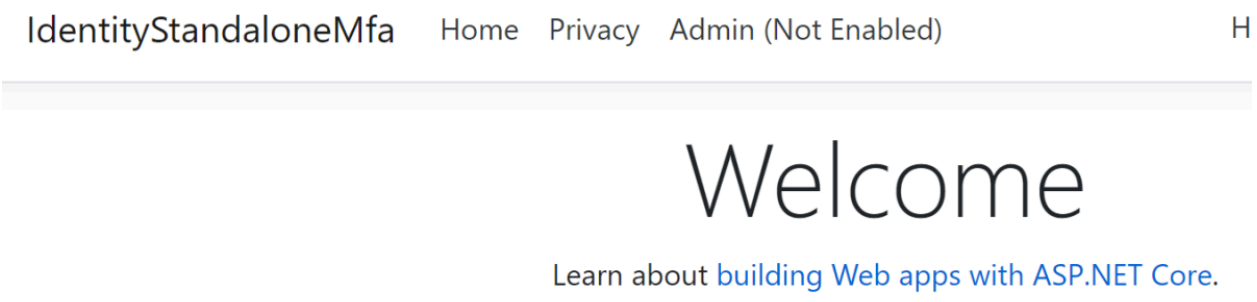
C#

```
services.AddAuthorization(options =>
    options.AddPolicy("TwoFactorEnabled",
        x => x.RequireClaim("amr", "mfa")));
```

This policy can then be used in the `_Layout` view to show or hide the **Admin** menu with the warning:

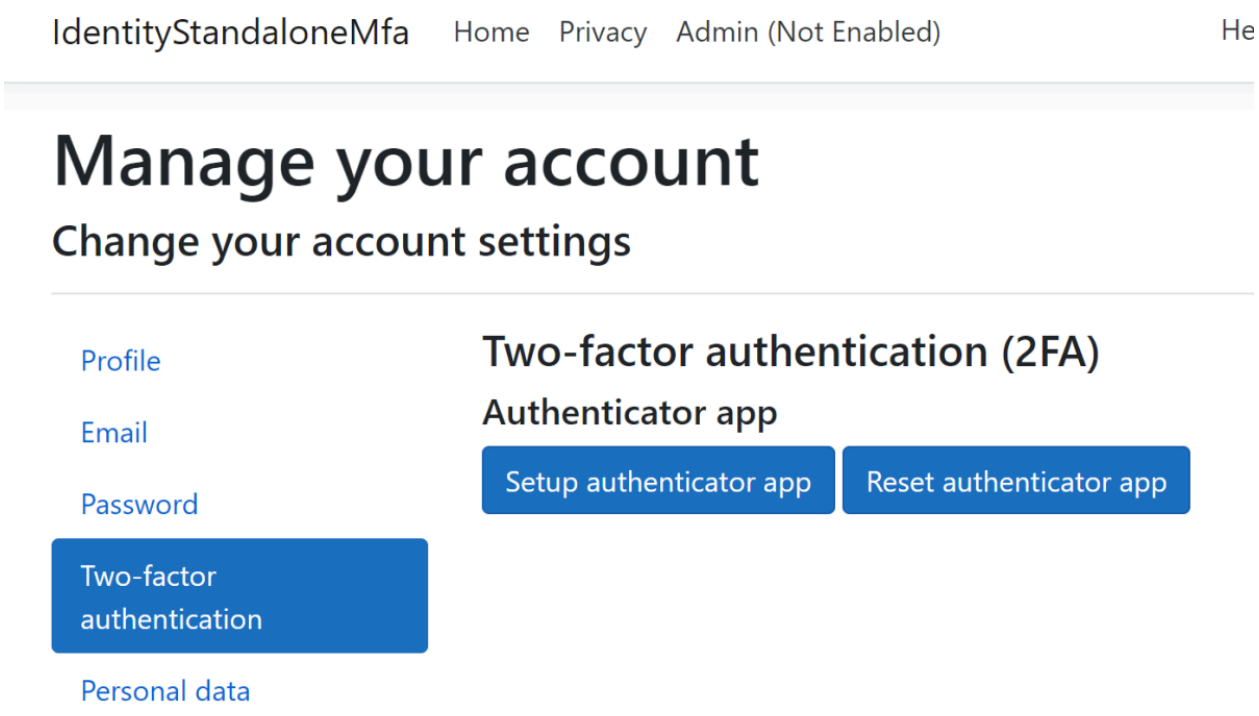
CSHTML

```
@using Microsoft.AspNetCore.Authorization
@using Microsoft.AspNetCore.Identity
@inject SignInManager<IdentityUser> SignInManager
@inject UserManager<IdentityUser> UserManager
@inject IAuthorizationService AuthorizationService
```



If the identity has logged in using MFA, the **Admin** menu is displayed without the tooltip warning. When the user has logged in without MFA, the **Admin (Not Enabled)** menu is displayed along with the tooltip that informs the user (explaining the warning).

CSHTML



```
@if (SignInManager.IsSignedIn(User))
{
```

```
    @if ((AuthorizationService.AuthorizeAsync(User,
"TwoFactorEnabled")).Result.Succeeded)
    {
        <li class="nav-item">
            <a class="nav-link text-dark" asp-area="" asp-
page="/Admin">Admin</a>
        </li>
    }
    else
    {
        <li class="nav-item">
            <a class="nav-link text-dark" asp-area="" asp-page="/Admin"
               id="tooltip-demo"
               data-toggle="tooltip"
               data-placement="bottom"
               title="MFA is NOT enabled. This is required for the Admin
Page. If you have activated MFA, then logout, login again.">
                Admin (Not Enabled)
            </a>
        </li>
    }
}
```

If the user logs in without MFA, the warning is displayed:

The user is redirected to the MFA enable view when clicking the **Admin** link:

Send MFA sign-in requirement to OpenID Connect server

The `acr_values` parameter can be used to pass the `mfa` required value from the client to the server in an authentication request.

> **Note**
>
> The `acr_values` parameter needs to be handled on the OpenID Connect server for this to work.

OpenID Connect ASP.NET Core client

The ASP.NET Core Razor Pages OpenID Connect client app uses the `AddOpenIdConnect` method to login to the OpenID Connect server. The `acr_values` parameter is set with the `mfa` value and sent with the authentication request. The `OpenIdConnectEvents` is used to add this.

For recommended `acr_values` parameter values, see Authentication Method Reference Values.

```
C#
```

```
build.Services.AddAuthentication(options =>
{
    options.DefaultScheme =
        CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme =
        OpenIdConnectDefaults.AuthenticationScheme;
})
.AddCookie()
.AddOpenIdConnect(options =>
{
    options.SignInScheme =
        CookieAuthenticationDefaults.AuthenticationScheme;
    options.Authority = "<OpenID Connect server URL>";
    options.RequireHttpsMetadata = true;
    options.ClientId = "<OpenID Connect client ID>";
    options.ClientSecret = "<>";
    options.ResponseType = "code";
    options.UsePkce = true;
    options.Scope.Add("profile");
    options.Scope.Add("offline_access");
    options.SaveTokens = true;
    options.AdditionalAuthorizationParameters.Add("acr_values", "mfa");
});
```

Example OpenID Connect Duende IdentityServer server with ASP.NET Core Identity

On the OpenID Connect server, which is implemented using ASP.NET Core Identity with Razor Pages, a new page named `ErrorEnable2FA.cshtml` is created. The view:

- Displays if the Identity comes from an app that requires MFA but the user hasn't activated this in Identity.
- Informs the user and adds a link to activate this.

CSHTML

```
@{
    ViewData["Title"] = "ErrorEnable2FA";
}

<h1>The client application requires you to have MFA enabled. Enable this,
try login again.</h1>

<br />

You can enable MFA to login here:

<br />
```

```
<a href="~/Identity/Account/Manage/TwoFactorAuthentication">Enable MFA</a>
```

In the `Login` method, the `IIdentityServerInteractionService` interface implementation `_interaction` is used to access the OpenID Connect request parameters. The `acr_values` parameter is accessed using the `AcrValues` property. As the client sent this with `mfa` set, this can then be checked.

If MFA is required, and the user in ASP.NET Core Identity has MFA enabled, then the login continues. When the user has no MFA enabled, the user is redirected to the custom view `ErrorEnable2FA.cshtml`. Then ASP.NET Core Identity signs the user in.

The Fido2Store is used to check if the user has activated MFA using a custom FIDO2 Token Provider.

C#

```
public async Task<IActionResult> OnPost()
{
    // check if we are in the context of an authorization request
    var context = await
_interaction.GetAuthorizationContextAsync(Input.ReturnUrl);

    var requires2Fa = context?.AcrValues.Count(t => t.Contains("mfa")) >= 1;

    var user = await _userManager.FindByNameAsync(Input.Username);
    if (user != null && !user.TwoFactorEnabled && requires2Fa)
    {
        return RedirectToPage("/Home/ErrorEnable2FA/Index");
    }

    // code omitted for brevity

    if (ModelState.IsValid)
    {
        var result = await
_signInManager.PasswordSignInAsync(Input.Username, Input.Password,
Input.RememberLogin, lockoutOnFailure: true);
        if (result.Succeeded)
        {
            // code omitted for brevity
        }
        if (result.RequiresTwoFactor)
        {
            var fido2ItemExistsForUser = await
_fido2Store.GetCredentialsByUserNameAsync(user.UserName);
            if (fido2ItemExistsForUser.Count > 0)
            {
                return RedirectToPage("/Account/LoginFido2Mfa", new { area =
"Identity", Input.ReturnUrl, Input.RememberLogin });
```

```
            }

            return RedirectToPage("/Account/LoginWith2fa", new { area =
"Identity", Input.ReturnUrl, RememberMe = Input.RememberLogin });
        }

        await _events.RaiseAsync(new UserLoginFailureEvent(Input.Username,
"invalid credentials", clientId: context?.Client.ClientId));
        ModelState.AddModelError(string.Empty,
LoginOptions.InvalidCredentialsErrorMessage);
    }

    // something went wrong, show form with error
    await BuildModelAsync(Input.ReturnUrl);
    return Page();
}
```

If the user is already logged in, the client app:

- Still validates the `amr` claim.
- Can set up the MFA with a link to the ASP.NET Core Identity view.

Force ASP.NET Core OpenID Connect client to require MFA

This example shows how an ASP.NET Core Razor Page app, which uses OpenID Connect to sign in, can require that users have authenticated using MFA.

To validate the MFA requirement, an `IAuthorizationRequirement` requirement is created. This will be added to the pages using a policy that requires MFA.

C#

```
using Microsoft.AspNetCore.Authorization;

namespace AspNetCoreRequireMfaOidc;

public class RequireMfa : IAuthorizationRequirement{}
```

An `AuthorizationHandler` is implemented that will use the `amr` claim and check for the value `mfa`. The `amr` is returned in the `id_token` of a successful authentication and can have many different values as defined in the Authentication Method Reference Values specification.

The returned value depends on how the identity authenticated and on the OpenID Connect server implementation.

The `AuthorizationHandler` uses the `RequireMfa` requirement and validates the `amr` claim. The OpenID Connect server can be implemented using Duende Identity Server with ASP.NET Core Identity. When a user logs in using TOTP, the `amr` claim is returned with an MFA value. If using a different OpenID Connect server implementation or a different MFA type, the `amr` claim will, or can, have a different value. The code must be extended to accept this as well.

C#

```
public class RequireMfaHandler : AuthorizationHandler<RequireMfa>
{
    protected override Task HandleRequirementAsync(
        AuthorizationHandlerContext context,
        RequireMfa requirement)
    {
        if (context == null)
            throw new ArgumentNullException(nameof(context));
        if (requirement == null)
            throw new ArgumentNullException(nameof(requirement));
```

```
        var amrClaim =
            context.User.Claims.FirstOrDefault(t => t.Type == "amr");

        if (amrClaim != null && amrClaim.Value == Amr.Mfa)
        {
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }
}
```

In the program file, the `AddOpenIdConnect` method is used as the default challenge scheme. The authorization handler, which is used to check the `amr` claim, is added to the Inversion of Control container. A policy is then created which adds the `RequireMfa` requirement.

C#

```
builder.Services.ConfigureApplicationCookie(options =>
        options.Cookie.SecurePolicy =
            CookieSecurePolicy.Always);

builder.Services.AddSingleton<IAuthorizationHandler, RequireMfaHandler>();

builder.Services.AddAuthentication(options =>
{
    options.DefaultScheme =
        CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme =
        OpenIdConnectDefaults.AuthenticationScheme;
})
.AddCookie()
.AddOpenIdConnect(options =>
{
    options.SignInScheme =
        CookieAuthenticationDefaults.AuthenticationScheme;
    options.Authority = "https://localhost:44352";
    options.RequireHttpsMetadata = true;
    options.ClientId = "AspNetCoreRequireMfaOidc";
    options.ClientSecret = "AspNetCoreRequireMfaOidcSecret";
    options.ResponseType = "code";
    options.UsePkce = true;
    options.Scope.Add("profile");
    options.Scope.Add("offline_access");
    options.SaveTokens = true;
});

builder.Services.AddAuthorization(options =>
{
    options.AddPolicy("RequireMfa", policyIsAdminRequirement =>
    {
```

```
        policyIsAdminRequirement.Requirements.Add(new RequireMfa());
    });
});

builder.Services.AddRazorPages();
```

This policy is then used in the Razor page as required. The policy could be added globally for the entire app as well.

C#

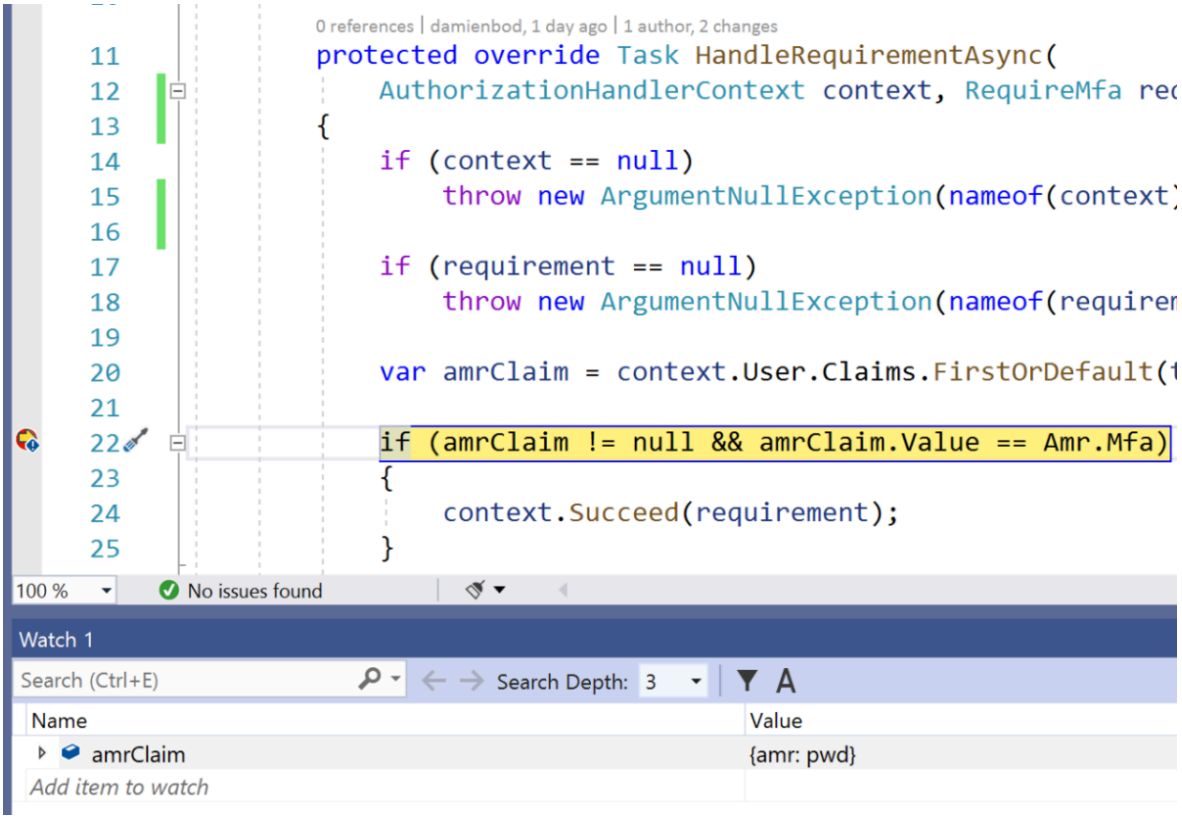
```
[Authorize(Policy= "RequireMfa")]
public class IndexModel : PageModel
{
    public void OnGet()
    {
    }
}
```

If the user authenticates without MFA, the `amr` claim will probably have a `pwd` value. The request won't be authorized to access the page. Using the default values, the user will be redirected to the *Account/AccessDenied* page. This behavior can be changed or you can implement your own custom logic here. In this example, a link is added so that the valid user can set up MFA for their account.

CSHTML

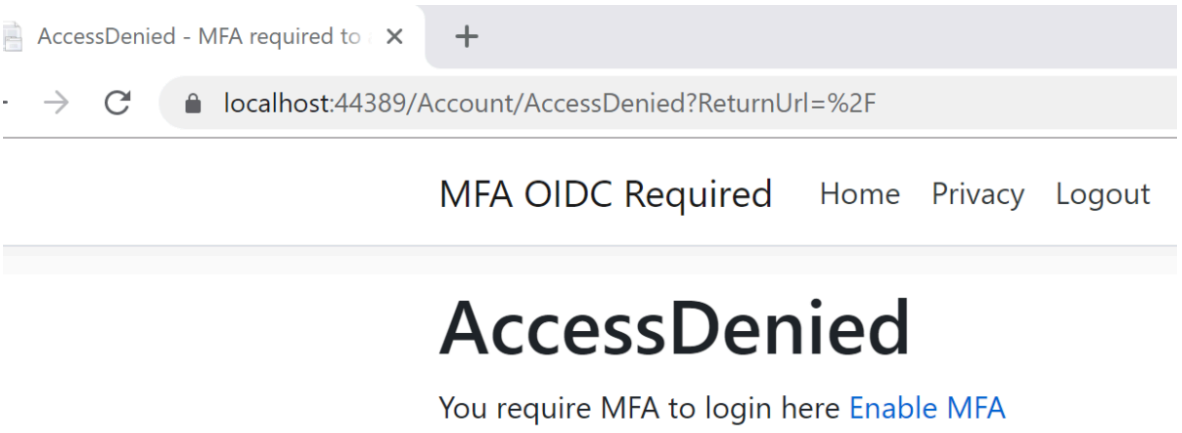
```
@page
@model AspNetCoreRequireMfaOidc.AccessDeniedModel
@{
    ViewData["Title"] = "AccessDenied";
    Layout = "~/Pages/Shared/_Layout.cshtml";
}

<h1>AccessDenied</h1>



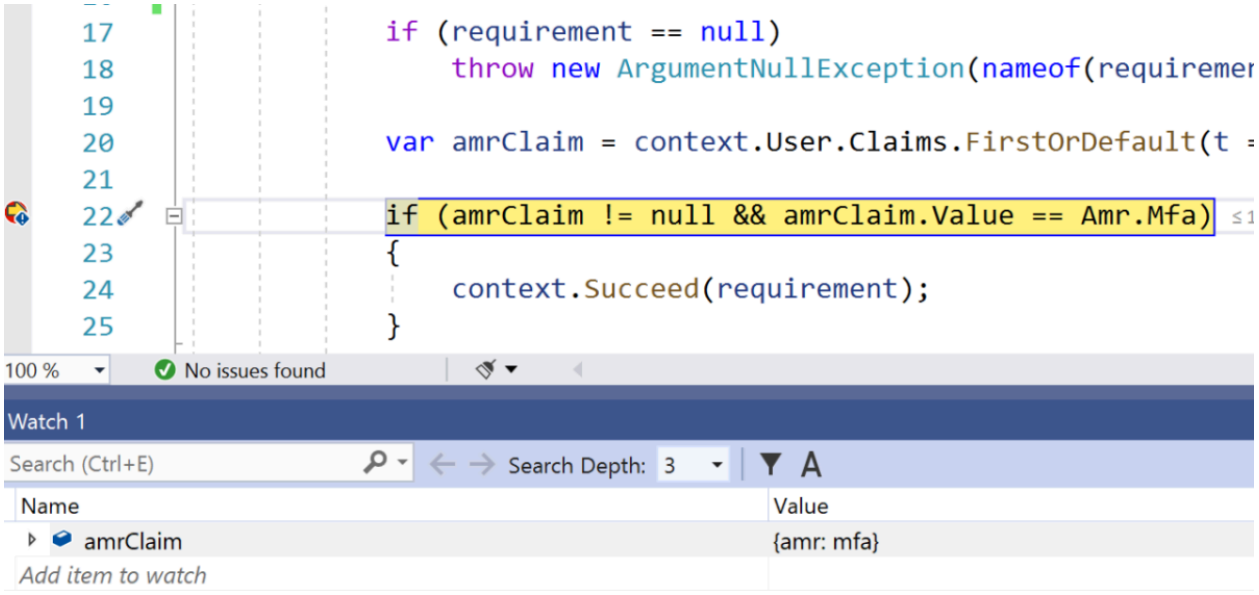
You require MFA to login here

<a href="https://localhost:44352/Manage/TwoFactorAuthentication">Enable
MFA</a>
```



Now only users that authenticate with MFA can access the page or website. If different MFA types are used or if 2FA is okay, the `amr` claim will have different values and needs to be processed correctly. Different OpenID Connect servers also return different values for this claim and might not follow the Authentication Method Reference Values specification.

When logging in without MFA (for example, using just a password):



- The `amr` has the `pwd` value:

- Access is denied:

Alternatively, logging in using OTP with Identity:

OIDC and OAuth Parameter Customization

The OAuth and OIDC authentication handlers AdditionalAuthorizationParameters option allows customization of authorization message parameters that are usually included as part of the redirect query string:

C#

```
builder.Services.AddAuthentication().AddOpenIdConnect(options =>
{
    options.AdditionalAuthorizationParameters.Add("prompt", "login");
    options.AdditionalAuthorizationParameters.Add("audience",
"https://api.example.com");
});
```

Introduction to authorization in ASP.NET Core

Article • 06/03/2022

Authorization refers to the process that determines what a user is able to do. For example, an administrative user is allowed to create a document library, add documents, edit documents, and delete them. A non-administrative user working with the library is only authorized to read the documents.

Authorization is orthogonal and independent from authentication. However, authorization requires an authentication mechanism. Authentication is the process of ascertaining who a user is. Authentication may create one or more identities for the current user.

For more information about authentication in ASP.NET Core, see Overview of ASP.NET Core Authentication.

Authorization types

ASP.NET Core authorization provides a simple, declarative role and a rich policy-based model. Authorization is expressed in requirements, and handlers evaluate a user's claims against requirements. Imperative checks can be based on simple policies or policies which evaluate both the user identity and properties of the resource that the user is attempting to access.

Namespaces

Authorization components, including the `AuthorizeAttribute` and `AllowAnonymousAttribute` attributes, are found in the `Microsoft.AspNetCore.Authorization` namespace.

Consult the documentation on simple authorization.

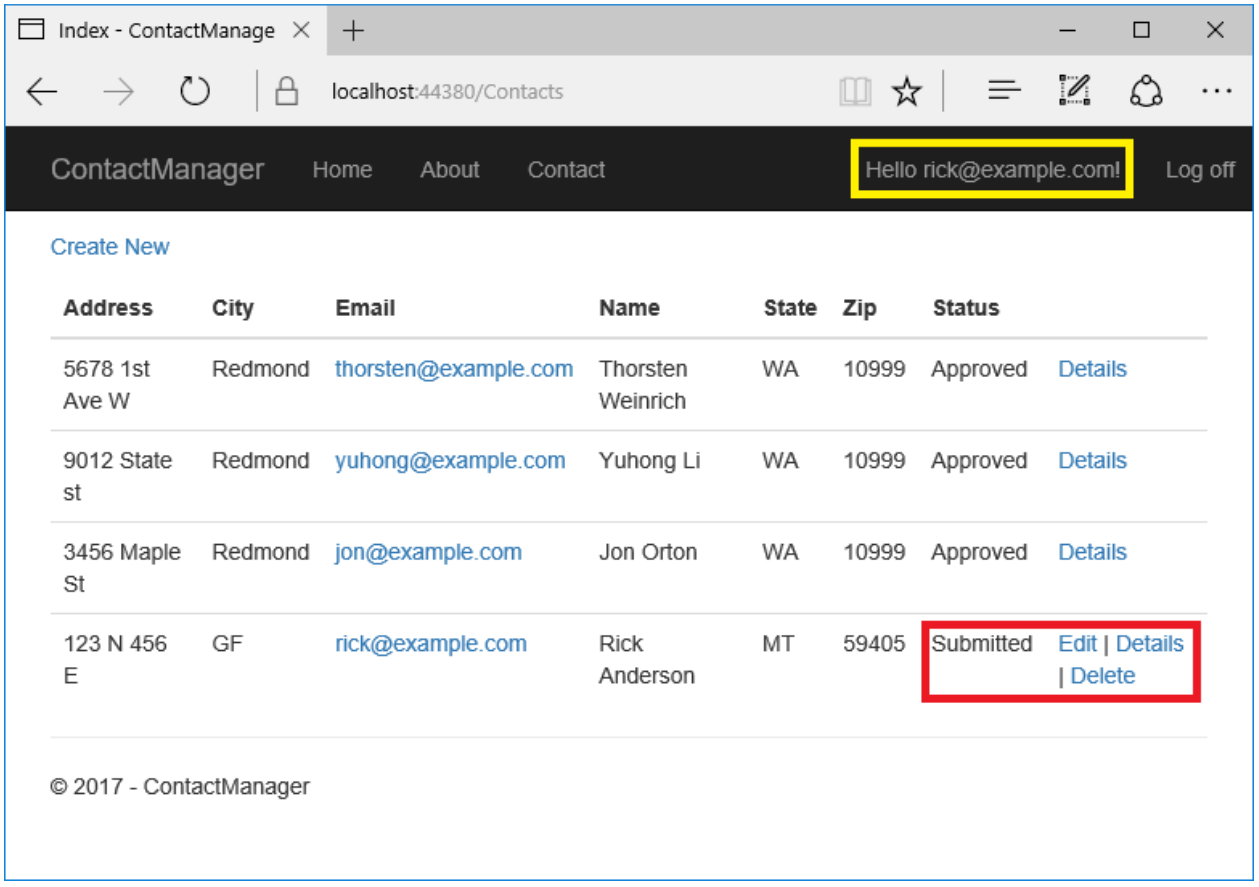
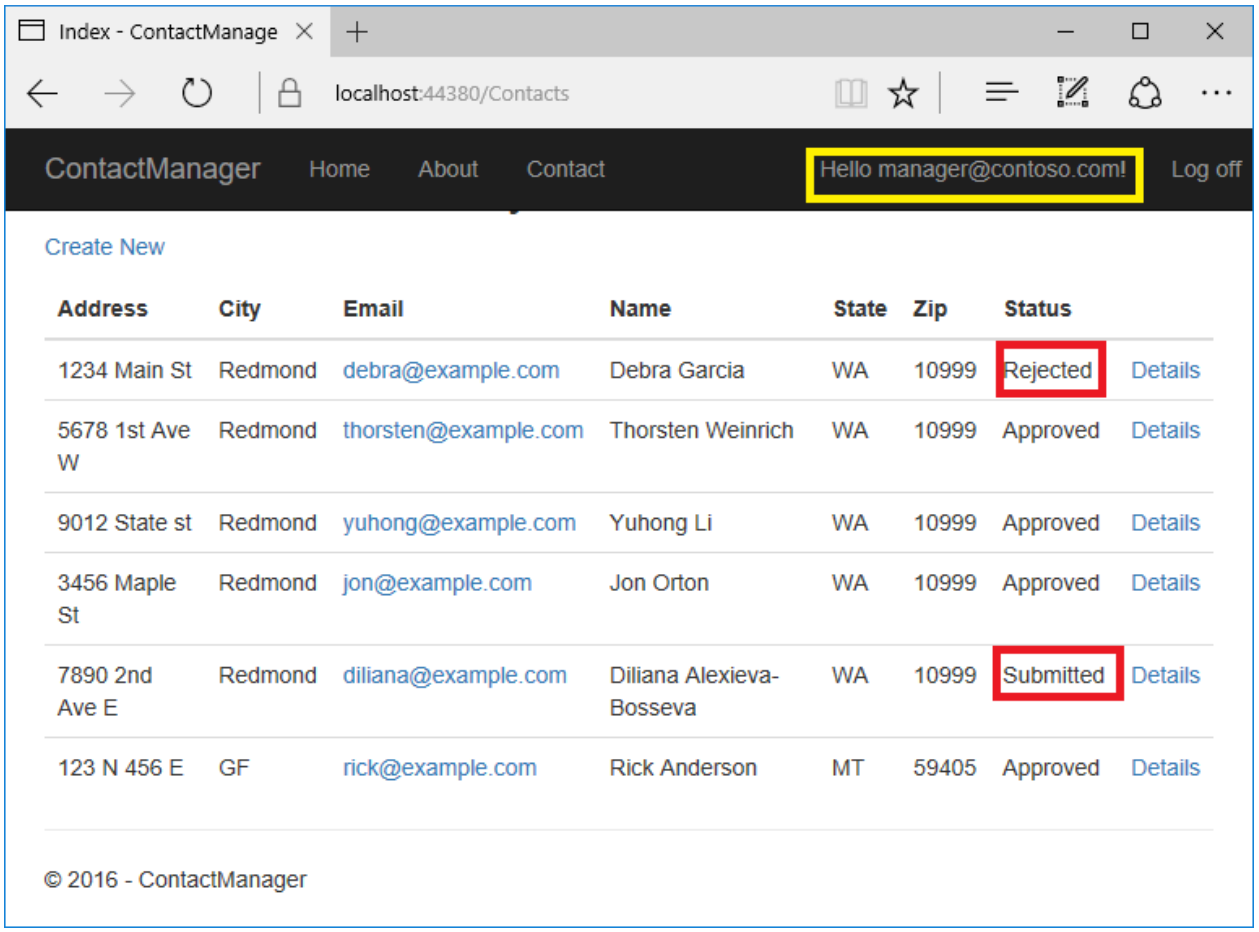
Create an ASP.NET Core web app with user data protected by authorization

Article • 10/04/2024



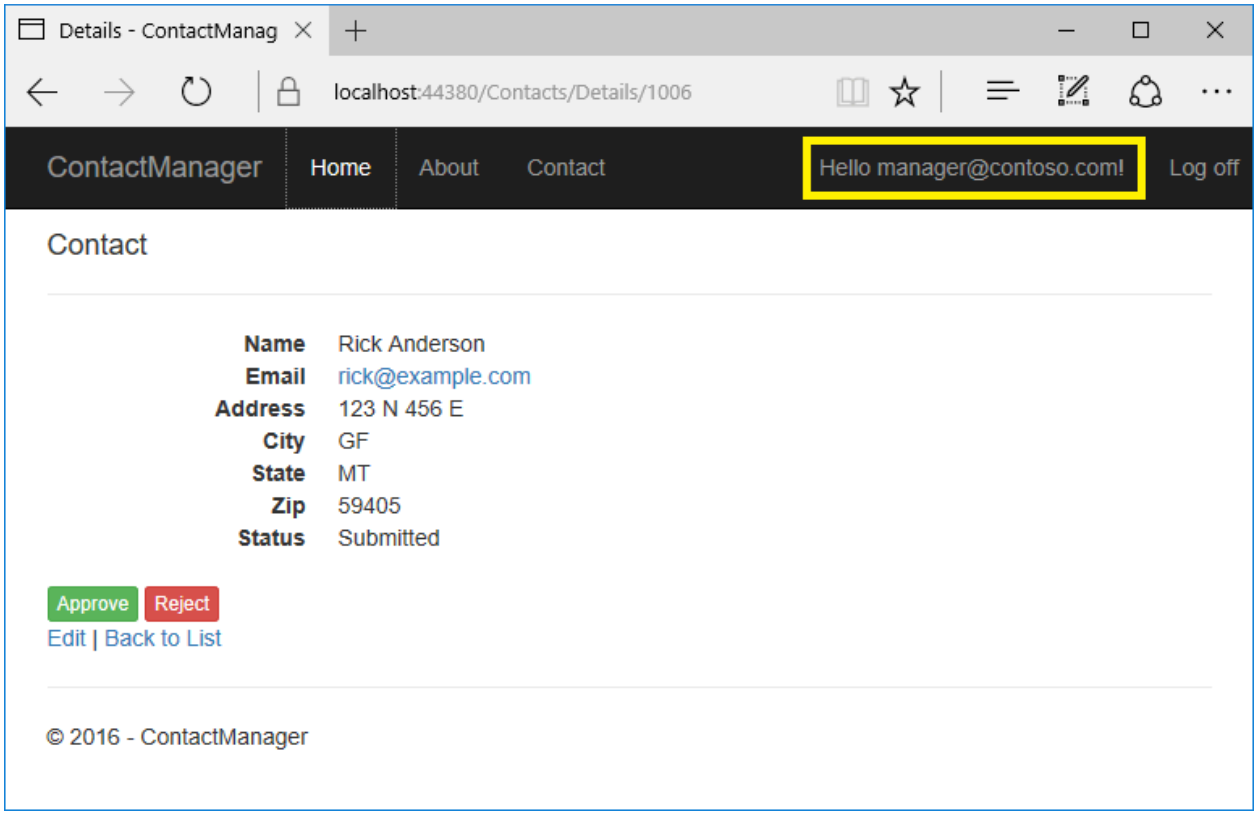
By Rick Anderson and Joe Audette

This tutorial shows how to create an ASP.NET Core web app with user data protected by authorization. It displays a list of contacts that authenticated (registered) users have created. There are three security groups:



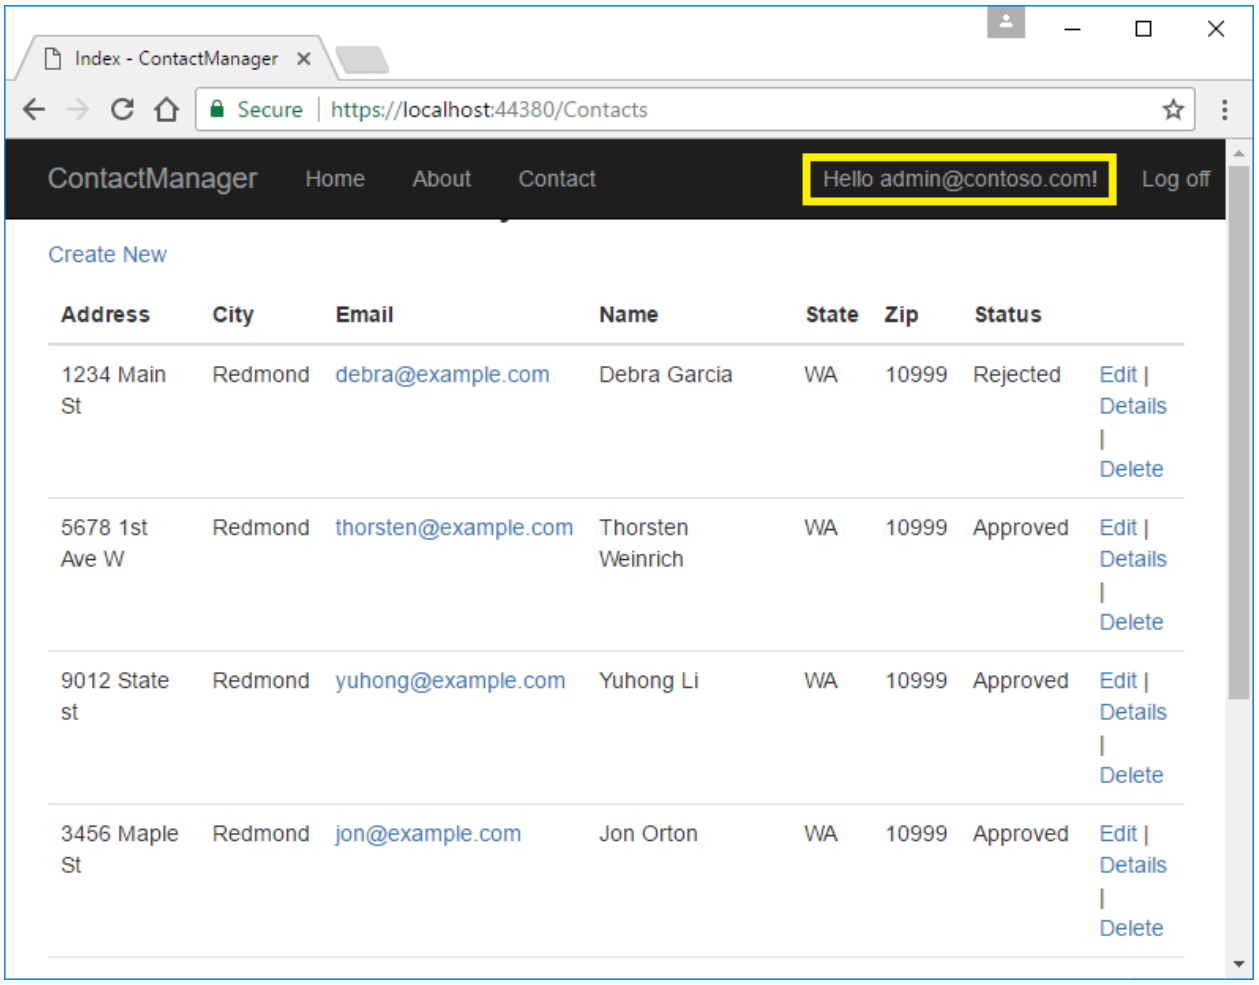
- **Registered users** can view all the approved data and can edit/delete their own data.
- **Managers** can approve or reject contact data. Only approved contacts are visible to users.
- **Administrators** can approve/reject and edit/delete any data.

The images in this document don't exactly match the latest templates.



In the following image, user Rick (`rick@example.com`) is signed in. Rick can only view approved contacts and **Edit/Delete/Create New** links for his contacts. Only the last record, created by Rick, displays **Edit** and **Delete** links. Other users won't see the last record until a manager or administrator changes the status to "Approved".

In the following image, `manager@contoso.com` is signed in and in the manager's role:



The following image shows the managers details view of a contact:

The **Approve** and **Reject** buttons are only displayed for managers and administrators.

In the following image, `admin@contoso.com` is signed in and in the administrator's role:

The administrator has all privileges. She can read, edit, or delete any contact and change the status of contacts.

The app was created by scaffolding the following `Contact` model:

C#

```
public class Contact
{
    public int ContactId { get; set; }
    public string Name { get; set; }
    public string Address { get; set; }
    public string City { get; set; }
    public string State { get; set; }
    public string Zip { get; set; }
    [DataType(DataType.EmailAddress)]
    public string Email { get; set; }
}
```

The sample contains the following authorization handlers:

- `ContactIsOwnerAuthorizationHandler`: Ensures that a user can only edit their data.

- `ContactManagerAuthorizationHandler`: Allows managers to approve or reject contacts.
- `ContactAdministratorsAuthorizationHandler`: Allows administrators to approve or reject contacts and to edit/delete contacts.

Prerequisites

This tutorial is advanced. You should be familiar with:

- ASP.NET Core
- Authentication
- Account Confirmation and Password Recovery
- Authorization
- Entity Framework Core

The starter and completed app

Download the completed app. Test the completed app so you become familiar with its security features.

The starter app

Download the starter app.

Run the app, tap the **ContactManager** link, and verify you can create, edit, and delete a contact. To create the starter app, see Create the starter app.

Secure user data

The following sections have all the major steps to create the secure user data app. You may find it helpful to refer to the completed project.

Tie the contact data to the user

Use the ASP.NET Identity user ID to ensure users can edit their data, but not other users data. Add `OwnerID` and `ContactStatus` to the `Contact` model:

C#

```
public class Contact
{
```

```
    public int ContactId { get; set; }

    // user ID from AspNetUser table.
    public string? OwnerID { get; set; }

    public string? Name { get; set; }
    public string? Address { get; set; }
    public string? City { get; set; }
    public string? State { get; set; }
    public string? Zip { get; set; }
    [DataType(DataType.EmailAddress)]
    public string? Email { get; set; }

    public ContactStatus Status { get; set; }
}

public enum ContactStatus
{
    Submitted,
    Approved,
    Rejected
}
```

`OwnerID` is the user's ID from the `AspNetUser` table in the Identity database. The `Status` field determines if a contact is viewable by general users.

Create a new migration and update the database:

.NET CLI

```
dotnet ef migrations add userID_Status
dotnet ef database update
```

Add Role services to Identity

Append AddRoles to add Role services:

C#

```
var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(
    options => options.SignIn.RequireConfirmedAccount = true)
```

```
    .AddRoles<IdentityRole>()
    .AddEntityFrameworkStores<ApplicationDbContext>();
```

Require authenticated users

Set the fallback authorization policy to require users to be authenticated:

C#

```
var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(
    options => options.SignIn.RequireConfirmedAccount = true)
    .AddRoles<IdentityRole>()
    .AddEntityFrameworkStores<ApplicationDbContext>();

builder.Services.AddRazorPages();

builder.Services.AddAuthorization(options =>
{
    options.FallbackPolicy = new AuthorizationPolicyBuilder()
        .RequireAuthenticatedUser()
        .Build();
});
```

The preceding highlighted code sets the fallback authorization policy. The fallback authorization policy requires ***all*** users to be authenticated, except for Razor Pages, controllers, or action methods with an authorization attribute. For example, Razor Pages, controllers, or action methods with `[AllowAnonymous]` or `[Authorize(PolicyName="MyPolicy")]` use the applied authorization attribute rather than the fallback authorization policy.

RequireAuthenticatedUser adds DenyAnonymousAuthorizationRequirement to the current instance, which enforces that the current user is authenticated.

The fallback authorization policy:

- Is applied to all requests that don't explicitly specify an authorization policy. For requests served by endpoint routing, this includes any endpoint that doesn't specify an authorization attribute. For requests served by other middleware after

the authorization middleware, such as static files, this applies the policy to all requests.

Setting the fallback authorization policy to require users to be authenticated protects newly added Razor Pages and controllers. Having authorization required by default is more secure than relying on new controllers and Razor Pages to include the `[Authorize]` attribute.

The AuthorizationOptions class also contains AuthorizationOptions.DefaultPolicy. The `DefaultPolicy` is the policy used with the `[Authorize]` attribute when no policy is specified. `[Authorize]` doesn't contain a named policy, unlike `[Authorize(PolicyName="MyPolicy")]`.

For more information on policies, see Policy-based authorization in ASP.NET Core.

An alternative way for MVC controllers and Razor Pages to require all users be authenticated is adding an authorization filter:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using ContactManager.Data;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.Authorization;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(
    options => options.SignIn.RequireConfirmedAccount = true)
    .AddRoles<IdentityRole>()
    .AddEntityFrameworkStores<ApplicationDbContext>();

builder.Services.AddRazorPages();

builder.Services.AddControllers(config =>
{
    var policy = new AuthorizationPolicyBuilder()
                     .RequireAuthenticatedUser()
                     .Build();
    config.Filters.Add(new AuthorizeFilter(policy));
});
```

```
var app = builder.Build();
```

The preceding code uses an authorization filter, setting the fallback policy uses endpoint routing. Setting the fallback policy is the preferred way to require all users be authenticated.

Add AllowAnonymous to the `Index` and `Privacy` pages so anonymous users can get information about the site before they register:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace ContactManager.Pages;

[AllowAnonymous]
public class IndexModel : PageModel
{
    private readonly ILogger<IndexModel> _logger;

    public IndexModel(ILogger<IndexModel> logger)
    {
        _logger = logger;
    }

    public void OnGet()
    {

    }
}
```

Configure the test account

The `SeedData` class creates two accounts: administrator and manager. Use the Secret Manager tool to set a password for these accounts. Set the password from the project directory (the directory containing `Program.cs`):

.NET CLI

```
dotnet user-secrets set SeedUserPW <PW>
```

If a weak password is specified, an exception is thrown when `SeedData.Initialize` is called.

Update the app to use the test password:

C#

```
var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(
    options => options.SignIn.RequireConfirmedAccount = true)
    .AddRoles<IdentityRole>()
    .AddEntityFrameworkStores<ApplicationDbContext>();

builder.Services.AddRazorPages();

builder.Services.AddAuthorization(options =>
{
    options.FallbackPolicy = new AuthorizationPolicyBuilder()
        .RequireAuthenticatedUser()
        .Build();
});

// Authorization handlers.
builder.Services.AddScoped<IAuthorizationHandler,
                      ContactIsOwnerAuthorizationHandler>();

builder.Services.AddSingleton<IAuthorizationHandler,
                      ContactAdministratorsAuthorizationHandler>();

builder.Services.AddSingleton<IAuthorizationHandler,
                      ContactManagerAuthorizationHandler>();

var app = builder.Build();

using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;
    var context = services.GetRequiredService<ApplicationDbContext>();
    context.Database.Migrate();
    // requires using Microsoft.Extensions.Configuration;
    // Set password with the Secret Manager tool.
    // dotnet user-secrets set SeedUserPW <pw>

    var testUserPw = builder.Configuration.GetValue<string>("SeedUserPW");

   await SeedData.Initialize(services, testUserPw);
}
```

Create the test accounts and update the contacts

Update the `Initialize` method in the `SeedData` class to create the test accounts:

C#

```
public static async Task Initialize(IServiceProvider serviceProvider, string
testUserPw)
{
    using (var context = new ApplicationDbContext(

serviceProvider.GetRequiredService<DbContextOptions<ApplicationDbContext>>
()))
    {
        // For sample purposes seed both with the same password.
        // Password is set with the following:
        // dotnet user-secrets set SeedUserPW <pw>
        // The admin user can do anything

        var adminID = await EnsureUser(serviceProvider, testUserPw,
"admin@contoso.com");
        await EnsureRole(serviceProvider, adminID,
Constants.ContactAdministratorsRole);

        // allowed user can create and edit contacts that they create
        var managerID = await EnsureUser(serviceProvider, testUserPw,
"manager@contoso.com");
        await EnsureRole(serviceProvider, managerID,
Constants.ContactManagersRole);

        SeedDB(context, adminID);
    }
}

private static async Task<string> EnsureUser(IServiceProvider
serviceProvider,
                                            string testUserPw, string
UserName)
{
    var userManager = serviceProvider.GetService<UserManager<IdentityUser>>
();

    var user = await userManager.FindByNameAsync(UserName);
    if (user == null)
    {
        user = new IdentityUser
        {
            UserName = UserName,
            EmailConfirmed = true
        };
        await userManager.CreateAsync(user, testUserPw);
    }
```

```
    if (user == null)
    {
        throw new Exception("The password is probably not strong enough!");
    }

    return user.Id;
}

private static async Task<IdentityResult> EnsureRole(IServiceProvider
serviceProvider,
                                                     string uid,
string role)
{
    var roleManager = serviceProvider.GetService<RoleManager<IdentityRole>>
();

    if (roleManager == null)
    {
        throw new Exception("roleManager null");
    }

    IdentityResult IR;
    if (!await roleManager.RoleExistsAsync(role))
    {
        IR = await roleManager.CreateAsync(new IdentityRole(role));
    }

    var userManager = serviceProvider.GetService<UserManager<IdentityUser>>
();

    //if (userManager == null)
    //{
    //    throw new Exception("userManager is null");
    //}

    var user = await userManager.FindByIdAsync(uid);

    if (user == null)
    {
        throw new Exception("The testUserPw password was probably not strong
enough!");
    }

    IR = await userManager.AddToRoleAsync(user, role);

    return IR;
}
```

Add the administrator user ID and `ContactStatus` to the contacts. Make one of the contacts "Submitted" and one "Rejected". Add the user ID and status to all the contacts. Only one contact is shown:

```
C#
```

```
public static void SeedDB(ApplicationDbContext context, string adminID)
{
    if (context.Contact.Any())
    {
        return;   // DB has been seeded
    }

    context.Contact.AddRange(
        new Contact
        {
            Name = "Debra Garcia",
            Address = "1234 Main St",
            City = "Redmond",
            State = "WA",
            Zip = "10999",
            Email = "debra@example.com",
            Status = ContactStatus.Approved,
            OwnerID = adminID
        },
```

Create owner, manager, and administrator authorization handlers

Create a `ContactIsOwnerAuthorizationHandler` class in the *Authorization* folder. The `ContactIsOwnerAuthorizationHandler` verifies that the user acting on a resource owns the resource.

C#

```
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Infrastructure;
using Microsoft.AspNetCore.Identity;
using System.Threading.Tasks;

namespace ContactManager.Authorization
{
    public class ContactIsOwnerAuthorizationHandler
                  : AuthorizationHandler<OperationAuthorizationRequirement,
Contact>
    {
        UserManager<IdentityUser> _userManager;

        public ContactIsOwnerAuthorizationHandler(UserManager<IdentityUser>
            userManager)
        {
            _userManager = userManager;
        }
```

```
        protected override Task
            HandleRequirementAsync(AuthorizationHandlerContext context,
                                   OperationAuthorizationRequirement
requirement,
                                   Contact resource)
        {
            if (context.User == null || resource == null)
            {
                return Task.CompletedTask;
            }

            // If not asking for CRUD permission, return.

            if (requirement.Name != Constants.CreateOperationName &&
                requirement.Name != Constants.ReadOperationName   &&
                requirement.Name != Constants.UpdateOperationName &&
                requirement.Name != Constants.DeleteOperationName )
            {
                return Task.CompletedTask;
            }

            if (resource.OwnerID == _userManager.GetUserId(context.User))
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

The `ContactIsOwnerAuthorizationHandler` calls context.Succeed if the current authenticated user is the contact owner. Authorization handlers generally:

- Call `context.Succeed` when the requirements are met.
- Return `Task.CompletedTask` when requirements aren't met. Returning `Task.CompletedTask` without a prior call to `context.Success` or `context.Fail`, is not a success or failure, it allows other authorization handlers to run.

If you need to explicitly fail, call context.Fail.

The app allows contact owners to edit/delete/create their own data. `ContactIsOwnerAuthorizationHandler` doesn't need to check the operation passed in the requirement parameter.

Create a manager authorization handler

Create a `ContactManagerAuthorizationHandler` class in the *Authorization* folder. The `ContactManagerAuthorizationHandler` verifies the user acting on the resource is a manager. Only managers can approve or reject content changes (new or changed).

C#

```
using System.Threading.Tasks;
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Infrastructure;
using Microsoft.AspNetCore.Identity;

namespace ContactManager.Authorization
{
    public class ContactManagerAuthorizationHandler :
        AuthorizationHandler<OperationAuthorizationRequirement, Contact>
    {
        protected override Task
            HandleRequirementAsync(AuthorizationHandlerContext context,
                                   OperationAuthorizationRequirement
requirement,
                                   Contact resource)
        {
            if (context.User == null || resource == null)
            {
                return Task.CompletedTask;
            }

            // If not asking for approval/reject, return.
            if (requirement.Name != Constants.ApproveOperationName &&
                requirement.Name != Constants.RejectOperationName)
            {
                return Task.CompletedTask;
            }

            // Managers can approve or reject.
            if (context.User.IsInRole(Constants.ContactManagersRole))
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

Create an administrator authorization handler

Create a `ContactAdministratorsAuthorizationHandler` class in the *Authorization* folder. The `ContactAdministratorsAuthorizationHandler` verifies the user acting on the resource

is an administrator. Administrator can do all operations.

C#

```
using System.Threading.Tasks;
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Infrastructure;

namespace ContactManager.Authorization
{
    public class ContactAdministratorsAuthorizationHandler
                      :
AuthorizationHandler<OperationAuthorizationRequirement, Contact>
    {
        protected override Task HandleRequirementAsync(
                                                AuthorizationHandlerContext
context,
                                       OperationAuthorizationRequirement
requirement,
                                        Contact resource)
        {
            if (context.User == null)
            {
                return Task.CompletedTask;
            }

            // Administrators can do anything.
            if (context.User.IsInRole(Constants.ContactAdministratorsRole))
            {
                context.Succeed(requirement);
            }

            return Task.CompletedTask;
        }
    }
}
```

Register the authorization handlers

Services using Entity Framework Core must be registered for dependency injection using AddScoped. The `ContactIsOwnerAuthorizationHandler` uses ASP.NET Core Identity, which is built on Entity Framework Core. Register the handlers with the service collection so they're available to the `ContactsController` through dependency injection. Add the following code to the end of `ConfigureServices`:

C#

```
var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(
    options => options.SignIn.RequireConfirmedAccount = true)
    .AddRoles<IdentityRole>()
    .AddEntityFrameworkStores<ApplicationDbContext>();

builder.Services.AddRazorPages();

builder.Services.AddAuthorization(options =>
{
    options.FallbackPolicy = new AuthorizationPolicyBuilder()
        .RequireAuthenticatedUser()
        .Build();
});

// Authorization handlers.
builder.Services.AddScoped<IAuthorizationHandler,
                      ContactIsOwnerAuthorizationHandler>();

builder.Services.AddSingleton<IAuthorizationHandler,
                      ContactAdministratorsAuthorizationHandler>();

builder.Services.AddSingleton<IAuthorizationHandler,
                      ContactManagerAuthorizationHandler>();

var app = builder.Build();

using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;
    var context = services.GetRequiredService<ApplicationDbContext>();
    context.Database.Migrate();
    // requires using Microsoft.Extensions.Configuration;
    // Set password with the Secret Manager tool.
    // dotnet user-secrets set SeedUserPW <pw>

    var testUserPw = builder.Configuration.GetValue<string>("SeedUserPW");

   await SeedData.Initialize(services, testUserPw);
}
```

`ContactAdministratorsAuthorizationHandler` and `ContactManagerAuthorizationHandler` are added as singletons. They're singletons because they don't use EF and all the information needed is in the `Context` parameter of the `HandleRequirementAsync` method.

Support authorization

In this section, you update the Razor Pages and add an operations requirements class.

Review the contact operations requirements class

Review the `ContactOperations` class. This class contains the requirements the app supports:

C#

```
using Microsoft.AspNetCore.Authorization.Infrastructure;

namespace ContactManager.Authorization
{
    public static class ContactOperations
    {
        public static OperationAuthorizationRequirement Create =
          new OperationAuthorizationRequirement
{Name=Constants.CreateOperationName};
        public static OperationAuthorizationRequirement Read =
          new OperationAuthorizationRequirement
{Name=Constants.ReadOperationName};
        public static OperationAuthorizationRequirement Update =
          new OperationAuthorizationRequirement
{Name=Constants.UpdateOperationName};
        public static OperationAuthorizationRequirement Delete =
          new OperationAuthorizationRequirement
{Name=Constants.DeleteOperationName};
        public static OperationAuthorizationRequirement Approve =
          new OperationAuthorizationRequirement
{Name=Constants.ApproveOperationName};
        public static OperationAuthorizationRequirement Reject =
          new OperationAuthorizationRequirement
{Name=Constants.RejectOperationName};
    }

    public class Constants
    {
        public static readonly string CreateOperationName = "Create";
        public static readonly string ReadOperationName = "Read";
        public static readonly string UpdateOperationName = "Update";
        public static readonly string DeleteOperationName = "Delete";
        public static readonly string ApproveOperationName = "Approve";
        public static readonly string RejectOperationName = "Reject";

        public static readonly string ContactAdministratorsRole =

"ContactAdministrators";
        public static readonly string ContactManagersRole =
"ContactManagers";
```

```
    }
}
```

Create a base class for the Contacts Razor Pages

Create a base class that contains the services used in the contacts Razor Pages. The base class puts the initialization code in one location:

C#

```
using ContactManager.Data;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace ContactManager.Pages.Contacts
{
    public class DI_BasePageModel : PageModel
    {
        protected ApplicationDbContext Context { get; }
        protected IAuthorizationService AuthorizationService { get; }
        protected UserManager<IdentityUser> UserManager { get; }

        public DI_BasePageModel(
            ApplicationDbContext context,
            IAuthorizationService authorizationService,
            UserManager<IdentityUser> userManager) : base()
        {
            Context = context;
            UserManager = userManager;
            AuthorizationService = authorizationService;
        }
    }
}
```

The preceding code:

- Adds the `IAuthorizationService` service to access to the authorization handlers.
- Adds the Identity `UserManager` service.
- Add the `ApplicationDbContext`.

Update the CreateModel

Update the create page model:

- Constructor to use the `DI_BasePageModel` base class.
- `OnPostAsync` method to:

- Add the user ID to the `Contact` model.
- Call the authorization handler to verify the user has permission to create contacts.

C#

```
using ContactManager.Authorization;
using ContactManager.Data;
using ContactManager.Models;
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Mvc;

namespace ContactManager.Pages.Contacts
{
    public class CreateModel : DI_BasePageModel
    {
        public CreateModel(
            ApplicationDbContext context,
            IAuthorizationService authorizationService,
            UserManager<IdentityUser> userManager)
            : base(context, authorizationService, userManager)
        {
        }

        public IActionResult OnGet()
        {
            return Page();
        }

        [BindProperty]
        public Contact Contact { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            Contact.OwnerID = UserManager.GetUserId(User);

            var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                        User, Contact,

ContactOperations.Create);
            if (!isAuthorized.Succeeded)
            {
                return Forbid();
            }

            Context.Contact.Add(Contact);
            await Context.SaveChangesAsync();
```

```
            return RedirectToPage("./Index");
        }
    }
}
```

Update the IndexModel

Update the `OnGetAsync` method so only approved contacts are shown to general users:

C#

```
public class IndexModel : DI_BasePageModel
{
    public IndexModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    public IList<Contact> Contact { get; set; }

    public async Task OnGetAsync()
    {
        var contacts = from c in Context.Contact
                       select c;

        var isAuthorized = User.IsInRole(Constants.ContactManagersRole) ||

User.IsInRole(Constants.ContactAdministratorsRole);

        var currentUserId = UserManager.GetUserId(User);

        // Only approved contacts are shown UNLESS you're authorized to see
them
        // or you are the owner.
        if (!isAuthorized)
        {
            contacts = contacts.Where(c => c.Status ==
ContactStatus.Approved
                                        || c.OwnerID == currentUserId);
        }

        Contact = await contacts.ToListAsync();
    }
}
```

Update the EditModel

Add an authorization handler to verify the user owns the contact. Because resource authorization is being validated, the `[Authorize]` attribute is not enough. The app doesn't have access to the resource when attributes are evaluated. Resource-based authorization must be imperative. Checks must be performed once the app has access to the resource, either by loading it in the page model or by loading it within the handler itself. You frequently access the resource by passing in the resource key.

C#

```
public class EditModel : DI_BasePageModel
{
    public EditModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    [BindProperty]
    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact? contact = await Context.Contact.FirstOrDefaultAsync(
                                                          m => m.ContactId ==
id);
        if (contact == null)
        {
            return NotFound();
        }

        Contact = contact;

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                  User, Contact,
                                                  ContactOperations.Update);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }
```

```
        // Fetch Contact from DB to get OwnerID.
        var contact = await Context
            .Contact.AsNoTracking()
            .FirstOrDefaultAsync(m => m.ContactId == id);

        if (contact == null)
        {
            return NotFound();
        }

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                 User, contact,
                                                 ContactOperations.Update);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }

        Contact.OwnerID = contact.OwnerID;

        Context.Attach(Contact).State = EntityState.Modified;

        if (Contact.Status == ContactStatus.Approved)
        {
            // If the contact is updated after approval,
            // and the user cannot approve,
            // set the status back to submitted so the update can be
            // checked and approved.
            var canApprove = await AuthorizationService.AuthorizeAsync(User,
                                     Contact,
                                     ContactOperations.Approve);

            if (!canApprove.Succeeded)
            {
                Contact.Status = ContactStatus.Submitted;
            }
        }

        await Context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

Update the DeleteModel

Update the delete page model to use the authorization handler to verify the user has delete permission on the contact.

```
C#
```

```
public class DeleteModel : DI_BasePageModel
{
    public DeleteModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    [BindProperty]
    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact? _contact = await Context.Contact.FirstOrDefaultAsync(
                                            m => m.ContactId == id);

        if (_contact == null)
        {
            return NotFound();
        }
        Contact = _contact;

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                User, Contact,
                                                ContactOperations.Delete);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id)
    {
        var contact = await Context
            .Contact.AsNoTracking()
            .FirstOrDefaultAsync(m => m.ContactId == id);

        if (contact == null)
        {
            return NotFound();
        }

        var isAuthorized = await AuthorizationService.AuthorizeAsync(
                                                User, contact,
                                                ContactOperations.Delete);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }
```

```
            Context.Contact.Remove(contact);
            await Context.SaveChangesAsync();

            return RedirectToPage("./Index");
        }
    }
```

Inject the authorization service into the views

Currently, the UI shows edit and delete links for contacts the user can't modify.

Inject the authorization service in the `Pages/_ViewImports.cshtml` file so it's available to all views:

CSHTML

```
@using Microsoft.AspNetCore.Identity
@using ContactManager
@using ContactManager.Data
@namespace ContactManager.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@using ContactManager.Authorization;
@using Microsoft.AspNetCore.Authorization
@using ContactManager.Models
@inject IAuthorizationService AuthorizationService
```

The preceding markup adds several `using` statements.

Update the **Edit** and **Delete** links in `Pages/Contacts/Index.cshtml` so they're only rendered for users with the appropriate permissions:

CSHTML

```
@page
@model ContactManager.Pages.Contacts.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
```

```
                @Html.DisplayNameFor(model => model.Contact[0].Name)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Address)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].City)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].State)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Zip)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Contact[0].Email)
            </th>
             <th>
                @Html.DisplayNameFor(model => model.Contact[0].Status)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Contact) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Name)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Address)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.City)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.State)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Zip)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Email)
            </td>
                        <td>
```

```
                    @Html.DisplayFor(modelItem => item.Status)
                </td>
                <td>
                    @if ((await AuthorizationService.AuthorizeAsync(
                     User, item,
                     ContactOperations.Update)).Succeeded)
                    {
                        <a asp-page="./Edit" asp-route-
id="@item.ContactId">Edit</a>
                        <text> | </text>
                    }

                    <a asp-page="./Details" asp-route-
id="@item.ContactId">Details</a>

                    @if ((await AuthorizationService.AuthorizeAsync(
                     User, item,
                     ContactOperations.Delete)).Succeeded)
                    {
                        <text> | </text>
                        <a asp-page="./Delete" asp-route-
id="@item.ContactId">Delete</a>
                    }
                </td>
            </tr>
        }
    </tbody>
</table>
```

> ⚠ **Warning**
>
> Hiding links from users that don't have permission to change data doesn't secure the app. Hiding links makes the app more user-friendly by displaying only valid links. Users can hack the generated URLs to invoke edit and delete operations on data they don't own. The Razor Page or controller must enforce access checks to secure the data.

Update Details

Update the details view so managers can approve or reject contacts:

CSHTML

```
        @*Preceding markup omitted for brevity.*@
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Contact.Email)
        </dt>
```

```
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Contact.Email)
        </dd>
    <dt>
            @Html.DisplayNameFor(model => model.Contact.Status)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Contact.Status)
        </dd>
    </dl>
</div>

@if (Model.Contact.Status != ContactStatus.Approved)
{
    @if ((await AuthorizationService.AuthorizeAsync(
     User, Model.Contact, ContactOperations.Approve)).Succeeded)
    {
        <form style="display:inline;" method="post">
            <input type="hidden" name="id" value="@Model.Contact.ContactId"
/>
            <input type="hidden" name="status"
value="@ContactStatus.Approved" />
            <button type="submit" class="btn btn-xs btn-
success">Approve</button>
        </form>
    }
}

@if (Model.Contact.Status != ContactStatus.Rejected)
{
    @if ((await AuthorizationService.AuthorizeAsync(
     User, Model.Contact, ContactOperations.Reject)).Succeeded)
    {
        <form style="display:inline;" method="post">
            <input type="hidden" name="id" value="@Model.Contact.ContactId"
/>
            <input type="hidden" name="status"
value="@ContactStatus.Rejected" />
            <button type="submit" class="btn btn-xs btn-
danger">Reject</button>
        </form>
    }
}

<div>
    @if ((await AuthorizationService.AuthorizeAsync(
         User, Model.Contact,
         ContactOperations.Update)).Succeeded)
    {
        <a asp-page="./Edit" asp-route-
id="@Model.Contact.ContactId">Edit</a>
        <text> | </text>
    }
    <a asp-page="./Index">Back to List</a>
</div>
```

Update the details page model

C#

```
public class DetailsModel : DI_BasePageModel
{
    public DetailsModel(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
    }

    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact? _contact = await Context.Contact.FirstOrDefaultAsync(m =>
m.ContactId == id);

        if (_contact == null)
        {
            return NotFound();
        }
        Contact = _contact;

        var isAuthorized = User.IsInRole(Constants.ContactManagersRole) ||

User.IsInRole(Constants.ContactAdministratorsRole);

        var currentUserId = UserManager.GetUserId(User);

        if (!isAuthorized
            && currentUserId != Contact.OwnerID
            && Contact.Status != ContactStatus.Approved)
        {
            return Forbid();
        }

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id, ContactStatus
status)
    {
        var contact = await Context.Contact.FirstOrDefaultAsync(
                                                  m => m.ContactId == id);

        if (contact == null)
        {
```

```
            return NotFound();
        }

        var contactOperation = (status == ContactStatus.Approved)
                                                           ?
ContactOperations.Approve
                                                           :
ContactOperations.Reject;

        var isAuthorized = await AuthorizationService.AuthorizeAsync(User,
contact,
                                         contactOperation);
        if (!isAuthorized.Succeeded)
        {
            return Forbid();
        }
        contact.Status = status;
        Context.Contact.Update(contact);
        await Context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

Add or remove a user to a role

See this issue for information on:

- Removing privileges from a user. For example, muting a user in a chat app.
- Adding privileges to a user.

Differences between Challenge and Forbid

This app sets the default policy to require authenticated users. The following code allows anonymous users. Anonymous users are allowed to show the differences between Challenge vs Forbid.

C#

```
[AllowAnonymous]
public class Details2Model : DI_BasePageModel
{
    public Details2Model(
        ApplicationDbContext context,
        IAuthorizationService authorizationService,
        UserManager<IdentityUser> userManager)
        : base(context, authorizationService, userManager)
    {
```

```
    }

    public Contact Contact { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Contact? _contact = await Context.Contact.FirstOrDefaultAsync(m =>
m.ContactId == id);

        if (_contact == null)
        {
            return NotFound();
        }
        Contact = _contact;

        if (!User.Identity!.IsAuthenticated)
        {
            return Challenge();
        }

        var isAuthorized = User.IsInRole(Constants.ContactManagersRole) ||

User.IsInRole(Constants.ContactAdministratorsRole);

        var currentUserId = UserManager.GetUserId(User);

        if (!isAuthorized
            && currentUserId != Contact.OwnerID
            && Contact.Status != ContactStatus.Approved)
        {
            return Forbid();
        }

        return Page();
    }
}
```

In the preceding code:

- When the user is **not** authenticated, a `ChallengeResult` is returned. When a `ChallengeResult` is returned, the user is redirected to the sign-in page.
- When the user is authenticated, but not authorized, a `ForbidResult` is returned. When a `ForbidResult` is returned, the user is redirected to the access denied page.

Test the completed app

> ⚠ **Warning**

This article uses the Secret Manager tool to store the password for the seeded user accounts. The Secret Manager tool is used to store sensitive data during local development. For information on authentication procedures that can be used when an app is deployed to a test or production environment, see Secure authentication flows.

If you haven't already set a password for seeded user accounts, use the Secret Manager tool to set a password:

- Choose a strong password:
  - At least 12 characters long but 14 or more is better.
  - A combination of uppercase letters, lowercase letters, numbers, and symbols.
  - Not a word that can be found in a dictionary or the name of a person, character, product, or organization.
  - Significantly different from your previous passwords.
  - Easy for you to remember but difficult for others to guess. Consider using a memorable phrase like "6MonkeysRLooking^".
- Execute the following command from the project's folder, where `<PW>` is the password:

  .NET CLI

  ```
  dotnet user-secrets set SeedUserPW <PW>
  ```

If the app has contacts:

- Delete all of the records in the `Contact` table.
- Restart the app to seed the database.

An easy way to test the completed app is to launch three different browsers (or incognito/InPrivate sessions). In one browser, register a new user (for example, `test@example.com`). Sign in to each browser with a different user. Verify the following operations:

- Registered users can view all of the approved contact data.
- Registered users can edit/delete their own data.
- Managers can approve/reject contact data. The `Details` view shows **Approve** and **Reject** buttons.
- Administrators can approve/reject and edit/delete all data.

Expand table

User	Approve or reject contacts	Options
test@example.com	No	Edit and delete their data.
manager@contoso.com	Yes	Edit and delete their data.
admin@contoso.com	Yes	Edit and delete ***all*** data.

Create a contact in the administrator's browser. Copy the URL for delete and edit from the administrator contact. Paste these links into the test user's browser to verify the test user can't perform these operations.

Create the starter app

- Create a Razor Pages app named "ContactManager"
  - Create the app with **Individual User Accounts**.
  - Name it "ContactManager" so the namespace matches the namespace used in the sample.
  - `-uld` specifies LocalDB instead of SQLite

.NET CLI

```
dotnet new webapp -o ContactManager -au Individual -uld
```

- Add `Models/Contact.cs`: secure-data\samples\starter6\ContactManager\Models\Contact.cs

C#

```
using System.ComponentModel.DataAnnotations;

namespace ContactManager.Models
{
    public class Contact
    {
        public int ContactId { get; set; }
        public string? Name { get; set; }
        public string? Address { get; set; }
        public string? City { get; set; }
        public string? State { get; set; }
        public string? Zip { get; set; }
        [DataType(DataType.EmailAddress)]
        public string? Email { get; set; }
    }
}
```

- Scaffold the `Contact` model.
- Create initial migration and update the database:

.NET CLI

```
dotnet add package Microsoft.VisualStudio.Web.CodeGeneration.Design
dotnet tool install -g dotnet-aspnet-codegenerator
dotnet-aspnet-codegenerator razorpage -m Contact -udl -dc
ApplicationDbContext -outDir Pages\Contacts --referenceScriptLibraries
dotnet ef database drop -f
dotnet ef migrations add initial
dotnet ef database update
```

> **Note**
>
> By default the architecture of the .NET binaries to install represents the currently running OS architecture. To specify a different OS architecture, see dotnet tool install, --arch option. For more information, see GitHub issue dotnet/AspNetCore.Docs #29262.

- Update the **ContactManager** anchor in the `Pages/Shared/_Layout.cshtml` file:

CSHTML

```
<a class="nav-link text-dark" asp-area="" asp-
page="/Contacts/Index">Contact Manager</a>
```

- Test the app by creating, editing, and deleting a contact

Seed the database

Add the SeedData class to the *Data* folder:

C#

```
using ContactManager.Models;
using Microsoft.EntityFrameworkCore;

// dotnet aspnet-codegenerator razorpage -m Contact -dc ApplicationDbContext
-udl -outDir Pages\Contacts --referenceScriptLibraries

namespace ContactManager.Data
{
    public static class SeedData
    {
```

```
        public static async Task Initialize(IServiceProvider
serviceProvider, string testUserPw="")
        {
            using (var context = new ApplicationDbContext(

serviceProvider.GetRequiredService<DbContextOptions<ApplicationDbContext>>
()))
            {
                SeedDB(context, testUserPw);
            }
        }

        public static void SeedDB(ApplicationDbContext context, string
adminID)
        {
            if (context.Contact.Any())
            {
                return;   // DB has been seeded
            }

            context.Contact.AddRange(
                new Contact
                {
                    Name = "Debra Garcia",
                    Address = "1234 Main St",
                    City = "Redmond",
                    State = "WA",
                    Zip = "10999",
                    Email = "debra@example.com"
                },
                new Contact
                {
                    Name = "Thorsten Weinrich",
                    Address = "5678 1st Ave W",
                    City = "Redmond",
                    State = "WA",
                    Zip = "10999",
                    Email = "thorsten@example.com"
                },
                new Contact
                {
                    Name = "Yuhong Li",
                    Address = "9012 State st",
                    City = "Redmond",
                    State = "WA",
                    Zip = "10999",
                    Email = "yuhong@example.com"
                },
                new Contact
                {
                    Name = "Jon Orton",
                    Address = "3456 Maple St",
                    City = "Redmond",
                    State = "WA",
                    Zip = "10999",
```

```
                    Email = "jon@example.com"
                },
                new Contact
                {
                    Name = "Diliana Alexieva-Bosseva",
                    Address = "7890 2nd Ave E",
                    City = "Redmond",
                    State = "WA",
                    Zip = "10999",
                    Email = "diliana@example.com"
                }
             );
            context.SaveChanges();
        }

    }
}
```

Call `SeedData.Initialize` from `Program.cs`:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using ContactManager.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

var app = builder.Build();

using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    await SeedData.Initialize(services);
}

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
```

```
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Test that the app seeded the database. If there are any rows in the contact DB, the seed method doesn't run.

Razor Pages authorization conventions in ASP.NET Core

Article • 06/03/2022

One way to control access in your Razor Pages app is to use authorization conventions at startup. These conventions allow you to authorize users and allow anonymous users to access individual pages or folders of pages. The conventions described in this topic automatically apply authorization filters to control access.

View or download sample code (how to download)

The sample app uses cookie authentication without ASP.NET Core Identity. The concepts and examples shown in this topic apply equally to apps that use ASP.NET Core Identity. To use ASP.NET Core Identity, follow the guidance in Introduction to Identity on ASP.NET Core.

Require authorization to access a page

Use the AuthorizePage convention to add an AuthorizeFilter to the page at the specified path:

C#

```
services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/Contact");
    options.Conventions.AuthorizeFolder("/Private");
    options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
    options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
});
```

The specified path is the View Engine path, which is the Razor Pages root relative path without an extension and containing only forward slashes.

To specify an authorization policy, use an AuthorizePage overload:

C#

```
options.Conventions.AuthorizePage("/Contact", "AtLeast21");
```

Note

An **AuthorizeFilter** can be applied to a page model class with the `[Authorize]` filter attribute. For more information, see **Authorize filter attribute**.

Require authorization to access a folder of pages

Use the AuthorizeFolder convention to add an AuthorizeFilter to all of the pages in a folder at the specified path:

C#

```
services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/Contact");
    options.Conventions.AuthorizeFolder("/Private");
    options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
    options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
});
```

The specified path is the View Engine path, which is the Razor Pages root relative path.

To specify an authorization policy, use an AuthorizeFolder overload:

C#

```
options.Conventions.AuthorizeFolder("/Private", "AtLeast21");
```

Require authorization to access an area page

Use the AuthorizeAreaPage convention to add an AuthorizeFilter to the area page at the specified path:

C#

```
options.Conventions.AuthorizeAreaPage("Identity", "/Manage/Accounts");
```

The page name is the path of the file without an extension relative to the pages root directory for the specified area. For example, the page name for the file `Areas/Identity/Pages/Manage/Accounts.cshtml` is */Manage/Accounts*.

To specify an authorization policy, use an AuthorizeAreaPage overload:

C#

```
options.Conventions.AuthorizeAreaPage("Identity", "/Manage/Accounts",
"AtLeast21");
```

Require authorization to access a folder of areas

Use the AuthorizeAreaFolder convention to add an AuthorizeFilter to all of the areas in a folder at the specified path:

C#

```
options.Conventions.AuthorizeAreaFolder("Identity", "/Manage");
```

The folder path is the path of the folder relative to the pages root directory for the specified area. For example, the folder path for the files under *Areas/Identity/Pages/Manage/* is */Manage*.

To specify an authorization policy, use an AuthorizeAreaFolder overload:

C#

```
options.Conventions.AuthorizeAreaFolder("Identity", "/Manage", "AtLeast21");
```

Allow anonymous access to a page

Use the AllowAnonymousToPage convention to add an AllowAnonymousFilter to a page at the specified path:

C#

```
services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/Contact");
    options.Conventions.AuthorizeFolder("/Private");
    options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
    options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
});
```

The specified path is the View Engine path, which is the Razor Pages root relative path without an extension and containing only forward slashes.

Allow anonymous access to a folder of pages

Use the AllowAnonymousToFolder convention to add an AllowAnonymousFilter to all of the pages in a folder at the specified path:

```
C#

services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/Contact");
    options.Conventions.AuthorizeFolder("/Private");
    options.Conventions.AllowAnonymousToPage("/Private/PublicPage");
    options.Conventions.AllowAnonymousToFolder("/Private/PublicPages");
});
```

The specified path is the View Engine path, which is the Razor Pages root relative path.

Note on combining authorized and anonymous access

It's valid to specify that a folder of pages requires authorization and then specify that a page within that folder allows anonymous access:

```
C#

// This works.
.AuthorizeFolder("/Private").AllowAnonymousToPage("/Private/Public")
```

The reverse, however, isn't valid. You can't declare a folder of pages for anonymous access and then specify a page within that folder that requires authorization:

```
C#

// This doesn't work!
.AllowAnonymousToFolder("/Public").AuthorizePage("/Public/Private")
```

Requiring authorization on the Private page fails. When both the AllowAnonymousFilter and AuthorizeFilter are applied to the page, the AllowAnonymousFilter takes precedence and controls access.

Simple authorization in ASP.NET Core

Article • 05/02/2024

Authorization in ASP.NET Core is controlled with the [Authorize] attribute and its various parameters. In its most basic form, applying the `[Authorize]` attribute to a controller, action, or Razor Page, limits access to that component to authenticated users.

Prerequisites

This article assumes that you have a basic understanding of ASP.NET Core Razor Pages and MVC. If you're new to ASP.NET Core, see the following resources:

- Introduction to Razor Pages in ASP.NET Core
- Overview of ASP.NET Core MVC
- Tutorial: Get started with Razor Pages in ASP.NET Core
- Introduction to Identity on ASP.NET Core

Use the `[Authorize]` attribute

The following code limits access to the `AccountController` to authenticated users:

C#

```
[Authorize]
public class AccountController : Controller
{
    public ActionResult Login()
    {
    }

    public ActionResult Logout()
    {
    }
}
```

If you want to apply authorization to an action rather than the controller, apply the `AuthorizeAttribute` attribute to the action itself:

C#

```
public class AccountController : Controller
{
   public ActionResult Login()
```

```
    {
    }

    [Authorize]
    public ActionResult Logout()
    {
    }
}
```

Now only authenticated users can access the `Logout` function.

You can also use the `AllowAnonymous` attribute to allow access by non-authenticated users to individual actions. For example:

C#

```
[Authorize]
public class AccountController : Controller
{
    [AllowAnonymous]
    public ActionResult Login()
    {
    }

    public ActionResult Logout()
    {
    }
}
```

This would allow only authenticated users to the `AccountController`, except for the `Login` action, which is accessible by everyone, regardless of their authenticated or unauthenticated / anonymous status.

> ⚠ **Warning**
>
> `[AllowAnonymous]` bypasses authorization statements. If you combine `[AllowAnonymous]` and an `[Authorize]` attribute, the `[Authorize]` attributes are ignored. For example if you apply `[AllowAnonymous]` at the controller level:
>
> - Any authorization requirements from `[Authorize]` attributes on the same controller or action methods on the controller are ignored.
> - Authentication middleware is not short-circuited but doesn't need to succeed.

The following code limits access to the `LogoutModel` Razor Page to authenticated users:

C#

```
[Authorize]
public class LogoutModel : PageModel
{
    public async Task OnGetAsync()
    {

    }

    public async Task<IActionResult> OnPostAsync()
    {

    }
}
```

For information on how to globally require all users to be authenticated, see Require authenticated users.

Authorize attribute and Razor Pages

The AuthorizeAttribute can ***not*** be applied to Razor Page handlers. For example, `[Authorize]` can't be applied to `OnGet`, `OnPost`, or any other page handler. Consider using an ASP.NET Core MVC controller for pages with different authorization requirements for different handlers. Using an MVC controller when different authorization requirements are required:

- Is the least complex approach.
- Is the approach recommended by Microsoft.

If you decide not to use an MVC controller, the following two approaches can be used to apply authorization to Razor Page handler methods:

- Use separate pages for page handlers requiring different authorization. Move shared content into one or more partial views. When possible, this is the recommended approach.

- For content that must share a common page, write a filter that performs authorization as part of IAsyncPageFilter.OnPageHandlerSelectionAsync. The PageHandlerAuth GitHub project demonstrates this approach:
  - The AuthorizeIndexPageHandlerFilter implements the authorization filter:

    C#

    ```
    [TypeFilter(typeof(AuthorizeIndexPageHandlerFilter))]
    public class IndexModel : PageModel
    ```

```
{
    private readonly ILogger<IndexModel> _logger;

    public IndexModel(ILogger<IndexModel> logger)
    {
        _logger = logger;
    }

    public void OnGet()
    {

    }

    public void OnPost()
    {

    }

    [AuthorizePageHandler]
    public void OnPostAuthorized()
    {

    }
}
```

- The [AuthorizePageHandler] attribute is applied to the `OnPostAuthorized` page handler:

C#

```
public class AuthorizeIndexPageHandlerFilter : IAsyncPageFilter,
IOrderedFilter
{
    private readonly IAuthorizationPolicyProvider policyProvider;
    private readonly IPolicyEvaluator policyEvaluator;

    public AuthorizeIndexPageHandlerFilter(
        IAuthorizationPolicyProvider policyProvider,
        IPolicyEvaluator policyEvaluator)
    {
        this.policyProvider = policyProvider;
        this.policyEvaluator = policyEvaluator;
    }

    // Run late in the selection pipeline
    public int Order => 10000;

    public Task OnPageHandlerExecutionAsync(PageHandlerExecutingContext
context, PageHandlerExecutionDelegate next) => next();

    public async Task
OnPageHandlerSelectionAsync(PageHandlerSelectedContext context)
    {
        var attribute =
```

```
context.HandlerMethod?.MethodInfo?.GetCustomAttribute<AuthorizePageHand
lerAttribute>();
        if (attribute is null)
        {
            return;
        }

        var policy = await
AuthorizationPolicy.CombineAsync(policyProvider, new[] { attribute });
        if (policy is null)
        {
            return;
        }

        await AuthorizeAsync(context, policy);
    }

    #region AuthZ - do not change
    private async Task AuthorizeAsync(ActionContext actionContext,
AuthorizationPolicy policy)
    {
        var httpContext = actionContext.HttpContext;
        var authenticateResult = await
policyEvaluator.AuthenticateAsync(policy, httpContext);
        var authorizeResult = await
policyEvaluator.AuthorizeAsync(policy, authenticateResult, httpContext,
actionContext.ActionDescriptor);
        if (authorizeResult.Challenged)
        {
            if (policy.AuthenticationSchemes.Count > 0)
            {
                foreach (var scheme in policy.AuthenticationSchemes)
                {
                    await httpContext.ChallengeAsync(scheme);
                }
            }
            else
            {
                await httpContext.ChallengeAsync();
            }

            return;
        }
        else if (authorizeResult.Forbidden)
        {
            if (policy.AuthenticationSchemes.Count > 0)
            {
                foreach (var scheme in policy.AuthenticationSchemes)
                {
                    await httpContext.ForbidAsync(scheme);
                }
            }
            else
            {
                await httpContext.ForbidAsync();
```

```
            }

            return;
        }
    }
```

> ⚠ **Warning**
>
> The PageHandlerAuth sample approach does ***not***:
>
> - Compose with authorization attributes applied to the page, page model, or globally. Composing authorization attributes results in authentication and authorization executing multiple times when you have one more `AuthorizeAttribute` or `AuthorizeFilter` instances also applied to the page.
> - Work in conjunction with the rest of ASP.NET Core authentication and authorization system. You must verify using this approach works correctly for your application.

There are no plans to support the `AuthorizeAttribute` on Razor Page handlers.

Custom authorization policies with IAuthorizationRequirementData

Article • 06/16/2023

Consider the following sample that implements a custom `MinimumAgeAuthorizationHandler`:

C#

```
using AuthRequirementsData.Authorization;
using Microsoft.AspNetCore.Authorization;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAuthentication().AddJwtBearer();
builder.Services.AddAuthorization();
builder.Services.AddControllers();
builder.Services.AddSingleton<IAuthorizationHandler,
MinimumAgeAuthorizationHandler>();

var app = builder.Build();

app.MapControllers();

app.Run();
```

The `MinimumAgeAuthorizationHandler` class:

C#

```
using Microsoft.AspNetCore.Authorization;
using System.Globalization;
using System.Security.Claims;

namespace AuthRequirementsData.Authorization;

class MinimumAgeAuthorizationHandler :
AuthorizationHandler<MinimumAgeAuthorizeAttribute>
{
    private readonly ILogger<MinimumAgeAuthorizationHandler> _logger;

    public
MinimumAgeAuthorizationHandler(ILogger<MinimumAgeAuthorizationHandler>
logger)
    {
        _logger = logger;
    }
```

```
    // Check whether a given MinimumAgeRequirement is satisfied or not for a
particular
    // context.
    protected override Task
HandleRequirementAsync(AuthorizationHandlerContext context,
                                                MinimumAgeAuthorizeAttribute
requirement)
    {
        // Log as a warning so that it's very clear in sample output which
authorization
        // policies(and requirements/handlers) are in use.
        _logger.LogWarning("Evaluating authorization requirement for age >=
{age}",

requirement.Age);

        // Check the user's age.
        var dateOfBirthClaim = context.User.FindFirst(c => c.Type ==

ClaimTypes.DateOfBirth);
        if (dateOfBirthClaim != null)
        {
            // If the user has a date of birth claim, check their age.
            var dateOfBirth = Convert.ToDateTime(dateOfBirthClaim.Value,

CultureInfo.InvariantCulture);
            var age = DateTime.Now.Year - dateOfBirth.Year;
            if (dateOfBirth > DateTime.Now.AddYears(-age))
            {
                // Adjust age if the user hasn't had a birthday yet this
year.
                age--;
            }

            // If the user meets the age criterion, mark the authorization
requirement
            // succeeded.
            if (age >= requirement.Age)
            {
                _logger.LogInformation(
                    "Minimum age authorization requirement {age} satisfied",
                      requirement.Age);
                context.Succeed(requirement);
            }
            else
            {
                _logger.LogInformation("Current user's DateOfBirth claim
({dateOfBirth})"
                   + " does not satisfy the minimum age authorization
requirement {age}",
                    dateOfBirthClaim.Value,
                    requirement.Age);
            }
        }
        else
```

```
        {
            _logger.LogInformation("No DateOfBirth claim present");
        }

        return Task.CompletedTask;
    }
}
```

The custom `MinimumAgePolicyProvider`:

C#

```
using Microsoft.AspNetCore.Authentication.JwtBearer;
using Microsoft.AspNetCore.Authorization;
using Microsoft.Extensions.Options;

namespace AuthRequirementsData.Authorization;

class MinimumAgePolicyProvider : IAuthorizationPolicyProvider
{
    const string POLICY_PREFIX = "MinimumAge";
    public DefaultAuthorizationPolicyProvider FallbackPolicyProvider { get;
}
    public MinimumAgePolicyProvider(IOptions<AuthorizationOptions> options)
    {
        FallbackPolicyProvider = new
DefaultAuthorizationPolicyProvider(options);
    }
    public Task<AuthorizationPolicy> GetDefaultPolicyAsync() =>
                            FallbackPolicyProvider.GetDefaultPolicyAsync();
    public Task<AuthorizationPolicy?> GetFallbackPolicyAsync() =>
                            FallbackPolicyProvider.GetFallbackPolicyAsync();

    public Task<AuthorizationPolicy?> GetPolicyAsync(string policyName)
    {
        if (policyName.StartsWith(POLICY_PREFIX,
StringComparison.OrdinalIgnoreCase) &&
            int.TryParse(policyName.Substring(POLICY_PREFIX.Length), out var
age))
        {
            var policy = new AuthorizationPolicyBuilder(

JwtBearerDefaults.AuthenticationScheme);
            policy.AddRequirements(new MinimumAgeRequirement(age));
            return Task.FromResult<AuthorizationPolicy?>(policy.Build());
        }

        return Task.FromResult<AuthorizationPolicy?>(null);
    }
}
```

ASP.NET Core only uses one authorization policy provider. If the custom implementation doesn't handle all policies, including default policies, etc., it should fall back to an alternate provider. In the preceding sample, a default authorization policy provider is:

- Constructed with options from the dependency injection container.
- Used if this custom provider isn't able to handle a given policy name.

If a custom policy provider is able to handle all expected policy names, setting the fallback policy with GetFallbackPolicyAsync() isn't required.

C#

```
class MinimumAgePolicyProvider : IAuthorizationPolicyProvider
{
    const string POLICY_PREFIX = "MinimumAge";
    public DefaultAuthorizationPolicyProvider FallbackPolicyProvider { get;
}
    public MinimumAgePolicyProvider(IOptions<AuthorizationOptions> options)
    {
        FallbackPolicyProvider = new
DefaultAuthorizationPolicyProvider(options);
    }
    public Task<AuthorizationPolicy> GetDefaultPolicyAsync() =>
                            FallbackPolicyProvider.GetDefaultPolicyAsync();
    public Task<AuthorizationPolicy?> GetFallbackPolicyAsync() =>
                            FallbackPolicyProvider.GetFallbackPolicyAsync();
```

Policies are looked up by string name, therefore parameters, for example, `age`, are embedded in the policy names. This is abstracted away from developers by the more strongly-typed attributes derived from AuthorizeAttribute. For example, the `[MinimumAgeAuthorize()]` attribute in this sample looks up policies by string name.

C#

```
public Task<AuthorizationPolicy?> GetPolicyAsync(string policyName)
{
    if (policyName.StartsWith(POLICY_PREFIX,
StringComparison.OrdinalIgnoreCase) &&
        int.TryParse(policyName.Substring(POLICY_PREFIX.Length), out var
age))
    {
        var policy = new AuthorizationPolicyBuilder(

JwtBearerDefaults.AuthenticationScheme);
        policy.AddRequirements(new MinimumAgeRequirement(age));
        return Task.FromResult<AuthorizationPolicy?>(policy.Build());
    }
```

```
    return Task.FromResult<AuthorizationPolicy?>(null);
}
```

The `MinimumAgeAuthorizeAttribute` uses the IAuthorizationRequirementData interface that allows the attribute definition to specify the requirements associated with the authorization policy:

C#

```
using Microsoft.AspNetCore.Authorization;

namespace AuthRequirementsData.Authorization;

class MinimumAgeAuthorizeAttribute : AuthorizeAttribute,
IAuthorizationRequirement,
                                     IAuthorizationRequirementData
{
    public MinimumAgeAuthorizeAttribute(int age) => Age = age;
    public int Age { get; }

    public IEnumerable<IAuthorizationRequirement> GetRequirements()
    {
        yield return this;
    }
}
```

The `GreetingsController` displays the user's name when they satisfy the minimum age policy:

C#

```
using AuthRequirementsData.Authorization;
using Microsoft.AspNetCore.Mvc;

namespace AuthRequirementsData.Controllers;

[ApiController]
[Route("api/[controller]")]
public class GreetingsController : Controller
{
    [MinimumAgeAuthorize(16)]
    [HttpGet("hello")]
    public string Hello() => $"Hello {(HttpContext.User.Identity?.Name ??
"world")}!";
}
```

The complete sample can be found in the AuthRequirementsData folder of the AspNetCore.Docs.Samples repository.

The sample can be tested with dotnet user-jwts and curl:

- `dotnet user-jwts create --claim http://schemas.xmlsoap.org/ws/2005/05/identity/claims/dateofbirth=1989-01-01`
- `curl -i -H "Authorization: Bearer <token from dotnet user-jwts>" http://localhost:<port>/api/greetings/hello`

Role-based authorization in ASP.NET Core

Article • 09/27/2024

When an identity is created it may belong to one or more roles. For example, Tracy may belong to the `Administrator` and `User` roles while Scott may only belong to the `User` role. How these roles are created and managed depends on the backing store of the authorization process. Roles are exposed to the developer through the IsInRole method on the ClaimsPrincipal class. AddRoles must be added to Role services.

While roles are claims, not all claims are roles. Depending on the identity issuer a role may be a collection of users that may apply claims for group members, as well as an actual claim on an identity. However, claims are meant to be information about an individual user. Using roles to add claims to a user can confuse the boundary between the user and their individual claims. This confusion is why the SPA templates are not designed around roles. In addition, for organizations migrating from an on-premises legacy system the proliferation of roles over the years can mean a role claim may be too large to be contained within a token usable by SPAs. To secure SPAs, see Use Identity to secure a Web API backend for SPAs.

Add Role services to Identity

Register role-based authorization services in `Program.cs` by calling AddRoles with the role type in the app's Identity configuration. The role type in the following example is `IdentityRole`:

C#

```
builder.Services.AddDefaultIdentity<IdentityUser>( ... )
    .AddRoles<IdentityRole>()
    ...
```

The preceding code requires the Microsoft.AspNetCore.Identity.UI package and a `using` directive for `Microsoft.AspNetCore.Identity`.

Adding role checks

Role based authorization checks:

- Are declarative and specify roles which the current user must be a member of to access the requested resource.
- Are applied to Razor Pages, controllers, or actions within a controller.
- Can ***not*** be applied at the Razor Page handler level, they must be applied to the Page.

For example, the following code limits access to any actions on the `AdministrationController` to users who are a member of the `Administrator` role:

C#

```
[Authorize(Roles = "Administrator")]
public class AdministrationController : Controller
{
    public IActionResult Index() =>
        Content("Administrator");
}
```

Multiple roles can be specified as a comma separated list:

C#

```
[Authorize(Roles = "HRManager,Finance")]
public class SalaryController : Controller
{
    public IActionResult Payslip() =>
                    Content("HRManager || Finance");
}
```

The `SalaryController` is only accessible by users who are members of the `HRManager` role ***or*** the `Finance` role.

When multiple attributes are applied, an accessing user must be a member of ***all*** the roles specified. The following sample requires that a user must be a member of ***both*** the `PowerUser` ***and*** `ControlPanelUser` role:

C#

```
[Authorize(Roles = "PowerUser")]
[Authorize(Roles = "ControlPanelUser")]
public class ControlPanelController : Controller
{
    public IActionResult Index() =>
        Content("PowerUser && ControlPanelUser");
}
```

Access to an action can be limited by applying additional role authorization attributes at the action level:

C#

```
[Authorize(Roles = "Administrator, PowerUser")]
public class ControlAllPanelController : Controller
{
    public IActionResult SetTime() =>
        Content("Administrator || PowerUser");

    [Authorize(Roles = "Administrator")]
    public IActionResult ShutDown() =>
        Content("Administrator only");
}
```

In the preceding `ControlAllPanelController` controller:

- Members of the `Administrator` role or the `PowerUser` role can access the controller and the `SetTime` action.
- Only members of the `Administrator` role can access the `ShutDown` action.

A controller can be secured but allow anonymous, unauthenticated access to individual actions:

C#

```
[Authorize]
public class Control3PanelController : Controller
{
    public IActionResult SetTime() =>
        Content("[Authorize]");

    [AllowAnonymous]
    public IActionResult Login() =>
        Content("[AllowAnonymous]");
}
```

For Razor Pages, [Authorize] can be applied by either:

- Using a convention, or
- Applying the [Authorize] to the `PageModel` instance:

C#

```
[Authorize(Policy = "RequireAdministratorRole")]
public class UpdateModel : PageModel
{
```

```
    public IActionResult OnPost() =>
        Content("OnPost RequireAdministratorRole");
}
```

> **ⓘ Important**
>
> Filter attributes, including `AuthorizeAttribute`, can only be applied to PageModel and cannot be applied to specific page handler methods.

Policy based role checks

Role requirements can also be expressed using the Policy syntax, where a developer registers a policy at application startup as part of the Authorization service configuration. This typically occurs in the `Program.cs` file:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddAuthorization(options =>
{
    options.AddPolicy("RequireAdministratorRole",
        policy => policy.RequireRole("Administrator"));
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthentication();
app.UseAuthorization();

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.Run();
```

Policies are applied using the Policy property on the [Authorize] attribute:

```
C#

[Authorize(Policy = "RequireAdministratorRole")]
public IActionResult Shutdown()
{
    return View();
}
```

To specify multiple allowed roles in a requirement, specify them as parameters to the RequireRole method:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddAuthorization(options =>
{
    options.AddPolicy("ElevatedRights", policy =>
          policy.RequireRole("Administrator", "PowerUser",
"BackupAdministrator"));
});

var app = builder.Build();
```

The preceding code authorizes users who belong to the `Administrator`, `PowerUser` or `BackupAdministrator` roles.

Claims-based authorization in ASP.NET Core

Article • 11/10/2023

When an identity is created it may be assigned one or more claims issued by a trusted party. A claim is a name value pair that represents what the subject is, not what the subject can do. For example, you may have a driver's license, issued by a local driving license authority. Your driver's license has your date of birth on it. In this case the claim name would be `DateOfBirth`, the claim value would be your date of birth, for example `8th June 1970` and the issuer would be the driving license authority. Claims-based authorization, at its simplest, checks the value of a claim and allows access to a resource based upon that value. For example if you want access to a night club the authorization process might be:

The door security officer would evaluate the value of your date of birth claim and whether they trust the issuer (the driving license authority) before granting you access.

An identity can contain multiple claims with multiple values and can contain multiple claims of the same type.

Adding claims checks

Claim-based authorization checks:

- Are declarative.
- Are applied to Razor Pages, controllers, or actions within a controller.
- Can ***not*** be applied at the Razor Page handler level, they must be applied to the Page.

Claims in code specify claims which the current user must possess, and optionally the value the claim must hold to access the requested resource. Claims requirements are policy based; the developer must build and register a policy expressing the claims requirements.

The simplest type of claim policy looks for the presence of a claim and doesn't check the value.

Build and register the policy and call UseAuthorization. Registering the policy takes place as part of the Authorization service configuration, typically in the `Program.cs` file:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddAuthorization(options =>
{
   options.AddPolicy("EmployeeOnly", policy =>
policy.RequireClaim("EmployeeNumber"));
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthentication();
app.UseAuthorization();

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.Run();
```

In this case the `EmployeeOnly` policy checks for the presence of an `EmployeeNumber` claim on the current identity.

Apply the policy using the `Policy` property on the [Authorize] attribute to specify the policy name.

C#

```
[Authorize(Policy = "EmployeeOnly")]
public IActionResult VacationBalance()
{
    return View();
}
```

The `[Authorize]` attribute can be applied to an entire controller or Razor Page, in which case only identities matching the policy are allowed access to any Action on the controller.

C#

```
[Authorize(Policy = "EmployeeOnly")]
public class VacationController : Controller
{
    public IActionResult Index()
    {
        return View();
    }

    public ActionResult VacationBalance()
    {
        return View();
    }

    [AllowAnonymous]
    public ActionResult VacationPolicy()
    {
        return View();
    }
}
```

The following code applies the `[Authorize]` attribute to a Razor Page:

C#

```
[Authorize(Policy = "EmployeeOnly")]
public class IndexModel : PageModel
{
    public void OnGet()
    {

    }
}
```

Policies can ***not*** be applied at the Razor Page handler level, they must be applied to the Page.

If you have a controller that's protected by the `[Authorize]` attribute but want to allow anonymous access to particular actions, you apply the `AllowAnonymousAttribute` attribute.

C#

```
[Authorize(Policy = "EmployeeOnly")]
public class VacationController : Controller
{
    public IActionResult Index()
    {
        return View();
    }
```

```
    public ActionResult VacationBalance()
    {
        return View();
    }

    [AllowAnonymous]
    public ActionResult VacationPolicy()
    {
        return View();
    }
}
```

Because policies can ***not*** be applied at the Razor Page handler level, we recommend using a controller when policies must be applied at the page handler level. The rest of the app that doesn't require policies at the Razor Page handler level can use Razor Pages.

Most claims come with a value. You can specify a list of allowed values when creating the policy. The following example would only succeed for employees whose employee number was 1, 2, 3, 4, or 5.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddAuthorization(options =>
{
    options.AddPolicy("Founders", policy =>
                      policy.RequireClaim("EmployeeNumber", "1", "2", "3",
"4", "5"));
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthentication();
app.UseAuthorization();

app.MapDefaultControllerRoute();
```

```
app.MapRazorPages();

app.Run();
```

Add a generic claim check

If the claim value isn't a single value or a transformation is required, use RequireAssertion. For more information, see Use a func to fulfill a policy.

Multiple Policy Evaluation

If multiple policies are applied at the controller and action levels, ***all*** policies must pass before access is granted:

C#

```
[Authorize(Policy = "EmployeeOnly")]
public class SalaryController : Controller
{
    public IActionResult Index()
    {
        return View();
    }

    public IActionResult Payslip()
    {
        return View();
    }

    [Authorize(Policy = "HumanResources")]
    public IActionResult UpdateSalary()
    {
        return View();
    }
}
```

In the preceding example any identity which fulfills the `EmployeeOnly` policy can access the `Payslip` action as that policy is enforced on the controller. However, in order to call the `UpdateSalary` action the identity must fulfill *both* the `EmployeeOnly` policy and the `HumanResources` policy.

If you want more complicated policies, such as taking a date of birth claim, calculating an age from it, and then checking that the age is 21 or older, then you need to write custom policy handlers.

In the following sample, both page handler methods must fulfill *both* the `EmployeeOnly` policy and the `HumanResources` policy:

C#

```
[Authorize(Policy = "EmployeeOnly")]
[Authorize(Policy = "HumanResources")]
public class SalaryModel : PageModel
{
    public ContentResult OnGetPayStub()
    {
        return Content("OnGetPayStub");
    }

    public ContentResult OnGetSalary()
    {
        return Content("OnGetSalary");
    }
}
```

Policy-based authorization in ASP.NET Core

Article • 08/08/2024

Underneath the covers, role-based authorization and claims-based authorization use a requirement, a requirement handler, and a preconfigured policy. These building blocks support the expression of authorization evaluations in code. The result is a richer, reusable, testable authorization structure.

An authorization policy consists of one or more requirements. Register it as part of the authorization service configuration, in the app's `Program.cs` file:

C#

```
builder.Services.AddAuthorization(options =>
{
    options.AddPolicy("AtLeast21", policy =>
        policy.Requirements.Add(new MinimumAgeRequirement(21)));
});
```

In the preceding example, an "AtLeast21" policy is created. It has a single requirement—that of a minimum age, which is supplied as a parameter to the requirement.

IAuthorizationService

The primary service that determines if authorization is successful is IAuthorizationService:

C#

```
/// <summary>
/// Checks policy based permissions for a user
/// </summary>
public interface IAuthorizationService
{
    /// <summary>
    /// Checks if a user meets a specific set of requirements for the
specified resource
    /// </summary>
    /// <param name="user">The user to evaluate the requirements against.
</param>
    /// <param name="resource">
    /// An optional resource the policy should be checked with.
    /// If a resource is not required for policy evaluation you may pass
null as the value
```

```
    /// </param>
    /// <param name="requirements">The requirements to evaluate.</param>
    /// <returns>
    /// A flag indicating whether authorization has succeeded.
    /// This value is <value>true</value> when the user fulfills the policy;
    /// otherwise <value>false</value>.
    /// </returns>
    /// <remarks>
    /// Resource is an optional parameter and may be null. Please ensure
that you check
    /// it is not null before acting upon it.
    /// </remarks>
    Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user, object
resource,
                                        IEnumerable<IAuthorizationRequirement>
requirements);

    /// <summary>
    /// Checks if a user meets a specific authorization policy
    /// </summary>
    /// <param name="user">The user to check the policy against.</param>
    /// <param name="resource">
    /// An optional resource the policy should be checked with.
    /// If a resource is not required for policy evaluation you may pass
null as the value
    /// </param>
    /// <param name="policyName">The name of the policy to check against a
specific
    /// context.</param>
    /// <returns>
    /// A flag indicating whether authorization has succeeded.
    /// Returns a flag indicating whether the user, and optional resource
has fulfilled
    /// the policy.
    /// <value>true</value> when the policy has been fulfilled;
    /// otherwise <value>false</value>.
    /// </returns>
    /// <remarks>
    /// Resource is an optional parameter and may be null. Please ensure
that you check
    /// it is not null before acting upon it.
    /// </remarks>
    Task<AuthorizationResult> AuthorizeAsync(
                                    ClaimsPrincipal user, object resource,
string policyName);
}
```

The preceding code highlights the two methods of the IAuthorizationService.

IAuthorizationRequirement is a marker service with no methods, and the mechanism for tracking whether authorization is successful.

Each IAuthorizationHandler is responsible for checking if requirements are met:

C#

```
/// <summary>
/// Classes implementing this interface are able to make a decision if
authorization
/// is allowed.
/// </summary>
public interface IAuthorizationHandler
{
    /// <summary>
    /// Makes a decision if authorization is allowed.
    /// </summary>
    /// <param name="context">The authorization information.</param>
    Task HandleAsync(AuthorizationHandlerContext context);
}
```

The AuthorizationHandlerContext class is what the handler uses to mark whether requirements have been met:

C#

```
 context.Succeed(requirement)
```

The following code shows the simplified (and annotated with comments) default implementation of the authorization service:

C#

```
public async Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user,
             object resource, IEnumerable<IAuthorizationRequirement>
requirements)
{
    // Create a tracking context from the authorization inputs.
    var authContext = _contextFactory.CreateContext(requirements, user,
resource);

    // By default this returns an IEnumerable<IAuthorizationHandler> from
DI.
    var handlers = await _handlers.GetHandlersAsync(authContext);

    // Invoke all handlers.
    foreach (var handler in handlers)
    {
        await handler.HandleAsync(authContext);
    }

    // Check the context, by default success is when all requirements have
been met.
```

```
    return _evaluator.Evaluate(authContext);
}
```

The following code shows a typical authorization service configuration:

C#

```
// Add all of your handlers to DI.
builder.Services.AddSingleton<IAuthorizationHandler, MyHandler1>();
// MyHandler2, ...

builder.Services.AddSingleton<IAuthorizationHandler, MyHandlerN>();

// Configure your policies
builder.Services.AddAuthorization(options =>
      options.AddPolicy("Something",
      policy => policy.RequireClaim("Permission", "CanViewPage",
"CanViewAnything")));
```

Use IAuthorizationService, `[Authorize(Policy = "Something")]`, or `RequireAuthorization("Something")` for authorization.

Apply policies to MVC controllers

For apps that use Razor Pages, see the Apply policies to Razor Pages section.

Apply policies to controllers by using the `[Authorize]` attribute with the policy name:

C#

```
[Authorize(Policy = "AtLeast21")]
public class AtLeast21Controller : Controller
{
    public IActionResult Index() => View();
}
```

If multiple policies are applied at the controller and action levels, ***all*** policies must pass before access is granted:

C#

```
[Authorize(Policy = "AtLeast21")]
public class AtLeast21Controller2 : Controller
{
    [Authorize(Policy = "IdentificationValidated")]
```

```
    public IActionResult Index() => View();
}
```

Apply policies to Razor Pages

Apply policies to Razor Pages by using the `[Authorize]` attribute with the policy name. For example:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace AuthorizationPoliciesSample.Pages;

[Authorize(Policy = "AtLeast21")]
public class AtLeast21Model : PageModel { }
```

Policies can ***not*** be applied at the Razor Page handler level, they must be applied to the Page.

Policies can also be applied to Razor Pages by using an authorization convention.

Apply policies to endpoints

Apply policies to endpoints by using RequireAuthorization with the policy name. For example:

C#

```
app.MapGet("/helloworld", () => "Hello World!")
    .RequireAuthorization("AtLeast21");
```

Requirements

An authorization requirement is a collection of data parameters that a policy can use to evaluate the current user principal. In our "AtLeast21" policy, the requirement is a single parameter—the minimum age. A requirement implements IAuthorizationRequirement, which is an empty marker interface. A parameterized minimum age requirement could be implemented as follows:

C#

```
using Microsoft.AspNetCore.Authorization;

namespace AuthorizationPoliciesSample.Policies.Requirements;

public class MinimumAgeRequirement : IAuthorizationRequirement
{
    public MinimumAgeRequirement(int minimumAge) =>
        MinimumAge = minimumAge;

    public int MinimumAge { get; }
}
```

If an authorization policy contains multiple authorization requirements, all requirements must pass in order for the policy evaluation to succeed. In other words, multiple authorization requirements added to a single authorization policy are treated on an **AND** basis.

> ⓘ **Note**
>
> A requirement doesn't need to have data or properties.

Authorization handlers

An authorization handler is responsible for the evaluation of a requirement's properties. The authorization handler evaluates the requirements against a provided AuthorizationHandlerContext to determine if access is allowed.

A requirement can have multiple handlers. A handler may inherit AuthorizationHandler<TRequirement>, where `TRequirement` is the requirement to be handled. Alternatively, a handler may implement IAuthorizationHandler directly to handle more than one type of requirement.

Use a handler for one requirement

The following example shows a one-to-one relationship in which a minimum age handler handles a single requirement:

C#

```
using System.Security.Claims;
using AuthorizationPoliciesSample.Policies.Requirements;
using Microsoft.AspNetCore.Authorization;
```

```
namespace AuthorizationPoliciesSample.Policies.Handlers;

public class MinimumAgeHandler : AuthorizationHandler<MinimumAgeRequirement>
{
    protected override Task HandleRequirementAsync(
        AuthorizationHandlerContext context, MinimumAgeRequirement
requirement)
    {
        var dateOfBirthClaim = context.User.FindFirst(
            c => c.Type == ClaimTypes.DateOfBirth && c.Issuer ==
"http://contoso.com");

        if (dateOfBirthClaim is null)
        {
            return Task.CompletedTask;
        }

        var dateOfBirth = Convert.ToDateTime(dateOfBirthClaim.Value);
        int calculatedAge = DateTime.Today.Year - dateOfBirth.Year;
        if (dateOfBirth > DateTime.Today.AddYears(-calculatedAge))
        {
            calculatedAge--;
        }

        if (calculatedAge >= requirement.MinimumAge)
        {
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }
}
```

The preceding code determines if the current user principal has a date of birth claim that has been issued by a known and trusted Issuer. Authorization can't occur when the claim is missing, in which case a completed task is returned. When a claim is present, the user's age is calculated. If the user meets the minimum age defined by the requirement, authorization is considered successful. When authorization is successful, `context.Succeed` is invoked with the satisfied requirement as its sole parameter.

Use a handler for multiple requirements

The following example shows a one-to-many relationship in which a permission handler can handle three different types of requirements:

C#

```
using System.Security.Claims;
using AuthorizationPoliciesSample.Policies.Requirements;
using Microsoft.AspNetCore.Authorization;
```

```
namespace AuthorizationPoliciesSample.Policies.Handlers;

public class PermissionHandler : IAuthorizationHandler
{
    public Task HandleAsync(AuthorizationHandlerContext context)
    {
        var pendingRequirements = context.PendingRequirements.ToList();

        foreach (var requirement in pendingRequirements)
        {
            if (requirement is ReadPermission)
            {
                if (IsOwner(context.User, context.Resource)
                    || IsSponsor(context.User, context.Resource))
                {
                    context.Succeed(requirement);
                }
            }
            else if (requirement is EditPermission || requirement is
DeletePermission)
            {
                if (IsOwner(context.User, context.Resource))
                {
                    context.Succeed(requirement);
                }
            }
        }

        return Task.CompletedTask;
    }

    private static bool IsOwner(ClaimsPrincipal user, object? resource)
    {
        // Code omitted for brevity
        return true;
    }

    private static bool IsSponsor(ClaimsPrincipal user, object? resource)
    {
        // Code omitted for brevity
        return true;
    }
}
```

The preceding code traverses PendingRequirements—a property containing requirements not marked as successful. For a `ReadPermission` requirement, the user must be either an owner or a sponsor to access the requested resource. For an `EditPermission` or `DeletePermission` requirement, they must be an owner to access the requested resource.

Handler registration

Register handlers in the services collection during configuration. For example:

```
C#

builder.Services.AddSingleton<IAuthorizationHandler, MinimumAgeHandler>();
```

The preceding code registers `MinimumAgeHandler` as a singleton. Handlers can be registered using any of the built-in service lifetimes.

It's possible to bundle both a requirement and a handler into a single class implementing both IAuthorizationRequirement and IAuthorizationHandler. This bundling creates a tight coupling between the handler and requirement and is only recommended for simple requirements and handlers. Creating a class that implements both interfaces removes the need to register the handler in DI because of the built-in PassThroughAuthorizationHandler that allows requirements to handle themselves.

See the AssertionRequirement class for a good example where the `AssertionRequirement` is both a requirement and the handler in a fully self-contained class.

What should a handler return?

Note that the `Handle` method in the handler example returns no value. How is a status of either success or failure indicated?

- A handler indicates success by calling `context.Succeed(IAuthorizationRequirement requirement)`, passing the requirement that has been successfully validated.
- A handler doesn't need to handle failures generally, as other handlers for the same requirement may succeed.
- To guarantee failure, even if other requirement handlers succeed, call `context.Fail`.

If a handler calls `context.Succeed` or `context.Fail`, all other handlers are still called. This allows requirements to produce side effects, such as logging, which takes place even if another handler has successfully validated or failed a requirement. When set to `false`, the InvokeHandlersAfterFailure property short-circuits the execution of handlers when `context.Fail` is called. `InvokeHandlersAfterFailure` defaults to `true`, in which case all handlers are called.

> ⓘ Note
>
> Authorization handlers are called even if authentication fails. Also handlers can execute in any order, so do ***not*** depend on them being called in any particular order.

Why would I want multiple handlers for a requirement?

In cases where you want evaluation to be on an **OR** basis, implement multiple handlers for a single requirement. For example, Microsoft has doors that only open with key cards. If you leave your key card at home, the receptionist prints a temporary sticker and opens the door for you. In this scenario, you'd have a single requirement, *BuildingEntry*, but multiple handlers, each one examining a single requirement.

`BuildingEntryRequirement.cs`

C#

```
using Microsoft.AspNetCore.Authorization;

namespace AuthorizationPoliciesSample.Policies.Requirements;

public class BuildingEntryRequirement : IAuthorizationRequirement { }
```

`BadgeEntryHandler.cs`

C#

```
using AuthorizationPoliciesSample.Policies.Requirements;
using Microsoft.AspNetCore.Authorization;

namespace AuthorizationPoliciesSample.Policies.Handlers;

public class BadgeEntryHandler :
AuthorizationHandler<BuildingEntryRequirement>
{
    protected override Task HandleRequirementAsync(
        AuthorizationHandlerContext context, BuildingEntryRequirement
requirement)
    {
        if (context.User.HasClaim(
            c => c.Type == "BadgeId" && c.Issuer ==
"https://microsoftsecurity"))
        {
```

```
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }
}
```

`TemporaryStickerHandler.cs`

C#

```
using AuthorizationPoliciesSample.Policies.Requirements;
using Microsoft.AspNetCore.Authorization;

namespace AuthorizationPoliciesSample.Policies.Handlers;

public class TemporaryStickerHandler :
AuthorizationHandler<BuildingEntryRequirement>
{
    protected override Task HandleRequirementAsync(
        AuthorizationHandlerContext context, BuildingEntryRequirement
requirement)
    {
        if (context.User.HasClaim(
            c => c.Type == "TemporaryBadgeId" && c.Issuer ==
"https://microsoftsecurity"))
        {
            // Code to check expiration date omitted for brevity.
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }
}
```

Ensure that both handlers are registered. If either handler succeeds when a policy evaluates the `BuildingEntryRequirement`, the policy evaluation succeeds.

Use a func to fulfill a policy

There may be situations in which fulfilling a policy is simple to express in code. It's possible to supply a `Func<AuthorizationHandlerContext, bool>` when configuring a policy with the `RequireAssertion` policy builder.

For example, the previous `BadgeEntryHandler` could be rewritten as follows:

C#

```
builder.Services.AddAuthorization(options =>
{
    options.AddPolicy("BadgeEntry", policy =>
        policy.RequireAssertion(context => context.User.HasClaim(c =>
            (c.Type == "BadgeId" || c.Type == "TemporaryBadgeId")
            && c.Issuer == "https://microsoftsecurity")));
});
```

Access MVC request context in handlers

The `HandleRequirementAsync` method has two parameters: an `AuthorizationHandlerContext` and the `TRequirement` being handled. Frameworks such as MVC or SignalR are free to add any object to the `Resource` property on the `AuthorizationHandlerContext` to pass extra information.

When using endpoint routing, authorization is typically handled by the Authorization Middleware. In this case, the `Resource` property is an instance of HttpContext. The context can be used to access the current endpoint, which can be used to probe the underlying resource to which you're routing. For example:

C#

```
if (context.Resource is HttpContext httpContext)
{
    var endpoint = httpContext.GetEndpoint();
    var actionDescriptor =
endpoint.Metadata.GetMetadata<ControllerActionDescriptor>();
    ...
}
```

With traditional routing, or when authorization happens as part of MVC's authorization filter, the value of `Resource` is an AuthorizationFilterContext instance. This property provides access to `HttpContext`, `RouteData`, and everything else provided by MVC and Razor Pages.

The use of the `Resource` property is framework-specific. Using information in the `Resource` property limits your authorization policies to particular frameworks. Cast the `Resource` property using the `is` keyword, and then confirm the cast has succeeded to ensure your code doesn't crash with an `InvalidCastException` when run on other frameworks:

C#

```
// Requires the following import:
//     using Microsoft.AspNetCore.Mvc.Filters;
if (context.Resource is AuthorizationFilterContext mvcContext)
{
    // Examine MVC-specific things like routing data.
}
```

Globally require all users to be authenticated

For information on how to globally require all users to be authenticated, see Require authenticated users.

Authorization with external service sample

The sample code on AspNetCore.Docs.Samples shows how to implement additional authorization requirements with an external authorization service. The sample `Contoso.API` project is secured with Azure AD. An additional authorization check from the `Contoso.Security.API` project returns a payload describing whether the `Contoso.API` client app can invoke the `GetWeather` API.

Configure the sample

- Create an application registration in your Microsoft Entra ID tenant:
- Assign it an AppRole.
- Under API permissions, add the AppRole as a permission and grant Admin consent. Note that in this setup, this app registration represents both the API and the client invoking the API. If you like, you can create two app registrations. If you are using this setup, be sure to only perform the API permissions, add AppRole as a permission step for only the client. Only the client app registration requires a client secret to be generated.
- Configure the `Contoso.API` project with the following settings:

C#

```
{
  "AzureAd": {
    "Instance": "https://login.microsoftonline.com/",
    "Domain": "<Tenant name from AAD properties>.onmicrosoft.com",
    "TenantId": "<Tenant Id from AAD properties>",
    "ClientId": "<Client Id from App Registration representing the API>"
```

```
  },
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*"
}
```

- Configure `Contoso.Security.API` with the following settings:

C#

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "AllowedClients": [
    "<Use the appropriate Client Id representing the Client calling the
API>"
  ]
}
```

- Open the ContosoAPI.collection.json file and configure an environment with the following:
  - `ClientId`: Client Id from app registration representing the client calling the API.
  - `clientSecret`: Client Secret from app registration representing the client calling the API.
  - `TenantId`: Tenant Id from AAD properties

- Extract the commands from the `ContosoAPI.collection.json` file and use them to construct cURL commands to test the app.

- Run the solution and use cURL to invoke the API. You can add breakpoints in the `Contoso.Security.API.SecurityPolicyController` and observe the client Id is being passed in that is used to assert whether it is allowed to Get Weather.

Custom Authorization Policy Providers using IAuthorizationPolicyProvider in ASP.NET Core

Article • 06/03/2022

By Mike Rousos

Typically when using policy-based authorization, policies are registered by calling `AuthorizationOptions.AddPolicy` as part of authorization service configuration. In some scenarios, it may not be possible (or desirable) to register all authorization policies in this way. In those cases, you can use a custom IAuthorizationPolicyProvider to control how authorization policies are supplied.

Examples of scenarios where a custom IAuthorizationPolicyProvider may be useful include:

- Using an external service to provide policy evaluation.
- Using a large range of policies (for different room numbers or ages, for example), so it doesn't make sense to add each individual authorization policy with an `AuthorizationOptions.AddPolicy` call.
- Creating policies at runtime based on information in an external data source (like a database) or determining authorization requirements dynamically through another mechanism.

View or download sample code from the AspNetCore GitHub repository. Download the dotnet/AspNetCore repository ZIP file. Unzip the file. Navigate to the *src/Security/samples/CustomPolicyProvider* project folder.

Customize policy retrieval

ASP.NET Core apps use an implementation of the `IAuthorizationPolicyProvider` interface to retrieve authorization policies. By default, DefaultAuthorizationPolicyProvider is registered and used. `DefaultAuthorizationPolicyProvider` returns policies from the `AuthorizationOptions` provided in an `IServiceCollection.AddAuthorization` call.

Customize this behavior by registering a different `IAuthorizationPolicyProvider` implementation in the app's dependency injection container.

The `IAuthorizationPolicyProvider` interface contains three APIs:

- GetPolicyAsync returns an authorization policy for a given name.
- GetDefaultPolicyAsync returns the default authorization policy (the policy used for `[Authorize]` attributes without a policy specified).
- GetFallbackPolicyAsync returns the fallback authorization policy (the policy used by the Authorization Middleware when no policy is specified).

By implementing these APIs, you can customize how authorization policies are provided.

Parameterized authorize attribute example

One scenario where `IAuthorizationPolicyProvider` is useful is enabling custom `[Authorize]` attributes whose requirements depend on a parameter. For example, in policy-based authorization documentation, an age-based ("AtLeast21") policy was used as a sample. If different controller actions in an app should be made available to users of *different* ages, it might be useful to have many different age-based policies. Instead of registering all the different age-based policies that the application will need in `AuthorizationOptions`, you can generate the policies dynamically with a custom `IAuthorizationPolicyProvider`. To make using the policies easier, you can annotate actions with custom authorization attribute like `[MinimumAgeAuthorize(20)]`.

Custom Authorization attributes

Authorization policies are identified by their names. The custom `MinimumAgeAuthorizeAttribute` described previously needs to map arguments into a string that can be used to retrieve the corresponding authorization policy. You can do this by deriving from `AuthorizeAttribute` and making the `Age` property wrap the `AuthorizeAttribute.Policy` property.

C#

```
internal class MinimumAgeAuthorizeAttribute : AuthorizeAttribute
{
    const string POLICY_PREFIX = "MinimumAge";

    public MinimumAgeAuthorizeAttribute(int age) => Age = age;

    // Get or set the Age property by manipulating the underlying Policy
property
    public int Age
    {
        get
```

```
        {
            if (int.TryParse(Policy.Substring(POLICY_PREFIX.Length), out var
age))
            {
                return age;
            }
            return default(int);
        }
        set
        {
            Policy = $"{POLICY_PREFIX}{value.ToString()}";
        }
    }
}
```

This attribute type has a `Policy` string based on the hard-coded prefix (`"MinimumAge"`) and an integer passed in via the constructor.

You can apply it to actions in the same way as other `Authorize` attributes except that it takes an integer as a parameter.

C#

```
[MinimumAgeAuthorize(10)]
public IActionResult RequiresMinimumAge10()
```

Custom IAuthorizationPolicyProvider

The custom `MinimumAgeAuthorizeAttribute` makes it easy to request authorization policies for any minimum age desired. The next problem to solve is making sure that authorization policies are available for all of those different ages. This is where an `IAuthorizationPolicyProvider` is useful.

When using `MinimumAgeAuthorizationAttribute`, the authorization policy names will follow the pattern `"MinimumAge" + Age`, so the custom `IAuthorizationPolicyProvider` should generate authorization policies by:

- Parsing the age from the policy name.
- Using `AuthorizationPolicyBuilder` to create a new `AuthorizationPolicy`
- In this and following examples it will be assumed that the user is authenticated via a cookie. The `AuthorizationPolicyBuilder` should either be constructed with at least one authorization scheme name or always succeed. Otherwise there is no information on how to provide a challenge to the user and an exception will be thrown.

- Adding requirements to the policy based on the age with `AuthorizationPolicyBuilder.AddRequirements`. In other scenarios, you might use `RequireClaim`, `RequireRole`, or `RequireUserName` instead.

C#

```
internal class MinimumAgePolicyProvider : IAuthorizationPolicyProvider
{
    const string POLICY_PREFIX = "MinimumAge";

    // Policies are looked up by string name, so expect 'parameters' (like
age)
    // to be embedded in the policy names. This is abstracted away from
developers
    // by the more strongly-typed attributes derived from AuthorizeAttribute
    // (like [MinimumAgeAuthorize()] in this sample)
    public Task<AuthorizationPolicy> GetPolicyAsync(string policyName)
    {
        if (policyName.StartsWith(POLICY_PREFIX,
StringComparison.OrdinalIgnoreCase) &&
            int.TryParse(policyName.Substring(POLICY_PREFIX.Length), out var
age))
        {
            var policy = new
AuthorizationPolicyBuilder(CookieAuthenticationDefaults.AuthenticationScheme
);
            policy.AddRequirements(new MinimumAgeRequirement(age));
            return Task.FromResult(policy.Build());
        }

        return Task.FromResult<AuthorizationPolicy>(null);
    }
}
```

Multiple authorization policy providers

When using custom `IAuthorizationPolicyProvider` implementations, keep in mind that ASP.NET Core only uses one instance of `IAuthorizationPolicyProvider`. If a custom provider isn't able to provide authorization policies for all policy names that will be used, it should defer to a backup provider.

For example, consider an application that needs both custom age policies and more traditional role-based policy retrieval. Such an app could use a custom authorization policy provider that:

- Attempts to parse policy names.

- Calls into a different policy provider (like `DefaultAuthorizationPolicyProvider`) if the policy name doesn't contain an age.

The example `IAuthorizationPolicyProvider` implementation shown above can be updated to use the `DefaultAuthorizationPolicyProvider` by creating a backup policy provider in its constructor (to be used in case the policy name doesn't match its expected pattern of 'MinimumAge' + age).

```
C#

private DefaultAuthorizationPolicyProvider BackupPolicyProvider { get; }

public MinimumAgePolicyProvider(IOptions<AuthorizationOptions> options)
{
    // ASP.NET Core only uses one authorization policy provider, so if the
custom implementation
    // doesn't handle all policies it should fall back to an alternate
provider.
    BackupPolicyProvider = new DefaultAuthorizationPolicyProvider(options);
}
```

Then, the `GetPolicyAsync` method can be updated to use the `BackupPolicyProvider` instead of returning null:

```
C#

...
return BackupPolicyProvider.GetPolicyAsync(policyName);
```

Default policy

In addition to providing named authorization policies, a custom `IAuthorizationPolicyProvider` needs to implement `GetDefaultPolicyAsync` to provide an authorization policy for `[Authorize]` attributes without a policy name specified.

In many cases, this authorization attribute only requires an authenticated user, so you can make the necessary policy with a call to `RequireAuthenticatedUser`:

```
C#

public Task<AuthorizationPolicy> GetDefaultPolicyAsync() =>
    Task.FromResult(new
AuthorizationPolicyBuilder(CookieAuthenticationDefaults.AuthenticationScheme
).RequireAuthenticatedUser().Build());
```

As with all aspects of a custom `IAuthorizationPolicyProvider`, you can customize this, as needed. In some cases, it may be desirable to retrieve the default policy from a fallback `IAuthorizationPolicyProvider`.

Fallback policy

A custom `IAuthorizationPolicyProvider` can optionally implement `GetFallbackPolicyAsync` to provide a policy that's used when combining policies and when no policies are specified. If `GetFallbackPolicyAsync` returns a non-null policy, the returned policy is used by the Authorization Middleware when no policies are specified for the request.

If no fallback policy is required, the provider can return `null` or defer to the fallback provider:

```
C#

public Task<AuthorizationPolicy> GetFallbackPolicyAsync() =>
    Task.FromResult<AuthorizationPolicy>(null);
```

Use a custom IAuthorizationPolicyProvider

To use custom policies from an `IAuthorizationPolicyProvider`, you ***must***:

- Register the appropriate `AuthorizationHandler` types with dependency injection (described in policy-based authorization), as with all policy-based authorization scenarios.
- Register the custom `IAuthorizationPolicyProvider` type in the app's dependency injection service collection in `Startup.ConfigureServices` to replace the default policy provider.

  ```
  C#

  services.AddSingleton<IAuthorizationPolicyProvider,
  MinimumAgePolicyProvider>();
  ```

A complete custom `IAuthorizationPolicyProvider` sample is available in the dotnet/aspnetcore GitHub repository.

Customize the behavior of `AuthorizationMiddleware`

Article • 06/03/2022

Apps can register an IAuthorizationMiddlewareResultHandler to customize how AuthorizationMiddleware handles authorization results. Apps can use `IAuthorizationMiddlewareResultHandler` to:

- Return customized responses.
- Enhance the default challenge or forbid responses.

The following code shows an example implementation of `IAuthorizationMiddlewareResultHandler` that returns a custom response for specific authorization failures:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authorization.Policy;

public class SampleAuthorizationMiddlewareResultHandler :
IAuthorizationMiddlewareResultHandler
{
    private readonly AuthorizationMiddlewareResultHandler defaultHandler =
new();

    public async Task HandleAsync(
        RequestDelegate next,
        HttpContext context,
        AuthorizationPolicy policy,
        PolicyAuthorizationResult authorizeResult)
    {
        // If the authorization was forbidden and the resource had a
specific requirement,
        // provide a custom 404 response.
        if (authorizeResult.Forbidden
            && authorizeResult.AuthorizationFailure!.FailedRequirements
                .OfType<Show404Requirement>().Any())
        {
            // Return a 404 to make it appear as if the resource doesn't
exist.
            context.Response.StatusCode = StatusCodes.Status404NotFound;
            return;
        }

        // Fall back to the default implementation.
        await defaultHandler.HandleAsync(next, context, policy,
authorizeResult);
```

```
    }
}

public class Show404Requirement : IAuthorizationRequirement { }
```

Register this implementation of `IAuthorizationMiddlewareResultHandler` in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddSingleton<
    IAuthorizationMiddlewareResultHandler,
SampleAuthorizationMiddlewareResultHandler>();

var app = builder.Build();
```

Dependency injection in requirement handlers in ASP.NET Core

Article • 06/03/2022

Authorization handlers must be registered in the service collection during configuration using dependency injection.

Suppose you had a repository of rules you wanted to evaluate inside an authorization handler and that repository was registered in the service collection. Authorization resolves and injects that into the constructor.

For example, to use the .NET logging infrastructure, inject ILoggerFactory into the handler, as shown in the following example:

C#

```
public class SampleAuthorizationHandler :
AuthorizationHandler<SampleRequirement>
{
    private readonly ILogger _logger;

    public SampleAuthorizationHandler(ILoggerFactory loggerFactory)
        => _logger = loggerFactory.CreateLogger(GetType().FullName);

    protected override Task HandleRequirementAsync(
        AuthorizationHandlerContext context, SampleRequirement requirement)
    {
        _logger.LogInformation("Inside my handler");

        // ...

        return Task.CompletedTask;
    }
}
```

The preceding handler can be registered with any service lifetime. The following code uses AddSingleton to register the preceding handler:

C#

```
builder.Services.AddSingleton<IAuthorizationHandler,
SampleAuthorizationHandler>();
```

An instance of the handler is created when the app starts, and DI injects the registered `ILoggerFactory` into its constructor.

> **Note**
>
> Don't register authorization handlers that use Entity Framework (EF) as singletons.

Resource-based authorization in ASP.NET Core

Article • 06/18/2024

Authorization approach depends on the resource. For example, only the author of a document is authorized to update the document. Consequently, the document must be retrieved from the data store before authorization evaluation can occur.

Attribute evaluation occurs before data binding and before execution of the page handler or action that loads the document. For these reasons, declarative authorization with an `[Authorize]` attribute doesn't suffice. Instead, you can invoke a custom authorization method—a style known as *imperative authorization*.

View or download sample code (how to download).

Create an ASP.NET Core app with user data protected by authorization contains a sample app that uses resource-based authorization.

Use imperative authorization

Authorization is implemented as an IAuthorizationService service and is registered in the service collection at application startup. The service is made available via dependency injection to page handlers or actions.

C#

```
public class DocumentController : Controller
{
    private readonly IAuthorizationService _authorizationService;
    private readonly IDocumentRepository _documentRepository;

    public DocumentController(IAuthorizationService authorizationService,
                              IDocumentRepository documentRepository)
    {
        _authorizationService = authorizationService;
        _documentRepository = documentRepository;
    }
```

`IAuthorizationService` has two `AuthorizeAsync` method overloads: one accepting the resource and the policy name and the other accepting the resource and a list of requirements to evaluate.

C#

```
Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user,
                          object resource,
                          IEnumerable<IAuthorizationRequirement>
requirements);
Task<AuthorizationResult> AuthorizeAsync(ClaimsPrincipal user,
                          object resource,
                          string policyName);
```

In the following example, the resource to be secured is loaded into a custom `Document` object. An `AuthorizeAsync` overload is invoked to determine whether the current user is allowed to edit the provided document. A custom "EditPolicy" authorization policy is factored into the decision. See Custom policy-based authorization for more on creating authorization policies.

> **Note**
>
> The following code samples assume authentication has run and set the `User` property.

C#

```
public async Task<IActionResult> OnGetAsync(Guid documentId)
{
    Document = _documentRepository.Find(documentId);

    if (Document == null)
    {
        return new NotFoundResult();
    }

    var authorizationResult = await _authorizationService
            .AuthorizeAsync(User, Document, "EditPolicy");

    if (authorizationResult.Succeeded)
    {
        return Page();
    }
    else if (User.Identity.IsAuthenticated)
    {
        return new ForbidResult();
    }
    else
    {
        return new ChallengeResult();
    }
}
```

Write a resource-based handler

Writing a handler for resource-based authorization isn't much different than writing a plain requirements handler. Create a custom requirement class, and implement a requirement handler class. For more information on creating a requirement class, see Requirements.

The handler class specifies both the requirement and resource type. For example, a handler utilizing a `SameAuthorRequirement` and a `Document` resource follows:

C#

```
public class DocumentAuthorizationHandler :
    AuthorizationHandler<SameAuthorRequirement, Document>
{
    protected override Task
HandleRequirementAsync(AuthorizationHandlerContext context,
                                                    SameAuthorRequirement
requirement,
                                                    Document resource)
    {
        if (context.User.Identity?.Name == resource.Author)
        {
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }
}

public class SameAuthorRequirement : IAuthorizationRequirement { }
```

In the preceding example, imagine that `SameAuthorRequirement` is a special case of a more generic `SpecificAuthorRequirement` class. The `SpecificAuthorRequirement` class (not shown) contains a `Name` property representing the name of the author. The `Name` property could be set to the current user.

Register the requirement and handler in `Program.cs`:

C#

```
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();
```

```
builder.Services.AddAuthorization(options =>
{
    options.AddPolicy("EditPolicy", policy =>
        policy.Requirements.Add(new SameAuthorRequirement()));
});

builder.Services.AddSingleton<IAuthorizationHandler,
DocumentAuthorizationHandler>();
builder.Services.AddSingleton<IAuthorizationHandler,
DocumentAuthorizationCrudHandler>();
builder.Services.AddScoped<IDocumentRepository, DocumentRepository>();
```

Operational requirements

If you're making decisions based on the outcomes of CRUD (Create, Read, Update, Delete) operations, use the OperationAuthorizationRequirement helper class. This class enables you to write a single handler instead of an individual class for each operation type. To use it, provide some operation names:

C#

```
public static class Operations
{
    public static OperationAuthorizationRequirement Create =
        new OperationAuthorizationRequirement { Name = nameof(Create) };
    public static OperationAuthorizationRequirement Read =
        new OperationAuthorizationRequirement { Name = nameof(Read) };
    public static OperationAuthorizationRequirement Update =
        new OperationAuthorizationRequirement { Name = nameof(Update) };
    public static OperationAuthorizationRequirement Delete =
        new OperationAuthorizationRequirement { Name = nameof(Delete) };
}
```

The handler is implemented as follows, using an `OperationAuthorizationRequirement` requirement and a `Document` resource:

C#

```
public class DocumentAuthorizationCrudHandler :
    AuthorizationHandler<OperationAuthorizationRequirement, Document>
{
    protected override Task
HandleRequirementAsync(AuthorizationHandlerContext context,

OperationAuthorizationRequirement requirement,
                                                    Document resource)
    {
        if (context.User.Identity?.Name == resource.Author &&
            requirement.Name == Operations.Read.Name)
```

```
        {
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }
}
```

The preceding handler validates the operation using the resource, the user's identity, and the requirement's `Name` property.

Challenge and forbid with an operational resource handler

This section shows how the challenge and forbid action results are processed and how challenge and forbid differ.

To call an operational resource handler, specify the operation when invoking `AuthorizeAsync` in your page handler or action. The following example determines whether the authenticated user is permitted to view the provided document.

> ⓘ Note
>
> The following code samples assume authentication has run and set the `User` property.

C#

```
public async Task<IActionResult> OnGetAsync(Guid documentId)
{
    Document = _documentRepository.Find(documentId);

    if (Document == null)
    {
        return new NotFoundResult();
    }

    var authorizationResult = await _authorizationService
            .AuthorizeAsync(User, Document, Operations.Read);

    if (authorizationResult.Succeeded)
    {
        return Page();
    }
    else if (User.Identity.IsAuthenticated)
    {
```

```
            return new ForbidResult();
        }
        else
        {
            return new ChallengeResult();
        }
    }
```

If authorization succeeds, the page for viewing the document is returned. If authorization fails but the user is authenticated, returning `ForbidResult` informs any authentication middleware that authorization failed. A `ChallengeResult` is returned when authentication must be performed. For interactive browser clients, it may be appropriate to redirect the user to a login page.

View-based authorization in ASP.NET Core MVC

Article • 09/27/2024

A developer often wants to show, hide, or otherwise modify a UI based on the current user identity. You can access the authorization service within MVC views via dependency injection. To inject the authorization service into a Razor view, use the `@inject` directive:

CSHTML

```
@using Microsoft.AspNetCore.Authorization
@inject IAuthorizationService AuthorizationService
```

If you want the authorization service in every view, place the `@inject` directive into the `_ViewImports.cshtml` file of the `Views` directory. For more information, see Dependency injection into views.

Use the injected authorization service to invoke `AuthorizeAsync` in exactly the same way you would check during resource-based authorization:

CSHTML

```
@if ((await AuthorizationService.AuthorizeAsync(User,
"PolicyName")).Succeeded)
{
    <p>This paragraph is displayed because you fulfilled PolicyName.</p>
}
```

In some cases, the resource will be your view model. Invoke `AuthorizeAsync` in exactly the same way you would check during resource-based authorization:

CSHTML

```
@if ((await AuthorizationService.AuthorizeAsync(User, Model,
Operations.Edit)).Succeeded)
{
    <p><a class="btn btn-default" role="button"
        href="@Url.Action("Edit", "Document", new { id = Model.Id
})">Edit</a></p>
}
```

In the preceding code, the model is passed as a resource the policy evaluation should take into consideration.

> **⚠ Warning**
>
> Don't rely on toggling visibility of your app's UI elements as the sole authorization check. Hiding a UI element may not completely prevent access to its associated controller action. For example, consider the button in the preceding code snippet. A user can invoke the `Edit` action method if they know the relative resource URL is `/Document/Edit/1`. For this reason, the `Edit` action method should perform its own authorization check.

Authorize with a specific scheme in ASP.NET Core

Article • 06/03/2022

For an introduction to authentication schemes in ASP.NET Core, see Authentication scheme.

In some scenarios, such as Single Page Applications (SPAs), it's common to use multiple authentication methods. For example, the app may use cookie-based authentication to log in and JWT bearer authentication for JavaScript requests. In some cases, the app may have multiple instances of an authentication handler. For example, two cookie handlers where one contains a basic identity and one is created when a multi-factor authentication (MFA) has been triggered. MFA may be triggered because the user requested an operation that requires extra security. For more information on enforcing MFA when a user requests a resource that requires MFA, see the GitHub issue Protect section with MFA.

An authentication scheme is named when the authentication service is configured during authentication. For example:

C#

```
using Microsoft.AspNetCore.Authentication;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication()
        .AddCookie(options =>
        {
            options.LoginPath = "/Account/Unauthorized/";
            options.AccessDeniedPath = "/Account/Forbidden/";
        })
        .AddJwtBearer(options =>
        {
            options.Audience = "http://localhost:5001/";
            options.Authority = "http://localhost:5000/";
        });

builder.Services.AddAuthentication()
        .AddIdentityServerJwt();

builder.Services.AddControllersWithViews();
builder.Services.AddRazorPages();

var app = builder.Build();
```

```
if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseAuthentication();
app.UseIdentityServer();
app.UseAuthorization();

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.MapFallbackToFile("index.html");

app.Run();
```

In the preceding code, two authentication handlers have been added: one for cookies and one for bearer.

> **Note**
>
> Specifying the default scheme results in the `HttpContext.User` property being set to that identity. If that behavior isn't desired, disable it by invoking the parameterless form of `AddAuthentication`.

Selecting the scheme with the Authorize attribute

At the point of authorization, the app indicates the handler to be used. Select the handler with which the app will authorize by passing a comma-delimited list of authentication schemes to `[Authorize]`. The [Authorize] attribute specifies the authentication scheme or schemes to use regardless of whether a default is configured. For example:

```
C#
```

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Authentication.Cookies;
using Microsoft.AspNetCore.Authentication.JwtBearer;
using Microsoft.AspNetCore.Mvc;

namespace AuthScheme.Controllers;

[Authorize(AuthenticationSchemes = AuthSchemes)]
public class MixedController : Controller
{
    private const string AuthSchemes =
        CookieAuthenticationDefaults.AuthenticationScheme + "," +
        JwtBearerDefaults.AuthenticationScheme;
    public ContentResult Index() => Content(MyWidgets.GetMyContent());

}
```

In the preceding example, both the cookie and bearer handlers run and have a chance to create and append an identity for the current user. By specifying a single scheme only, the corresponding handler runs:

C#

```
[Authorize(AuthenticationSchemes=JwtBearerDefaults.AuthenticationScheme)]
public class Mixed2Controller : Controller
{
    public ContentResult Index() => Content(MyWidgets.GetMyContent());
}
```

In the preceding code, only the handler with the "Bearer" scheme runs. Any cookie-based identities are ignored.

Selecting the scheme with policies

If you prefer to specify the desired schemes in policy, you can set the AuthenticationSchemes collection when adding a policy:

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.JwtBearer;

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddAuthorization(options =>
{
    options.AddPolicy("Over18", policy =>
    {

policy.AuthenticationSchemes.Add(JwtBearerDefaults.AuthenticationScheme);
        policy.RequireAuthenticatedUser();
        policy.Requirements.Add(new MinimumAgeRequirement(18));
    });
});
builder.Services.AddAuthentication()
                .AddIdentityServerJwt();

builder.Services.AddControllersWithViews();
builder.Services.AddRazorPages();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseAuthentication();
app.UseIdentityServer();
app.UseAuthorization();

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.MapFallbackToFile("index.html");

app.Run();
```

In the preceding example, the "Over18" policy only runs against the identity created by the "Bearer" handler. Use the policy by setting the `[Authorize]` attribute's `Policy` property:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Mvc;

namespace AuthScheme.Controllers;
```

```
[Authorize(Policy = "Over18")]
public class RegistrationController : Controller
{
    // Do Registration
```

Use multiple authentication schemes

Some apps may need to support multiple types of authentication. For example, your app might authenticate users from Azure Active Directory and from a users database. Another example is an app that authenticates users from both Active Directory Federation Services and Azure Active Directory B2C. In this case, the app should accept a JWT bearer token from several issuers.

Add all authentication schemes you'd like to accept. For example, the following code adds two JWT bearer authentication schemes with different issuers:

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.JwtBearer;
using Microsoft.AspNetCore.Authorization;

var builder = WebApplication.CreateBuilder(args);

// Authentication
builder.Services.AddAuthentication(JwtBearerDefaults.AuthenticationScheme)
        .AddJwtBearer(options =>
        {
            options.Audience = "https://localhost:5000/";
            options.Authority = "https://localhost:5000/identity/";
        })
        .AddJwtBearer("AzureAD", options =>
        {
            options.Audience = "https://localhost:5000/";
            options.Authority = "https://login.microsoftonline.com/eb971100-
7f436/";
        });

// Authorization
builder.Services.AddAuthorization(options =>
{
    var defaultAuthorizationPolicyBuilder = new AuthorizationPolicyBuilder(
        JwtBearerDefaults.AuthenticationScheme,
        "AzureAD");
    defaultAuthorizationPolicyBuilder =
        defaultAuthorizationPolicyBuilder.RequireAuthenticatedUser();
    options.DefaultPolicy = defaultAuthorizationPolicyBuilder.Build();
});

builder.Services.AddAuthentication()
```

```
        .AddIdentityServerJwt();

builder.Services.AddControllersWithViews();
builder.Services.AddRazorPages();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseAuthentication();
app.UseIdentityServer();
app.UseAuthorization();

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.MapFallbackToFile("index.html");

app.Run();
```

> **Note**
>
> Only one JWT bearer authentication is registered with the default authentication scheme `JwtBearerDefaults.AuthenticationScheme`. Additional authentication has to be registered with a unique authentication scheme.

Update the default authorization policy to accept both authentication schemes. For example:

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.JwtBearer;
using Microsoft.AspNetCore.Authorization;

var builder = WebApplication.CreateBuilder(args);

// Authentication
builder.Services.AddAuthentication(JwtBearerDefaults.AuthenticationScheme)
```

```
        .AddJwtBearer(options =>
        {
            options.Audience = "https://localhost:5000/";
            options.Authority = "https://localhost:5000/identity/";
        })
        .AddJwtBearer("AzureAD", options =>
        {
            options.Audience = "https://localhost:5000/";
            options.Authority = "https://login.microsoftonline.com/eb971100-
7f436/";
        });

// Authorization
builder.Services.AddAuthorization(options =>
{
    var defaultAuthorizationPolicyBuilder = new AuthorizationPolicyBuilder(
        JwtBearerDefaults.AuthenticationScheme,
        "AzureAD");
    defaultAuthorizationPolicyBuilder =
        defaultAuthorizationPolicyBuilder.RequireAuthenticatedUser();
    options.DefaultPolicy = defaultAuthorizationPolicyBuilder.Build();
});

builder.Services.AddAuthentication()
        .AddIdentityServerJwt();

builder.Services.AddControllersWithViews();
builder.Services.AddRazorPages();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseAuthentication();
app.UseIdentityServer();
app.UseAuthorization();

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.MapFallbackToFile("index.html");

app.Run();
```

As the default authorization policy is overridden, it's possible to use the `[Authorize]` attribute in controllers. The controller then accepts requests with JWT issued by the first or second issuer.

See this GitHub issue on using multiple authentication schemes.

The following example uses Azure Active Directory B2C and another Azure Active Directory tenant:

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.IdentityModel.Tokens;
using Microsoft.Net.Http.Headers;
using System.IdentityModel.Tokens.Jwt;

var builder = WebApplication.CreateBuilder(args);

// Authentication
```

```
builder.Services.AddAuthentication(options =>
{
    options.DefaultScheme = "B2C_OR_AAD";
    options.DefaultChallengeScheme = "B2C_OR_AAD";
})
.AddJwtBearer("B2C", jwtOptions =>
{
    jwtOptions.MetadataAddress = "B2C-MetadataAddress";
    jwtOptions.Authority = "B2C-Authority";
    jwtOptions.Audience = "B2C-Audience";
})
.AddJwtBearer("AAD", jwtOptions =>
{
    jwtOptions.MetadataAddress = "AAD-MetadataAddress";
    jwtOptions.Authority = "AAD-Authority";
    jwtOptions.Audience = "AAD-Audience";
    jwtOptions.TokenValidationParameters = new TokenValidationParameters
    {
        ValidateIssuer = true,
        ValidateAudience = true,
        ValidateIssuerSigningKey = true,
        ValidAudiences =
builder.Configuration.GetSection("ValidAudiences").Get<string[]>(),
        ValidIssuers =
builder.Configuration.GetSection("ValidIssuers").Get<string[]>()
    };
})
.AddPolicyScheme("B2C_OR_AAD", "B2C_OR_AAD", options =>
{
    options.ForwardDefaultSelector = context =>
    {
        string authorization =
context.Request.Headers[HeaderNames.Authorization];
        if (!string.IsNullOrEmpty(authorization) &&
authorization.StartsWith("Bearer "))
        {
            var token = authorization.Substring("Bearer ".Length).Trim();
            var jwtHandler = new JwtSecurityTokenHandler();

            return (jwtHandler.CanReadToken(token) &&
jwtHandler.ReadJwtToken(token).Issuer.Equals("B2C-Authority"))
                ? "B2C" : "AAD";
        }
        return "AAD";
    };
});
```

```
builder.Services.AddAuthentication()
        .AddIdentityServerJwt();

builder.Services.AddControllersWithViews();
builder.Services.AddRazorPages();

var app = builder.Build();
```

```
if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseAuthentication();
app.UseIdentityServer();
app.UseAuthorization();

app.MapDefaultControllerRoute().RequireAuthorization();
app.MapRazorPages().RequireAuthorization();

app.MapFallbackToFile("index.html");

app.Run();
```

In the preceding code, ForwardDefaultSelector is used to select a default scheme for the current request that authentication handlers should forward all authentication operations to by default. The default forwarding logic checks the most specific ForwardAuthenticate, ForwardChallenge, ForwardForbid, ForwardSignIn, and ForwardSignOut setting first, followed by checking the ForwardDefaultSelector, followed by ForwardDefault. The first non null result is used as the target scheme to forward to. For more information, see Policy schemes in ASP.NET Core.

ASP.NET Core Data Protection Overview

Article • 06/17/2024

ASP.NET Core provides a cryptographic API to protect data, including key management and rotation.

Web apps often need to store sensitive data. The Windows data protection API (DPAPI) isn't intended for use in web apps.

The ASP.NET Core data protection stack was designed to:

- Provide a built in solution for most Web scenarios.
- Address many of the deficiencies of the previous encryption system.
- Serve as the replacement for the `<machineKey>` element in ASP.NET 1.x - 4.x.

Problem statement

I need to persist trusted information for later retrieval, but I don't trust the persistence mechanism. In web terms, this might be written as *I need to round-trip trusted state via an untrusted client.*

Authenticity, integrity, and tamper-proofing is a requirement. The canonical example of this is an authentication cookie or bearer token. The server generates an ***I am Groot and have xyz permissions*** token and sends it to the client. The client presents that token back to the server, but the server needs some kind of assurance that the client hasn't forged the token.

Confidentiality is a requirement. Since the persisted state is trusted by the server, this state could contain information that shouldn't be disclosed to an untrusted client. For example:

- A file path.
- A permission.
- A handle or other indirect reference.
- Some server-specific data.

Isolation is a requirement. Since modern apps are componentized, individual components want to take advantage of this system without regard to other components in the system. For instance, consider a bearer token component using this stack. It should operate without any interference, for example, from an anti-CSRF mechanism also using the same stack.

Some common assumptions can narrow the scope of requirements:

- All services operating within the cryptosystem are equally trusted.
- The data doesn't need to be generated or consumed outside of the services under our direct control.
- Operations must be fast since each request to the web service might go through the cryptosystem one or more times. The speed requirement makes symmetric cryptography ideal. Asymmetric cryptography isn't used until it's required.

Design philosophy

ASP.NET Core data protection is an easy to use data protection stack. It's based on the following principles:

- Ease of configuration. The system strives for zero configuration. In situations where developers need to configure a specific aspect, such as the key repository, those specific configurations aren't difficult.
- Offer a basic consumer-facing API. The APIs are straight forward to use correctly and difficult to use incorrectly.
- Developers don't have to learn key management principles. The system handles algorithm selection and key lifetime on behalf of the developer. The developer doesn't have access to the raw key material.
- Keys are protected at rest as much as possible. The system figures out an appropriate default protection mechanism and applies it automatically.

The data protection APIs aren't primarily intended for indefinite persistence of confidential payloads. Other technologies, such as Windows CNG DPAPI and Azure Rights Management are more suited to the scenario of indefinite storage. They have correspondingly strong key management capabilities. That said, the ASP.NET Core data protection APIs can be used for long-term protection of confidential data.

Audience

The data protection system provides APIs that target three main audiences:

1. The consumer APIs target application and framework developers.

   I don't want to learn about how the stack operates or about how it's configured. I just want to perform some operation with high probability of using the APIs successfully.

2. The configuration APIs target app developers and system administrators.

I need to tell the data protection system that my environment requires non-default paths or settings.

3. The extensibility APIs target developers in charge of implementing custom policy. Usage of these APIs is limited to rare situations and developers with security experience.

   I need to replace an entire component within the system because I have truly unique behavioral requirements. I'm willing to learn uncommonly used parts of the API surface in order to build a plugin that fulfills my requirements.

Package layout

The data protection stack consists of five packages:

- Microsoft.AspNetCore.DataProtection.Abstractions contains:
  - IDataProtectionProvider and IDataProtector interfaces to create data protection services.
  - Useful extension methods for working with these types. for example, IDataProtector.Protect

  If the data protection system is instantiated elsewhere and you're consuming the API, reference `Microsoft.AspNetCore.DataProtection.Abstractions`.

- Microsoft.AspNetCore.DataProtection contains the core implementation of the data protection system, including:
  - Core cryptographic operations.
  - Key management.
  - Configuration and extensibility.

  To instantiate the data protection system, reference `Microsoft.AspNetCore.DataProtection`. You might need to reference the data protection system when:
  - Adding it to an IServiceCollection.
  - Modifying or extending its behavior.

- Microsoft.AspNetCore.DataProtection.Extensions contains additional APIs which developers might find useful but which don't belong in the core package. For instance, this package contains:
  - Factory methods to instantiate the data protection system to store keys at a location on the file system without dependency injection. See DataProtectionProvider.

    - Extension methods for limiting the lifetime of protected payloads. See ITimeLimitedDataProtector.

- Microsoft.AspNetCore.DataProtection.SystemWeb can be installed into an existing ASP.NET 4.x app to redirect its `<machineKey>` operations to use the new ASP.NET Core data protection stack. For more information, see Replace the ASP.NET machineKey in ASP.NET Core.

- Microsoft.AspNetCore.Cryptography.KeyDerivation provides an implementation of the PBKDF2 password hashing routine and can be used by systems that must handle user passwords securely. For more information, see Hash passwords in ASP.NET Core.

Get started with the Data Protection APIs in ASP.NET Core

Article • 06/17/2024

Basically, protecting data consists of the following steps:

1. Create a data protector from a data protection provider.
2. Call the `Protect` method with the data you want to protect.
3. Call the `Unprotect` method with the data you want to turn back into plain text.

Most frameworks and app models, such as ASP.NET Core or SignalR, already configure the data protection system and add it to a service container that is accessed via dependency injection. The following sample demonstrates:

- Configuring a service container for dependency injection and registering the data protection stack.
- Receiving the data protection provider via DI.
- Creating a protector.
- Protecting then unprotecting data.

C#

```
using System;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
    {
        // add data protection services
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection();
        var services = serviceCollection.BuildServiceProvider();

        // create an instance of MyClass using the service provider
        var instance = ActivatorUtilities.CreateInstance<MyClass>(services);
        instance.RunSample();
    }

    public class MyClass
    {
        IDataProtector _protector;

        // the 'provider' parameter is provided by DI
        public MyClass(IDataProtectionProvider provider)
        {
```

```
            _protector = provider.CreateProtector("Contoso.MyClass.v1");
        }

        public void RunSample()
        {
            Console.Write("Enter input: ");
            string input = Console.ReadLine();

            // protect the payload
            string protectedPayload = _protector.Protect(input);
            Console.WriteLine($"Protect returned: {protectedPayload}");

            // unprotect the payload
            string unprotectedPayload =
_protector.Unprotect(protectedPayload);
            Console.WriteLine($"Unprotect returned: {unprotectedPayload}");
        }
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Enter input: Hello world!
 * Protect returned: CfDJ8ICcgQwZZhlAlTZT...OdfH66i1PnGmpCR5e441xQ
 * Unprotect returned: Hello world!
 */
```

When you create a protector you must provide one or more Purpose Strings. A purpose string provides isolation between consumers. For example, a protector created with a purpose string of "green" wouldn't be able to unprotect data provided by a protector with a purpose of "purple".

> **Tip**
>
> Instances of `IDataProtectionProvider` and `IDataProtector` are thread-safe for multiple callers. It's intended that once a component gets a reference to an `IDataProtector` via a call to `CreateProtector`, it will use that reference for multiple calls to `Protect` and `Unprotect`.
>
> A call to `Unprotect` will throw CryptographicException if the protected payload cannot be verified or deciphered. Some components may wish to ignore errors during unprotect operations; a component which reads authentication cookies might handle this error and treat the request as if it had no cookie at all rather than fail the request outright. Components which want this behavior should specifically catch CryptographicException instead of swallowing all exceptions.

Use AddOptions to configure custom repository

Consider the following code which uses a service provider because the implementation of `IXmlRepository` has a dependency on a singleton service:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    // ...

    var sp = services.BuildServiceProvider();
    services.AddDataProtection()
      .AddKeyManagementOptions(o => o.XmlRepository =
sp.GetService<IXmlRepository>());
}
```

The preceding code logs the following warning:

Calling 'BuildServiceProvider' from application code results in an additional copy of singleton services being created. Consider alternatives such as dependency injecting services as parameters to 'Configure'.

The following code provides the `IXmlRepository` implementation without having to build the service provider and therefore making additional copies of singleton services:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<DataProtectionDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    // Register XmlRepository for data protection.
    services.AddOptions<KeyManagementOptions>()
    .Configure<IServiceScopeFactory>((options, factory) =>
    {
        options.XmlRepository = new CustomXmlRepository(factory);
    });

    services.AddRazorPages();
}
```

The preceding code removes the call to `GetService` and hides `IConfigureOptions<T>`.

The following code shows the custom XML repository:

C#

```
using CustomXMLrepo.Data;
using Microsoft.AspNetCore.DataProtection.Repositories;
using Microsoft.Extensions.DependencyInjection;
using System.Collections.Generic;
using System.Linq;
using System.Xml.Linq;

public class CustomXmlRepository : IXmlRepository
{
    private readonly IServiceScopeFactory factory;

    public CustomXmlRepository(IServiceScopeFactory factory)
    {
        this.factory = factory;
    }

    public IReadOnlyCollection<XElement> GetAllElements()
    {
        using (var scope = factory.CreateScope())
        {
            var context =
scope.ServiceProvider.GetRequiredService<DataProtectionDbContext>();
            var keys = context.XmlKeys.ToList()
                .Select(x => XElement.Parse(x.Xml))
                .ToList();
            return keys;
        }
    }

    public void StoreElement(XElement element, string friendlyName)
    {
        var key = new XmlKey
        {
            Xml = element.ToString(SaveOptions.DisableFormatting)
        };

        using (var scope = factory.CreateScope())
        {
            var context =
scope.ServiceProvider.GetRequiredService<DataProtectionDbContext>();
            context.XmlKeys.Add(key);
            context.SaveChanges();
        }
    }
}
```

The following code shows the XmlKey class:

C#

```
public class XmlKey
{
    public Guid Id { get; set; }
    public string Xml { get; set; }

    public XmlKey()
    {
        this.Id = Guid.NewGuid();
    }
}
```

Consumer APIs overview for ASP.NET Core

Article • 06/17/2024

The `IDataProtectionProvider` and `IDataProtector` interfaces are the basic interfaces through which consumers use the data protection system. They're located in the Microsoft.AspNetCore.DataProtection.Abstractions package.

IDataProtectionProvider

The provider interface represents the root of the data protection system. It cannot directly be used to protect or unprotect data. Instead, the consumer must get a reference to an `IDataProtector` by calling `IDataProtectionProvider.CreateProtector(purpose)`, where purpose is a string that describes the intended consumer use case. See Purpose Strings for much more information on the intent of this parameter and how to choose an appropriate value.

IDataProtector

The protector interface is returned by a call to `CreateProtector`, and it's this interface which consumers can use to perform protect and unprotect operations.

To protect a piece of data, pass the data to the `Protect` method. The basic interface defines a method which converts byte[] -> byte[], but there's also an overload (provided as an extension method) which converts string -> string. The security offered by the two methods is identical; the developer should choose whichever overload is most convenient for their use case. Irrespective of the overload chosen, the value returned by the Protect method is now protected (enciphered and tamper-proofed), and the application can send it to an untrusted client.

To unprotect a previously-protected piece of data, pass the protected data to the `Unprotect` method. (There are byte[]-based and string-based overloads for developer convenience.) If the protected payload was generated by an earlier call to `Protect` on this same `IDataProtector`, the `Unprotect` method will return the original unprotected payload. If the protected payload has been tampered with or was produced by a different `IDataProtector`, the `Unprotect` method will throw CryptographicException.

The concept of same vs. different `IDataProtector` ties back to the concept of purpose. If two `IDataProtector` instances were generated from the same root `IDataProtectionProvider` but via different purpose strings in the call to `IDataProtectionProvider.CreateProtector`, then they're considered different protectors, and one won't be able to unprotect payloads generated by the other.

Consuming these interfaces

For a DI-aware component, the intended usage is that the component takes an `IDataProtectionProvider` parameter in its constructor and that the DI system automatically provides this service when the component is instantiated.

> **Note**
>
> Some applications (such as console applications or ASP.NET 4.x applications) might not be DI-aware so cannot use the mechanism described here. For these scenarios consult the Non DI Aware Scenarios document for more information on getting an instance of an `IDataProtection` provider without going through DI.

The following sample demonstrates three concepts:

1. Add the data protection system to the service container,
2. Using DI to receive an instance of an `IDataProtectionProvider`, and
3. Creating an `IDataProtector` from an `IDataProtectionProvider` and using it to protect and unprotect data.

Console app

C#

```
using System;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
    {
        // add data protection services
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection();
```

```
        var services = serviceCollection.BuildServiceProvider();

        // create an instance of MyClass using the service provider
        var instance = ActivatorUtilities.CreateInstance<MyClass>(services);
        instance.RunSample();
    }

    public class MyClass
    {
        IDataProtector _protector;

        // the 'provider' parameter is provided by DI
        public MyClass(IDataProtectionProvider provider)
        {
            _protector = provider.CreateProtector("Contoso.MyClass.v1");
        }

        public void RunSample()
        {
            Console.Write("Enter input: ");
            string input = Console.ReadLine();

            // protect the payload
            string protectedPayload = _protector.Protect(input);
            Console.WriteLine($"Protect returned: {protectedPayload}");

            // unprotect the payload
            string unprotectedPayload =
_protector.Unprotect(protectedPayload);
            Console.WriteLine($"Unprotect returned: {unprotectedPayload}");
        }
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Enter input: Hello world!
 * Protect returned: CfDJ8ICcgQwZZhlAlTZT...OdfH66i1PnGmpCR5e441xQ
 * Unprotect returned: Hello world!
 */
```

Web app

Call AddDataProtection(IServiceCollection, Action<DataProtectionOptions>) in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);
```

```
// Add services to the container.
builder.Services.AddControllersWithViews();
builder.Services.AddDataProtection();

var app = builder.Build();
```

The following highlighted code shows how to use IDataProtector in a controller:

C#

```
public class HomeController : Controller
{
    private readonly IDataProtector _dataProtector;

    public HomeController(IDataProtectionProvider dataProtectionProvider)
    {
        _dataProtector =
dataProtectionProvider.CreateProtector("HomeControllerPurpose");
    }

    // ...

    public IActionResult Privacy()
    {
        // The original data to protect
        string originalData = "original data";

        // Protect the data (encrypt)
        string protectedData = _dataProtector.Protect(originalData);
        Console.WriteLine($"Protected Data: {protectedData}");

        // Unprotect the data (decrypt)
        string unprotectedData = _dataProtector.Unprotect(protectedData);
        Console.WriteLine($"Unprotected Data: {unprotectedData}");

        return View();
    }

    // ...
```

The package `Microsoft.AspNetCore.DataProtection.Abstractions` contains an extension method GetDataProtector as a developer convenience. It encapsulates as a single operation both retrieving an IDataProtectionProvider from the service provider and calling IDataProtectionProvider.CreateProtector. The following sample demonstrates its usage:

C#

```
using System;
using Microsoft.AspNetCore.DataProtection;
```

```
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
    {
        // add data protection services
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection();
        var services = serviceCollection.BuildServiceProvider();

        // get an IDataProtector from the IServiceProvider
        var protector = services.GetDataProtector("Contoso.Example.v2");
        Console.Write("Enter input: ");
        string input = Console.ReadLine();

        // protect the payload
        string protectedPayload = protector.Protect(input);
        Console.WriteLine($"Protect returned: {protectedPayload}");

        // unprotect the payload
        string unprotectedPayload = protector.Unprotect(protectedPayload);
        Console.WriteLine($"Unprotect returned: {unprotectedPayload}");
    }
}
```

Tip

Instances of `IDataProtectionProvider` and `IDataProtector` are thread-safe for multiple callers. It's intended that once a component gets a reference to an `IDataProtector` via a call to `CreateProtector`, it will use that reference for multiple calls to `Protect` and `Unprotect`. A call to `Unprotect` will throw CryptographicException if the protected payload cannot be verified or deciphered. Some components may wish to ignore errors during unprotect operations; a component which reads authentication cookies might handle this error and treat the request as if it had no cookie at all rather than fail the request outright. Components which want this behavior should specifically catch CryptographicException instead of swallowing all exceptions.

Purpose strings in ASP.NET Core

Article • 06/17/2024

Components which consume `IDataProtectionProvider` must pass a unique *purposes* parameter to the `CreateProtector` method. The purposes *parameter* is inherent to the security of the data protection system, as it provides isolation between cryptographic consumers, even if the root cryptographic keys are the same.

When a consumer specifies a purpose, the purpose string is used along with the root cryptographic keys to derive cryptographic subkeys unique to that consumer. This isolates the consumer from all other cryptographic consumers in the application: no other component can read its payloads, and it cannot read any other component's payloads. This isolation also renders infeasible entire categories of attack against the component.

In the diagram above, `IDataProtector` instances A and B **cannot** read each other's payloads, only their own.

The purpose string doesn't have to be secret. It should simply be unique in the sense that no other well-behaved component will ever provide the same purpose string.

> **Tip**
>
> Using the namespace and type name of the component consuming the data protection APIs is a good rule of thumb, as in practice this information will never conflict.
>
> A Contoso-authored component which is responsible for minting bearer tokens might use Contoso.Security.BearerToken as its purpose string. Or - even better - it might use Contoso.Security.BearerToken.v1 as its purpose string. Appending the version number allows a future version to use Contoso.Security.BearerToken.v2 as

its purpose, and the different versions would be completely isolated from one another as far as payloads go.

Since the purposes parameter to `CreateProtector` is a string array, the above could've been instead specified as `[ "Contoso.Security.BearerToken", "v1" ]`. This allows establishing a hierarchy of purposes and opens up the possibility of multi-tenancy scenarios with the data protection system.

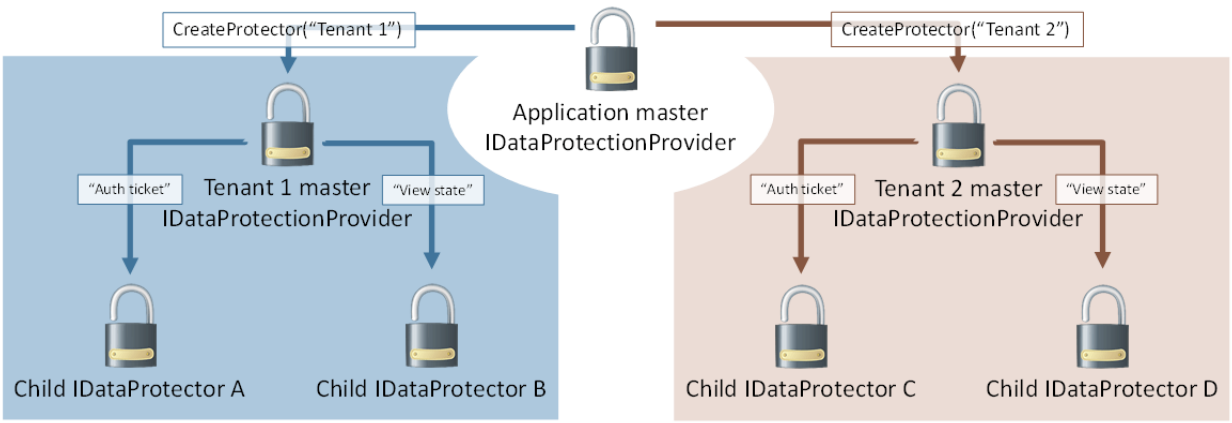
> ⚠ **Warning**
>
> Components shouldn't allow untrusted user input to be the sole source of input for the purposes chain.
>
> For example, consider a component Contoso.Messaging.SecureMessage which is responsible for storing secure messages. If the secure messaging component were to call `CreateProtector([ username ])`, then a malicious user might create an account with username "Contoso.Security.BearerToken" in an attempt to get the component to call `CreateProtector([ "Contoso.Security.BearerToken" ])`, thus inadvertently causing the secure messaging system to mint payloads that could be perceived as authentication tokens.
>
> A better purposes chain for the messaging component would be `CreateProtector([ "Contoso.Messaging.SecureMessage", $"User: {username}" ])`, which provides proper isolation.

The isolation provided by and behaviors of `IDataProtectionProvider`, `IDataProtector`, and purposes are as follows:

- For a given `IDataProtectionProvider` object, the `CreateProtector` method will create an `IDataProtector` object uniquely tied to both the `IDataProtectionProvider` object which created it and the purposes parameter which was passed into the method.
- The purpose parameter must not be null. (If purposes is specified as an array, this means that the array must not be of zero length and all elements of the array must be non-null.) An empty string purpose is technically allowed but is discouraged.
- Two purposes arguments are equivalent if and only if they contain the same strings (using an ordinal comparer) in the same order. A single purpose argument is equivalent to the corresponding single-element purposes array.

- Two `IDataProtector` objects are equivalent if and only if they're created from equivalent `IDataProtectionProvider` objects with equivalent purposes parameters.
- For a given `IDataProtector` object, a call to `Unprotect(protectedData)` will return the original `unprotectedData` if and only if `protectedData := Protect(unprotectedData)` for an equivalent `IDataProtector` object.

> **Note**
>
> We're not considering the case where some component intentionally chooses a purpose string which is known to conflict with another component. Such a component would essentially be considered malicious, and this system isn't intended to provide security guarantees in the event that malicious code is already running inside of the worker process.



Purpose hierarchy and multi-tenancy in ASP.NET Core

Article • 06/03/2022

Since an `IDataProtector` is also implicitly an `IDataProtectionProvider`, purposes can be chained together. In this sense, `provider.CreateProtector([ "purpose1", "purpose2" ])` is equivalent to `provider.CreateProtector("purpose1").CreateProtector("purpose2")`.

This allows for some interesting hierarchical relationships through the data protection system. In the earlier example of Contoso.Messaging.SecureMessage, the SecureMessage component can call `provider.CreateProtector("Contoso.Messaging.SecureMessage")` once up-front and cache the result into a private `_myProvider` field. Future protectors can then be created via calls to `_myProvider.CreateProtector("User: username")`, and these protectors would be used for securing the individual messages.

This can also be flipped. Consider a single logical application which hosts multiple tenants (a CMS seems reasonable), and each tenant can be configured with its own authentication and state management system. The umbrella application has a single master provider, and it calls `provider.CreateProtector("Tenant 1")` and `provider.CreateProtector("Tenant 2")` to give each tenant its own isolated slice of the data protection system. The tenants could then derive their own individual protectors based on their own needs, but no matter how hard they try they cannot create protectors which collide with any other tenant in the system. Graphically, this is represented as below.

> ⚠ **Warning**
>
> This assumes the umbrella application controls which APIs are available to individual tenants and that tenants cannot execute arbitrary code on the server. If a

tenant can execute arbitrary code, they could perform private reflection to break the isolation guarantees, or they could just read the master keying material directly and derive whatever subkeys they desire.

The data protection system actually uses a sort of multi-tenancy in its default out-of-the-box configuration. By default master keying material is stored in the worker process account's user profile folder (or the registry, for IIS application pool identities). But it's actually fairly common to use a single account to run multiple applications, and thus all these applications would end up sharing the master keying material. To solve this, the data protection system automatically inserts a unique-per-application identifier as the first element in the overall purpose chain. This implicit purpose serves to isolate individual applications from one another by effectively treating each application as a unique tenant within the system, and the protector creation process looks identical to the image above.

Hash passwords in ASP.NET Core

Article • 07/19/2022

This article shows how to call the KeyDerivation.Pbkdf2 method which allows hashing a password using the PBKDF2 algorithm.

> **⚠ Warning**
>
> The `KeyDerivation.Pbkdf2` API is a low-level cryptographic primitive and is intended to be used to integrate apps into an existing protocol or cryptographic system. `KeyDerivation.Pbkdf2` should not be used in new apps which support password based login and need to store hashed passwords in a datastore. New apps should use **PasswordHasher**. For more information on `PasswordHasher`, see **Exploring the ASP.NET Core Identity PasswordHasher**.

The data protection code base includes a NuGet package Microsoft.AspNetCore.Cryptography.KeyDerivation which contains cryptographic key derivation functions. This package is a standalone component and has no dependencies on the rest of the data protection system. It can be used independently. The source exists alongside the data protection code base as a convenience.

> **⚠ Warning**
>
> The following code shows how to use `KeyDerivation.Pbkdf2` to generate a shared secret key. It should not be used to hash a password for storage in a datastore.

```
using Microsoft.AspNetCore.Cryptography.KeyDerivation;
using System.Security.Cryptography;

Console.Write("Enter a password: ");
string? password = Console.ReadLine();

// Generate a 128-bit salt using a sequence of
// cryptographically strong random bytes.
byte[] salt = RandomNumberGenerator.GetBytes(128 / 8); // divide by 8 to
convert bits to bytes
Console.WriteLine($"Salt: {Convert.ToBase64String(salt)}");

// derive a 256-bit subkey (use HMACSHA256 with 100,000 iterations)
string hashed = Convert.ToBase64String(KeyDerivation.Pbkdf2(
    password: password!,
    salt: salt,
```

```
    prf: KeyDerivationPrf.HMACSHA256,
    iterationCount: 100000,
    numBytesRequested: 256 / 8));

Console.WriteLine($"Hashed: {hashed}");

/*
 * SAMPLE OUTPUT
 *
 * Enter a password: Xtw9NMgx
 * Salt: CGYzqeN4plZekNC88Umm1Q==
 * Hashed: Gt9Yc4AiIvmsC1QQbe2RZsCIqvoYlst2xbz0Fs8aHnw=
 */
```

See the source code for ASP.NET Core Identity's `PasswordHasher` type for a real-world use case.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see **How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205)**.

Limit the lifetime of protected payloads in ASP.NET Core

Article • 06/03/2022

There are scenarios where the application developer wants to create a protected payload that expires after a set period of time. For instance, the protected payload might represent a password reset token that should only be valid for one hour. It's certainly possible for the developer to create their own payload format that contains an embedded expiration date, and advanced developers may wish to do this anyway, but for the majority of developers managing these expirations can grow tedious.

To make this easier for our developer audience, the package Microsoft.AspNetCore.DataProtection.Extensions contains utility APIs for creating payloads that automatically expire after a set period of time. These APIs implement the `ITimeLimitedDataProtector` interface.

API usage

The `ITimeLimitedDataProtector` interface is the core interface for protecting and unprotecting time-limited / self-expiring payloads. To create an instance of an `ITimeLimitedDataProtector`, you'll first need an instance of a regular IDataProtector constructed with a specific purpose. Once the `IDataProtector` instance is available, call the `IDataProtector.ToTimeLimitedDataProtector` extension method to get back a protector with built-in expiration capabilities.

`ITimeLimitedDataProtector` exposes the following API surface and extension methods:

- CreateProtector(string purpose) : ITimeLimitedDataProtector - This API is similar to the existing `IDataProtectionProvider.CreateProtector` in that it can be used to create purpose chains from a root time-limited protector.
- Protect(byte[] plaintext, DateTimeOffset expiration) : byte[]
- Protect(byte[] plaintext, TimeSpan lifetime) : byte[]
- Protect(byte[] plaintext) : byte[]
- Protect(string plaintext, DateTimeOffset expiration) : string
- Protect(string plaintext, TimeSpan lifetime) : string

- Protect(string plaintext) : string

In addition to the core `Protect` methods which take only the plaintext, there are new overloads which allow specifying the payload's expiration date. The expiration date can be specified as an absolute date (via a `DateTimeOffset`) or as a relative time (from the current system time, via a `TimeSpan`). If an overload which doesn't take an expiration is called, the payload is assumed never to expire.

- Unprotect(byte[] protectedData, out DateTimeOffset expiration) : byte[]
- Unprotect(byte[] protectedData) : byte[]
- Unprotect(string protectedData, out DateTimeOffset expiration) : string
- Unprotect(string protectedData) : string

The `Unprotect` methods return the original unprotected data. If the payload hasn't yet expired, the absolute expiration is returned as an optional out parameter along with the original unprotected data. If the payload is expired, all overloads of the Unprotect method will throw CryptographicException.

> ⚠ **Warning**
>
> It's not advised to use these APIs to protect payloads which require long-term or indefinite persistence. "Can I afford for the protected payloads to be permanently unrecoverable after a month?" can serve as a good rule of thumb; if the answer is no then developers should consider alternative APIs.

The sample below uses the non-DI code paths for instantiating the data protection system. To run this sample, ensure that you have first added a reference to the Microsoft.AspNetCore.DataProtection.Extensions package.

C#

```
using System;
using System.IO;
using System.Threading;
using Microsoft.AspNetCore.DataProtection;

public class Program
{
    public static void Main(string[] args)
    {
        // create a protector for my application

        var provider = DataProtectionProvider.Create(new
```

```
DirectoryInfo(@"c:\myapp-keys\"));
        var baseProtector =
provider.CreateProtector("Contoso.TimeLimitedSample");

        // convert the normal protector into a time-limited protector
        var timeLimitedProtector =
baseProtector.ToTimeLimitedDataProtector();

        // get some input and protect it for five seconds
        Console.Write("Enter input: ");
        string input = Console.ReadLine();
        string protectedData = timeLimitedProtector.Protect(input, lifetime:
TimeSpan.FromSeconds(5));
        Console.WriteLine($"Protected data: {protectedData}");

        // unprotect it to demonstrate that round-tripping works properly
        string roundtripped = timeLimitedProtector.Unprotect(protectedData);
        Console.WriteLine($"Round-tripped data: {roundtripped}");

        // wait 6 seconds and perform another unprotect, demonstrating that
the payload self-expires
        Console.WriteLine("Waiting 6 seconds...");
        Thread.Sleep(6000);
        timeLimitedProtector.Unprotect(protectedData);
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Enter input: Hello!
 * Protected data: CfDJ8Hu5z0zwxn...nLk7Ok
 * Round-tripped data: Hello!
 * Waiting 6 seconds...
 * <<throws CryptographicException with message 'The payload expired at
...'>>

 */
```

Unprotect payloads whose keys have been revoked in ASP.NET Core

Article • 09/27/2024

The ASP.NET Core data protection APIs are not primarily intended for indefinite persistence of confidential payloads. Other technologies like Windows CNG DPAPI and Azure Rights Management are more suited to the scenario of indefinite storage, and they have correspondingly strong key management capabilities. That said, there's nothing prohibiting a developer from using the ASP.NET Core data protection APIs for long-term protection of confidential data. Keys are never removed from the key ring, so `IDataProtector.Unprotect` can always recover existing payloads as long as the keys are available and valid.

However, an issue arises when the developer tries to unprotect data that has been protected with a revoked key, as `IDataProtector.Unprotect` will throw an exception in this case. This might be fine for short-lived or transient payloads (like authentication tokens), as these kinds of payloads can easily be recreated by the system, and at worst the site visitor might be required to log in again. But for persisted payloads, having `Unprotect` throw could lead to unacceptable data loss.

IPersistedDataProtector

To support the scenario of allowing payloads to be unprotected even in the face of revoked keys, the data protection system contains an `IPersistedDataProtector` type. To get an instance of `IPersistedDataProtector`, simply get an instance of `IDataProtector` in the normal fashion and try casting the `IDataProtector` to `IPersistedDataProtector`.

> **Note**
>
> Not all `IDataProtector` instances can be cast to `IPersistedDataProtector`. Developers should use the C# as operator or similar to avoid runtime exceptions caused by invalid casts, and they should be prepared to handle the failure case appropriately.

`IPersistedDataProtector` exposes the following API surface:

```
C#
```

```
DangerousUnprotect(byte[] protectedData, bool ignoreRevocationErrors,
     out bool requiresMigration, out bool wasRevoked) : byte[]
```

This API takes the protected payload (as a byte array) and returns the unprotected payload. There's no string-based overload. The two out parameters are as follows.

- `requiresMigration`: Is set to `true` if the key used to protect this payload is no longer the active default key. For example, the key used to protect this payload is old and a key rolling operation has since taken place. The caller may wish to consider reprotecting the payload depending on their business needs.
- `wasRevoked`: Is set to `true` if the key used to protect this payload was revoked.

> ⚠ **Warning**
>
> Exercise extreme caution when passing `ignoreRevocationErrors: true` to the `DangerousUnprotect` method. If after calling this method the `wasRevoked` value is true, then the key used to protect this payload was revoked, and the payload's authenticity should be treated as suspect. In this case, only continue operating on the unprotected payload if you have some separate assurance that it's authentic, for example that it's coming from a secure database rather than being sent by an untrusted web client.

C#

```
using System;
using System.IO;
using System.Text;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.AspNetCore.DataProtection.KeyManagement;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
    {
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection()
            // point at a specific folder and use DPAPI to encrypt keys
            .PersistKeysToFileSystem(new DirectoryInfo(@"c:\temp-keys"))
            .ProtectKeysWithDpapi();
        var services = serviceCollection.BuildServiceProvider();

        // get a protector and perform a protect operation
        var protector =
services.GetDataProtector("Sample.DangerousUnprotect");
```

```
        Console.Write("Input: ");
        byte[] input = Encoding.UTF8.GetBytes(Console.ReadLine());
        var protectedData = protector.Protect(input);
        Console.WriteLine($"Protected payload:
{Convert.ToBase64String(protectedData)}");

        // demonstrate that the payload round-trips properly
        var roundTripped = protector.Unprotect(protectedData);
        Console.WriteLine($"Round-tripped payload:
{Encoding.UTF8.GetString(roundTripped)}");

        // get a reference to the key manager and revoke all keys in the key
ring
        var keyManager = services.GetService<IKeyManager>();
        Console.WriteLine("Revoking all keys in the key ring...");
        keyManager.RevokeAllKeys(DateTimeOffset.Now, "Sample revocation.");

        // try calling Protect - this should throw
        Console.WriteLine("Calling Unprotect...");
        try
        {
            var unprotectedPayload = protector.Unprotect(protectedData);
            Console.WriteLine($"Unprotected payload:
{Encoding.UTF8.GetString(unprotectedPayload)}");
        }
        catch (Exception ex)
        {
            Console.WriteLine($"{ex.GetType().Name}: {ex.Message}");
        }

        // try calling DangerousUnprotect
        Console.WriteLine("Calling DangerousUnprotect...");
        try
        {
            IPersistedDataProtector persistedProtector = protector as
IPersistedDataProtector;
            if (persistedProtector == null)
            {
                throw new Exception("Can't call DangerousUnprotect.");
            }

            bool requiresMigration, wasRevoked;
            var unprotectedPayload = persistedProtector.DangerousUnprotect(
                protectedData: protectedData,
                ignoreRevocationErrors: true,
                requiresMigration: out requiresMigration,
                wasRevoked: out wasRevoked);
            Console.WriteLine($"Unprotected payload:
{Encoding.UTF8.GetString(unprotectedPayload)}");
            Console.WriteLine($"Requires migration = {requiresMigration},
was revoked = {wasRevoked}");
        }
        catch (Exception ex)
        {
            Console.WriteLine($"{ex.GetType().Name}: {ex.Message}");
```

```
        }
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Input: Hello!
 * Protected payload: CfDJ8LHIzUCX1ZVBn2BZ...
 * Round-tripped payload: Hello!
 * Revoking all keys in the key ring...
 * Calling Unprotect...
 * CryptographicException: The key {...} has been revoked.
 * Calling DangerousUnprotect...
 * Unprotected payload: Hello!
 * Requires migration = True, was revoked = True
 */
```

Data Protection configuration in ASP.NET Core

Configure ASP.NET Core Data Protection

Article • 11/04/2024

When the Data Protection system is initialized, it applies default settings based on the operational environment. These settings are appropriate for apps running on a single machine. However, there are cases where a developer may want to change the default settings:

- The app is spread across multiple machines.
- For compliance reasons.

For these scenarios, the Data Protection system offers a rich configuration API.

> **⚠ Warning**
>
> Similar to configuration files, the data protection key ring should be protected using appropriate permissions. You can choose to encrypt keys at rest, but this doesn't prevent cyberattackers from creating new keys. Consequently, your app's security is impacted. The storage location configured with Data Protection should have its access limited to the app itself, similar to the way you would protect configuration files. For example, if you choose to store your key ring on disk, use file system permissions. Ensure only the identity under which your web app runs has read, write, and create access to that directory. If you use Azure Blob Storage, only the web app should have the ability to read, write, or create new entries in the blob store, etc.
>
> The extension method AddDataProtection returns an IDataProtectionBuilder. `IDataProtectionBuilder` exposes extension methods that you can chain together to configure Data Protection options.

> **ⓘ Note**
>
> This article was written for an app that runs within a docker container. In a docker container the app always has the same path and, therefore, the same application discriminator. Apps that need to run in multiple environments (for example local and deployed), must set the default application discriminator for the environment. Running an app in multiple environments is beyond the scope of this article.

The following NuGet packages are required for the Data Protection extensions used in this article:

- Azure.Extensions.AspNetCore.DataProtection.Blobs
- Azure.Extensions.AspNetCore.DataProtection.Keys

ProtectKeysWithAzureKeyVault

Sign in to Azure using the CLI, for example:

Azure CLI

```
az login
```

To manage keys with Azure Key Vault, configure the system with ProtectKeysWithAzureKeyVault in `Program.cs`. `blobUriWithSasToken` is the full URI where the key file should be stored. The URI must contain the SAS token as a query string parameter:

C#

```
builder.Services.AddDataProtection()
    .PersistKeysToAzureBlobStorage(new Uri("<blobUriWithSasToken>"))
    .ProtectKeysWithAzureKeyVault(new Uri("<keyIdentifier>"), new
DefaultAzureCredential());
```

For an app to communicate and authorize itself with KeyVault, the Azure.Identity package must be added.

Set the key ring storage location (for example, PersistKeysToAzureBlobStorage). The location must be set because calling `ProtectKeysWithAzureKeyVault` implements an IXmlEncryptor that disables automatic data protection settings, including the key ring storage location. The preceding example uses Azure Blob Storage to persist the key ring. For more information, see Key storage providers: Azure Storage. You can also persist the key ring locally with PersistKeysToFileSystem.

The `keyIdentifier` is the key vault key identifier used for key encryption. For example, a key created in key vault named `dataprotection` in the `contosokeyvault` has the key identifier `https://contosokeyvault.vault.azure.net/keys/dataprotection/`. Provide the app with **Get**, **Unwrap Key** and **Wrap Key** permissions to the key vault.

`ProtectKeysWithAzureKeyVault` overloads:

- ProtectKeysWithAzureKeyVault(IDataProtectionBuilder, Uri, TokenCredential) permits the use of a keyIdentifier Uri and a tokenCredential to enable the data protection system to use the key vault.

- ProtectKeysWithAzureKeyVault(IDataProtectionBuilder, String, IKeyEncryptionKeyResolver) permits the use of a keyIdentifier string and IKeyEncryptionKeyResolver to enable the data protection system to use the key vault.

If the app uses the older Azure packages (Microsoft.AspNetCore.DataProtection.AzureStorage and Microsoft.AspNetCore.DataProtection.AzureKeyVault), we recommend ***removing*** these references and upgrading to the Azure.Extensions.AspNetCore.DataProtection.Blobs and Azure.Extensions.AspNetCore.DataProtection.Keys. These packages are where new updates are provided, and address some key security and stability issues with the older packages.

C#

```
builder.Services.AddDataProtection()
    // This blob must already exist before the application is run
    .PersistKeysToAzureBlobStorage("<storageAccountConnectionString", "
<containerName>", "<blobName>")
    // Removing this line below for an initial run will ensure the file is
created correctly
    .ProtectKeysWithAzureKeyVault(new Uri("<keyIdentifier>"), new
DefaultAzureCredential());
```

PersistKeysToFileSystem

To store keys on a UNC share instead of at the *%LOCALAPPDATA%* default location, configure the system with PersistKeysToFileSystem:

C#

```
builder.Services.AddDataProtection()
    .PersistKeysToFileSystem(new
DirectoryInfo(@"\\server\share\directory\"));
```

> ⚠ **Warning**
>
> If you change the key persistence location, the system no longer automatically encrypts keys at rest, since it doesn't know whether DPAPI is an appropriate encryption mechanism.

PersistKeysToDbContext

To store keys in a database using EntityFramework, configure the system with the Microsoft.AspNetCore.DataProtection.EntityFrameworkCore package:

```
C#

builder.Services.AddDataProtection()
    .PersistKeysToDbContext<SampleDbContext>();
```

The preceding code stores the keys in the configured database. The database context being used must implement `IDataProtectionKeyContext`. `IDataProtectionKeyContext` exposes the property `DataProtectionKeys`

```
C#

public DbSet<DataProtectionKey> DataProtectionKeys { get; set; } = null!;
```

This property represents the table in which the keys are stored. Create the table manually or with `DbContext` Migrations. For more information, see DataProtectionKey.

ProtectKeysWith*

You can configure the system to protect keys at rest by calling any of the ProtectKeysWith* configuration APIs. Consider the example below, which stores keys on a UNC share and encrypts those keys at rest with a specific X.509 certificate:

```
C#

builder.Services.AddDataProtection()
    .PersistKeysToFileSystem(new
DirectoryInfo(@"\\server\share\directory\"))

.ProtectKeysWithCertificate(builder.Configuration["CertificateThumbprint"]);
```

You can provide an X509Certificate2 to ProtectKeysWithCertificate, such as a certificate loaded from a file:

```
C#

builder.Services.AddDataProtection()
    .PersistKeysToFileSystem(new
DirectoryInfo(@"\\server\share\directory\"))
    .ProtectKeysWithCertificate(
        new X509Certificate2("certificate.pfx",
builder.Configuration["CertificatePassword"]));
```

See Key Encryption At Rest for more examples and discussion on the built-in key encryption mechanisms.

UnprotectKeysWithAnyCertificate

You can rotate certificates and decrypt keys at rest using an array of X509Certificate2 certificates with UnprotectKeysWithAnyCertificate:

C#

```
builder.Services.AddDataProtection()
    .PersistKeysToFileSystem(new
DirectoryInfo(@"\\server\share\directory\"))
    .ProtectKeysWithCertificate(
        new X509Certificate2("certificate.pfx",
builder.Configuration["CertificatePassword"]))
    .UnprotectKeysWithAnyCertificate(
        new X509Certificate2("certificate_1.pfx",
builder.Configuration["CertificatePassword_1"]),
        new X509Certificate2("certificate_2.pfx",
builder.Configuration["CertificatePassword_2"]));
```

SetDefaultKeyLifetime

To configure the system to use a key lifetime of 14 days instead of the default 90 days, use SetDefaultKeyLifetime:

C#

```
builder.Services.AddDataProtection()
    .SetDefaultKeyLifetime(TimeSpan.FromDays(14));
```

SetApplicationName

By default, the Data Protection system isolates apps from one another based on their content root paths, even if they share the same physical key repository. This isolation prevents the apps from understanding each other's protected payloads.

To share protected payloads among apps:

- Configure SetApplicationName in each app with the same value.
- Use the same version of the Data Protection API stack across the apps. Perform **either** of the following in the apps' project files:

- Reference the same shared framework version via the Microsoft.AspNetCore.App metapackage.
- Reference the same Data Protection package version.

```
C#

builder.Services.AddDataProtection()
    .SetApplicationName("<sharedApplicationName>");
```

SetApplicationName internally sets DataProtectionOptions.ApplicationDiscriminator. For troubleshooting purposes, the value assigned to the discriminator by the framework can be logged with the following code placed after the WebApplication is built in `Program.cs`:

```
C#

var discriminator =
app.Services.GetRequiredService<IOptions<DataProtectionOptions>>()
    .Value.ApplicationDiscriminator;
app.Logger.LogInformation("ApplicationDiscriminator:
{ApplicationDiscriminator}", discriminator);
```

For more information on how the discriminator is used, see the following sections later in this article:

- Per-application isolation
- Data Protection and app isolation

> ⚠ **Warning**
>
> In .NET 6, WebApplicationBuilder normalizes the content root path to end with a DirectorySeparatorChar. For example, on Windows the content root path ends in `\` and on Linux `/`. Other hosts don't normalize the path. Most apps migrating from HostBuilder or WebHostBuilder won't share the same app name because they won't have the terminating `DirectorySeparatorChar`. To work around this issue, remove the directory separator character and set the app name manually, as shown in the following code:
>
> ```
> C#
>
> using Microsoft.AspNetCore.DataProtection;
> using System.Reflection;
>
> var builder = WebApplication.CreateBuilder(args);
> var trimmedContentRootPath =
> ```

```
builder.Environment.ContentRootPath.TrimEnd(Path.DirectorySeparatorChar
);
builder.Services.AddDataProtection()
 .SetApplicationName(trimmedContentRootPath);
var app = builder.Build();

app.MapGet("/", () => Assembly.GetEntryAssembly()!.GetName().Name);

app.Run();
```

DisableAutomaticKeyGeneration

You may have a scenario where you don't want an app to automatically roll keys (create new keys) as they approach expiration. One example of this scenario might be apps set up in a primary/secondary relationship, where only the primary app is responsible for key management concerns and secondary apps simply have a read-only view of the key ring. The secondary apps can be configured to treat the key ring as read-only by configuring the system with DisableAutomaticKeyGeneration:

C#

```
builder.Services.AddDataProtection()
    .DisableAutomaticKeyGeneration();
```

Per-application isolation

When the Data Protection system is provided by an ASP.NET Core host, it automatically isolates apps from one another, even if those apps are running under the same worker process account and are using the same master keying material. This is similar to the IsolateApps modifier from System.Web's `<machineKey>` element.

The isolation mechanism works by considering each app on the local machine as a unique tenant, thus the IDataProtector rooted for any given app automatically includes the app ID as a discriminator (ApplicationDiscriminator). The app's unique ID is the app's physical path:

- For apps hosted in IIS, the unique ID is the IIS physical path of the app. If an app is deployed in a web farm environment, this value is stable assuming that the IIS environments are configured similarly across all machines in the web farm.
- For self-hosted apps running on the Kestrel server, the unique ID is the physical path to the app on disk.

The unique identifier is designed to survive resets—both of the individual app and of the machine itself.

This isolation mechanism assumes that the apps aren't malicious. A malicious app can always impact any other app running under the same worker process account. In a shared hosting environment where apps are mutually untrusted, the hosting provider should take steps to ensure OS-level isolation between apps, including separating the apps' underlying key repositories.

If the Data Protection system isn't provided by an ASP.NET Core host (for example, if you instantiate it via the `DataProtectionProvider` concrete type) app isolation is disabled by default. When app isolation is disabled, all apps backed by the same keying material can share payloads as long as they provide the appropriate purposes. To provide app isolation in this environment, call the SetApplicationName method on the configuration object and provide a unique name for each app.

Data Protection and app isolation

Consider the following points for app isolation:

- When multiple apps are pointed at the same key repository, the intention is that the apps share the same master key material. Data Protection is developed with the assumption that all apps sharing a key ring can access all items in that key ring. The application unique identifier is used to isolate application specific keys derived from the key ring provided keys. It doesn't expect item level permissions, such as those provided by Azure KeyVault to be used to enforce extra isolation. Attempting item level permissions generates application errors. If you don't want to rely on the built-in application isolation, separate key store locations should be used and not shared between applications.

- The application discriminator (ApplicationDiscriminator) is used to allow different apps to share the same master key material but to keep their cryptographic payloads distinct from one another. For the apps to be able to read each other's cryptographic payloads, they must have the same application discriminator, which can be set by calling SetApplicationName.

- If an app is compromised (for example, by an RCE attack), all master key material accessible to that app must also be considered compromised, regardless of its protection-at-rest state. This implies that if two apps are pointed at the same repository, even if they use different app discriminators, a compromise of one is functionally equivalent to a compromise of both.

This "functionally equivalent to a compromise of both" clause holds even if the two apps use different mechanisms for key protection at rest. Typically, this isn't an expected configuration. The protection-at-rest mechanism is intended to provide protection in the event a cyberattacker gains read access to the repository. A cyberattacker who gains write access to the repository (perhaps because they attained code execution permission within an app) can insert malicious keys into storage. The Data Protection system intentionally doesn't provide protection against a cyberattacker who gains write access to the key repository.

- If apps need to remain truly isolated from one another, they should use different key repositories. This naturally falls out of the definition of "isolated". Apps are ***not*** isolated if they all have Read and Write access to each other's data stores.

Changing algorithms with UseCryptographicAlgorithms

The Data Protection stack allows you to change the default algorithm used by newly generated keys. The simplest way to do this is to call UseCryptographicAlgorithms from the configuration callback:

C#

```
builder.Services.AddDataProtection()
    .UseCryptographicAlgorithms(new AuthenticatedEncryptorConfiguration
    {
        EncryptionAlgorithm = EncryptionAlgorithm.AES_256_CBC,
        ValidationAlgorithm = ValidationAlgorithm.HMACSHA256
    });
```

The default EncryptionAlgorithm is AES-256-CBC, and the default ValidationAlgorithm is HMACSHA256. The default policy can be set by a system administrator via a machine-wide policy, but an explicit call to `UseCryptographicAlgorithms` overrides the default policy.

Calling `UseCryptographicAlgorithms` allows you to specify the desired algorithm from a predefined built-in list. You don't need to worry about the implementation of the algorithm. In the scenario above, the Data Protection system attempts to use the CNG implementation of AES if running on Windows. Otherwise, it falls back to the managed System.Security.Cryptography.Aes class.

You can manually specify an implementation via a call to UseCustomCryptographicAlgorithms.

> **Tip**
>
> Changing algorithms doesn't affect existing keys in the key ring. It only affects newly-generated keys.

Specifying custom managed algorithms

To specify custom managed algorithms, create a ManagedAuthenticatedEncryptorConfiguration instance that points to the implementation types:

C#

```
builder.Services.AddDataProtection()
    .UseCustomCryptographicAlgorithms(new
ManagedAuthenticatedEncryptorConfiguration
    {
        // A type that subclasses SymmetricAlgorithm
        EncryptionAlgorithmType = typeof(Aes),

        // Specified in bits
        EncryptionAlgorithmKeySize = 256,

        // A type that subclasses KeyedHashAlgorithm
        ValidationAlgorithmType = typeof(HMACSHA256)
    });
```

Generally the *Type properties must point to concrete, instantiable (via a public parameterless ctor) implementations of SymmetricAlgorithm and KeyedHashAlgorithm, though the system special-cases some values like `typeof(Aes)` for convenience.

> **Note**
>
> The SymmetricAlgorithm must have a key length of ≥ 128 bits and a block size of ≥ 64 bits, and it must support CBC-mode encryption with PKCS #7 padding. The KeyedHashAlgorithm must have a digest size of >= 128 bits, and it must support keys of length equal to the hash algorithm's digest length. The KeyedHashAlgorithm isn't strictly required to be HMAC.

Specifying custom Windows CNG algorithms

To specify a custom Windows CNG algorithm using CBC-mode encryption with HMAC validation, create a CngCbcAuthenticatedEncryptorConfiguration instance that contains the algorithmic information:

C#

```
builder.Services.AddDataProtection()
    .UseCustomCryptographicAlgorithms(new
CngCbcAuthenticatedEncryptorConfiguration
    {
        // Passed to BCryptOpenAlgorithmProvider
        EncryptionAlgorithm = "AES",
        EncryptionAlgorithmProvider = null,

        // Specified in bits
        EncryptionAlgorithmKeySize = 256,

        // Passed to BCryptOpenAlgorithmProvider
        HashAlgorithm = "SHA256",
        HashAlgorithmProvider = null
    });
```

> **Note**
>
> The symmetric block cipher algorithm must have a key length of >= 128 bits, a block size of >= 64 bits, and it must support CBC-mode encryption with PKCS #7 padding. The hash algorithm must have a digest size of >= 128 bits and must support being opened with the BCRYPT_ALG_HANDLE_HMAC_FLAG flag. The *Provider properties can be set to null to use the default provider for the specified algorithm. For more information, see the BCryptOpenAlgorithmProvider documentation.

To specify a custom Windows CNG algorithm using Galois/Counter Mode encryption with validation, create a CngGcmAuthenticatedEncryptorConfiguration instance that contains the algorithmic information:

C#

```
builder.Services.AddDataProtection()
    .UseCustomCryptographicAlgorithms(new
CngGcmAuthenticatedEncryptorConfiguration
    {
        // Passed to BCryptOpenAlgorithmProvider
        EncryptionAlgorithm = "AES",
        EncryptionAlgorithmProvider = null,

        // Specified in bits
```

```
        EncryptionAlgorithmKeySize = 256
    });
```

> **Note**
>
> The symmetric block cipher algorithm must have a key length of >= 128 bits, a block size of exactly 128 bits, and it must support GCM encryption. You can set the EncryptionAlgorithmProvider property to null to use the default provider for the specified algorithm. For more information, see the BCryptOpenAlgorithmProvider documentation.

Specifying other custom algorithms

Though not exposed as a first-class API, the Data Protection system is extensible enough to allow specifying almost any kind of algorithm. For example, it's possible to keep all keys contained within a Hardware Security Module (HSM) and to provide a custom implementation of the core encryption and decryption routines. For more information, see IAuthenticatedEncryptor in Core cryptography extensibility.

Persisting keys when hosting in a Docker container

When hosting in a Docker container, keys should be maintained in either:

- A folder that's a Docker volume that persists beyond the container's lifetime, such as a shared volume or a host-mounted volume.
- An external provider, such as Azure Blob Storage (shown in the ProtectKeysWithAzureKeyVault section) or Redis.

Persisting keys with Redis

Only Redis versions supporting Redis Data Persistence should be used to store keys. Azure Blob storage is persistent and can be used to store keys. For more information, see this GitHub issue.

Logging DataProtection

Enable `Information` level logging of DataProtection to help diagnosis problem. The following `appsettings.json` file enables information logging of the DataProtection API:

C#

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning",
      "Microsoft.AspNetCore.DataProtection": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

For more information on logging, see Logging in .NET Core and ASP.NET Core.

Data Protection key management and lifetime in ASP.NET Core

Article • 08/21/2024

By Rick Anderson

Key management

The app attempts to detect its operational environment and handle key configuration on its own.

1. If the app is hosted in Azure Apps, keys are persisted to the *%HOME%\ASP.NET\DataProtection-Keys* folder. This folder is backed by network storage and is synchronized across all machines hosting the app.

   - Keys aren't protected at rest.
   - The *DataProtection-Keys* folder supplies the key ring to all instances of an app in a single deployment slot.
   - Separate deployment slots, such as Staging and Production, don't share a key ring. When you swap between deployment slots, for example swapping Staging to Production or using A/B testing, any app using Data Protection won't be able to decrypt stored data using the key ring inside the previous slot. This leads to users being logged out of an app that uses the standard ASP.NET Core cookie authentication, as it uses Data Protection to protect its cookies. If you desire slot-independent key rings, use an external key ring provider, such as Azure Blob Storage, Azure Key Vault, a SQL store, or Redis cache.

2. If the user profile is available, keys are persisted to the *%LOCALAPPDATA%\ASP.NET\DataProtection-Keys* folder. If the operating system is Windows, the keys are encrypted at rest using DPAPI.

   The app pool's setProfileEnvironment attribute must also be enabled. The default value of `setProfileEnvironment` is `true`. In some scenarios (for example, Windows OS), `setProfileEnvironment` is set to `false`. If keys aren't stored in the user profile directory as expected:
   a. Navigate to the *%windir%/system32/inetsrv/config* folder.
   b. Open the *applicationHost.config* file.
   c. Locate the `<system.applicationHost><applicationPools><applicationPoolDefaults><processModel>` element.

   d. Confirm that the `setProfileEnvironment` attribute isn't present, which defaults the value to `true`, or explicitly set the attribute's value to `true`.

3. If the app is hosted in IIS, keys are persisted to the HKLM registry in a special registry key that's ACLed only to the worker process account. Keys are encrypted at rest using DPAPI.

4. If none of these conditions match, keys aren't persisted outside of the current process. When the process shuts down, all generated keys are lost.

The developer is always in full control and can override how and where keys are stored. The first three options above should provide good defaults for most apps similar to how the ASP.NET **<machineKey>** auto-generation routines worked in the past. The final, fallback option is the only scenario that requires the developer to specify configuration upfront if they want key persistence, but this fallback only occurs in rare situations.

When hosting in a Docker container, keys should be persisted in a folder that's a Docker volume (a shared volume or a host-mounted volume that persists beyond the container's lifetime) or in an external provider, such as Azure Key Vault or Redis. An external provider is also useful in web farm scenarios if apps can't access a shared network volume (see PersistKeysToFileSystem for more information).

> ⚠ **Warning**
>
> If the developer overrides the rules outlined above and points the Data Protection system at a specific key repository, automatic encryption of keys at rest is disabled. At-rest protection can be re-enabled via **configuration**.

Key lifetime

Keys have a 90-day lifetime by default. When a key expires, the app automatically generates a new key and sets the new key as the active key. As long as retired keys remain on the system, your app can decrypt any data protected with them. See key management for more information.

Default algorithms

The default payload protection algorithm used is AES-256-CBC for confidentiality and HMACSHA256 for authenticity. A 512-bit master key, changed every 90 days, is used to derive the two sub-keys used for these algorithms on a per-payload basis. See subkey derivation for more information.

Delete keys

Deleting a key makes its protected data permanently inaccessible. To mitigate that risk, we recommend not deleting keys. The resulting accumulation of keys generally has minimal impact because they're small. In exceptional cases, such as extremely long-running services, keys can be deleted. Only delete keys:

- That are old (no longer in use).
- When you can accept the risk of data loss in exchange for storage savings.

We recommend not deleting data protection keys.

C#

```
using Microsoft.AspNetCore.DataProtection.KeyManagement;

var services = new ServiceCollection();
services.AddDataProtection();

var serviceProvider = services.BuildServiceProvider();

var keyManager = serviceProvider.GetService<IKeyManager>();

if (keyManager is IDeletableKeyManager deletableKeyManager)
{
    var utcNow = DateTimeOffset.UtcNow;
    var yearAgo = utcNow.AddYears(-1);

    if (!deletableKeyManager.DeleteKeys(key => key.ExpirationDate <
yearAgo))
    {
        Console.WriteLine("Failed to delete keys.");
    }
    else
    {
        Console.WriteLine("Old keys deleted successfully.");
    }
}
else
{
    Console.WriteLine("Key manager does not support deletion.");
}
```

Data Protection machine-wide policy support in ASP.NET Core

Article • 06/17/2024

By Rick Anderson

When running on Windows, the Data Protection system has limited support for setting a default machine-wide policy for all apps that consume ASP.NET Core Data Protection. The general idea is that an administrator might wish to change a default setting, such as the algorithms used or key lifetime, without the need to manually update every app on the machine.

> ⚠ **Warning**
>
> The system administrator can set default policy, but they can't enforce it. The app developer can always override any value with one of their own choosing. The default policy only affects apps where the developer hasn't specified an explicit value for a setting.

Setting default policy

To set default policy, an administrator can set known values in the system registry under the following registry key:

HKLM\SOFTWARE\Microsoft\DotNetPackages\Microsoft.AspNetCore.DataProtection

If you're on a 64-bit operating system and want to affect the behavior of 32-bit apps, remember to configure the Wow6432Node equivalent of the above key.

The supported values are shown below.

Expand table

Value	Type	Description
EncryptionType	string	Specifies which algorithms should be used for data protection. The value must be CNG-CBC, CNG-GCM, or Managed and is described in more detail below.
DefaultKeyLifetime	DWORD	Specifies the lifetime for newly-generated keys. The value is specified in days and must be >= 7.

Value	Type	Description
KeyEscrowSinks	string	Specifies the types that are used for key escrow. The value is a semicolon-delimited list of key escrow sinks, where each element in the list is the assembly-qualified name of a type that implements IKeyEscrowSink.

Encryption types

If EncryptionType is CNG-CBC, the system is configured to use a CBC-mode symmetric block cipher for confidentiality and HMAC for authenticity with services provided by Windows CNG (see Specifying custom Windows CNG algorithms for more details). The following additional values are supported, each of which corresponds to a property on the CngCbcAuthenticatedEncryptionSettings type.

Expand table

Value	Type	Description
EncryptionAlgorithm	string	The name of a symmetric block cipher algorithm understood by CNG. This algorithm is opened in CBC mode.
EncryptionAlgorithmProvider	string	The name of the CNG provider implementation that can produce the algorithm EncryptionAlgorithm.
EncryptionAlgorithmKeySize	DWORD	The length (in bits) of the key to derive for the symmetric block cipher algorithm.
HashAlgorithm	string	The name of a hash algorithm understood by CNG. This algorithm is opened in HMAC mode.
HashAlgorithmProvider	string	The name of the CNG provider implementation that can produce the algorithm HashAlgorithm.

If EncryptionType is CNG-GCM, the system is configured to use a Galois/Counter Mode symmetric block cipher for confidentiality and authenticity with services provided by Windows CNG (see Specifying custom Windows CNG algorithms for more details). The following additional values are supported, each of which corresponds to a property on the CngGcmAuthenticatedEncryptionSettings type.

Expand table

Value	Type	Description
EncryptionAlgorithm	string	The name of a symmetric block cipher algorithm understood by CNG. This algorithm is opened in Galois/Counter Mode.
EncryptionAlgorithmProvider	string	The name of the CNG provider implementation that can produce the algorithm EncryptionAlgorithm.
EncryptionAlgorithmKeySize	DWORD	The length (in bits) of the key to derive for the symmetric block cipher algorithm.

If EncryptionType is Managed, the system is configured to use a managed SymmetricAlgorithm for confidentiality and KeyedHashAlgorithm for authenticity (see Specifying custom managed algorithms for more details). The following additional values are supported, each of which corresponds to a property on the ManagedAuthenticatedEncryptionSettings type.

Expand table

Value	Type	Description
EncryptionAlgorithmType	string	The assembly-qualified name of a type that implements SymmetricAlgorithm.
EncryptionAlgorithmKeySize	DWORD	The length (in bits) of the key to derive for the symmetric encryption algorithm.
ValidationAlgorithmType	string	The assembly-qualified name of a type that implements KeyedHashAlgorithm.

If EncryptionType has any other value other than null or empty, the Data Protection system throws an exception at startup.

> ⚠ **Warning**
>
> When configuring a default policy setting that involves type names (EncryptionAlgorithmType, ValidationAlgorithmType, KeyEscrowSinks), the types must be available to the app. This means that for apps running on Desktop CLR, the assemblies that contain these types should be present in the Global Assembly Cache (GAC). For ASP.NET Core apps running on .NET Core, the packages that contain these types should be installed.

Non-DI aware scenarios for Data Protection in ASP.NET Core

Article • 06/17/2024

By Rick Anderson

The ASP.NET Core Data Protection system is normally added to a service container and consumed by dependent components via dependency injection (DI). However, there are cases where this isn't feasible or desired, especially when importing the system into an existing app.

To support these scenarios, the Microsoft.AspNetCore.DataProtection.Extensions package provides a concrete type, DataProtectionProvider, which offers a simple way to use Data Protection without relying on DI. The `DataProtectionProvider` type implements IDataProtectionProvider. Constructing `DataProtectionProvider` only requires providing a DirectoryInfo instance to indicate where the provider's cryptographic keys should be stored, as seen in the following code sample:

C#

```
using System;
using System.IO;
using Microsoft.AspNetCore.DataProtection;

public class Program
{
    public static void Main(string[] args)
    {
        // Get the path to %LOCALAPPDATA%\myapp-keys
        var destFolder = Path.Combine(
            System.Environment.GetEnvironmentVariable("LOCALAPPDATA"),
            "myapp-keys");

        // Instantiate the data protection system at this folder
        var dataProtectionProvider = DataProtectionProvider.Create(
            new DirectoryInfo(destFolder));

        var protector = dataProtectionProvider.CreateProtector("Program.No-
DI");
        Console.Write("Enter input: ");
        var input = Console.ReadLine();

        // Protect the payload
        var protectedPayload = protector.Protect(input);
        Console.WriteLine($"Protect returned: {protectedPayload}");

        // Unprotect the payload
```

```
        var unprotectedPayload = protector.Unprotect(protectedPayload);
        Console.WriteLine($"Unprotect returned: {unprotectedPayload}");

        Console.WriteLine();
        Console.WriteLine("Press any key...");
        Console.ReadKey();
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Enter input: Hello world!
 * Protect returned: CfDJ8FWbAn6...ch3hAPm1NJA
 * Unprotect returned: Hello world!
 *
 * Press any key...
*/
```

By default, the `DataProtectionProvider` concrete type doesn't encrypt raw key material before persisting it to the file system. This is to support scenarios where the developer points to a network share and the Data Protection system can't automatically deduce an appropriate at-rest key encryption mechanism.

Additionally, the `DataProtectionProvider` concrete type doesn't isolate apps by default. All apps using the same key directory can share payloads as long as their purpose parameters match.

The DataProtectionProvider constructor accepts an optional configuration callback that can be used to adjust the behaviors of the system. The sample below demonstrates restoring isolation with an explicit call to SetApplicationName. The sample also demonstrates configuring the system to automatically encrypt persisted keys using Windows DPAPI. If the directory points to a UNC share, you may wish to distribute a shared certificate across all relevant machines and to configure the system to use certificate-based encryption with a call to ProtectKeysWithCertificate.

C#

```
using System;
using System.IO;
using Microsoft.AspNetCore.DataProtection;

public class Program
{
    public static void Main(string[] args)
    {
        // Get the path to %LOCALAPPDATA%\myapp-keys
        var destFolder = Path.Combine(
            System.Environment.GetEnvironmentVariable("LOCALAPPDATA"),
```

```
            "myapp-keys");

        // Instantiate the data protection system at this folder
        var dataProtectionProvider = DataProtectionProvider.Create(
            new DirectoryInfo(destFolder),
            configuration =>
            {
                configuration.SetApplicationName("my app name");
                configuration.ProtectKeysWithDpapi();
            });

        var protector = dataProtectionProvider.CreateProtector("Program.No-
DI");
        Console.Write("Enter input: ");
        var input = Console.ReadLine();

        // Protect the payload
        var protectedPayload = protector.Protect(input);
        Console.WriteLine($"Protect returned: {protectedPayload}");

        // Unprotect the payload
        var unprotectedPayload = protector.Unprotect(protectedPayload);
        Console.WriteLine($"Unprotect returned: {unprotectedPayload}");

        Console.WriteLine();
        Console.WriteLine("Press any key...");
        Console.ReadKey();
    }
}
```

Tip

Instances of the `DataProtectionProvider` concrete type are expensive to create. If an app maintains multiple instances of this type and if they're all using the same key storage directory, app performance might degrade. If you use the `DataProtectionProvider` type, we recommend that you create this type once and reuse it as much as possible. The `DataProtectionProvider` type and all IDataProtector instances created from it are thread-safe for multiple callers.

ASP.NET Core Data Protection extensibility APIs

Core cryptography extensibility in ASP.NET Core

Article • 09/27/2024

> ⚠ **Warning**
>
> Types that implement any of the following interfaces should be thread-safe for multiple callers.

IAuthenticatedEncryptor

The **IAuthenticatedEncryptor** interface is the basic building block of the cryptographic subsystem. There's generally one IAuthenticatedEncryptor per key, and the IAuthenticatedEncryptor instance wraps all cryptographic key material and algorithmic information necessary to perform cryptographic operations.

As its name suggests, the type is responsible for providing authenticated encryption and decryption services. It exposes the following two APIs.

- `Decrypt(ArraySegment<byte> ciphertext, ArraySegment<byte> additionalAuthenticatedData) : byte[]`
- `Encrypt(ArraySegment<byte> plaintext, ArraySegment<byte> additionalAuthenticatedData) : byte[]`

The Encrypt method returns a blob that includes the enciphered plaintext and an authentication tag. The authentication tag must encompass the additional authenticated data (AAD), though the AAD itself need not be recoverable from the final payload. The Decrypt method validates the authentication tag and returns the deciphered payload. All failures (except ArgumentNullException and similar) should be homogenized to CryptographicException.

> ⓘ **Note**
>
> The IAuthenticatedEncryptor instance itself doesn't actually need to contain the key material. For example, the implementation could delegate to an HSM for all operations.

How to create an IAuthenticatedEncryptor

ASP.NET Core 2.x

The **IAuthenticatedEncryptorFactory** interface represents a type that knows how to create an IAuthenticatedEncryptor instance. Its API is as follows.

- CreateEncryptorInstance(IKey key) : IAuthenticatedEncryptor

For any given IKey instance, any authenticated encryptors created by its CreateEncryptorInstance method should be considered equivalent, as in the below code sample.

C#

```
// we have an IAuthenticatedEncryptorFactory instance and an IKey
instance
IAuthenticatedEncryptorFactory factory = ...;
IKey key = ...;

// get an encryptor instance and perform an authenticated encryption
operation
ArraySegment<byte> plaintext = new ArraySegment<byte>
(Encoding.UTF8.GetBytes("plaintext"));
ArraySegment<byte> aad = new ArraySegment<byte>
(Encoding.UTF8.GetBytes("AAD"));
var encryptor1 = factory.CreateEncryptorInstance(key);
byte[] ciphertext = encryptor1.Encrypt(plaintext, aad);

// get another encryptor instance and perform an authenticated
decryption operation
var encryptor2 = factory.CreateEncryptorInstance(key);
byte[] roundTripped = encryptor2.Decrypt(new ArraySegment<byte>
(ciphertext), aad);

// the 'roundTripped' and 'plaintext' buffers should be equivalent
```

IAuthenticatedEncryptorDescriptor (ASP.NET Core 2.x only)

ASP.NET Core 2.x

The **IAuthenticatedEncryptorDescriptor** interface represents a type that knows how to export itself to XML. Its API is as follows.

- ExportToXml() : XmlSerializedDescriptorInfo

XML Serialization

The primary difference between IAuthenticatedEncryptor and IAuthenticatedEncryptorDescriptor is that the descriptor knows how to create the encryptor and supply it with valid arguments. Consider an IAuthenticatedEncryptor whose implementation relies on SymmetricAlgorithm and KeyedHashAlgorithm. The encryptor's job is to consume these types, but it doesn't necessarily know where these types came from, so it can't really write out a proper description of how to recreate itself if the application restarts. The descriptor acts as a higher level on top of this. Since the descriptor knows how to create the encryptor instance (for example it knows how to create the required algorithms), it can serialize that knowledge in XML form so that the encryptor instance can be recreated after an application reset.

The descriptor can be serialized via its ExportToXml routine. This routine returns an XmlSerializedDescriptorInfo which contains two properties: the XElement representation of the descriptor and the Type which represents an IAuthenticatedEncryptorDescriptorDeserializer which can be used to resurrect this descriptor given the corresponding XElement.

The serialized descriptor may contain sensitive information such as cryptographic key material. The data protection system has built-in support for encrypting information before it's persisted to storage. To take advantage of this, the descriptor should mark the element which contains sensitive information with the attribute name "requiresEncryption" (xmlns `"<http://schemas.asp.net/2015/03/dataProtection>"`), value "true".

> **Tip**
>
> There's a helper API for setting this attribute. Call the extension method XElement.MarkAsRequiresEncryption() located in namespace Microsoft.AspNetCore.DataProtection.AuthenticatedEncryption.ConfigurationModel .

There can also be cases where the serialized descriptor doesn't contain sensitive information. Consider again the case of a cryptographic key stored in an HSM. The descriptor cannot write out the key material when serializing itself since the HSM won't expose the material in plaintext form. Instead, the descriptor might write out the key-

wrapped version of the key (if the HSM allows export in this fashion) or the HSM's own unique identifier for the key.

IAuthenticatedEncryptorDescriptorDeserializer

The **IAuthenticatedEncryptorDescriptorDeserializer** interface represents a type that knows how to deserialize an IAuthenticatedEncryptorDescriptor instance from an XElement. It exposes a single method:

- ImportFromXml(XElement element) : IAuthenticatedEncryptorDescriptor

The ImportFromXml method takes the XElement that was returned by IAuthenticatedEncryptorDescriptor.ExportToXml and creates an equivalent of the original IAuthenticatedEncryptorDescriptor.

Types which implement IAuthenticatedEncryptorDescriptorDeserializer should have one of the following two public constructors:

- .ctor(IServiceProvider)
- .ctor()

> ⓘ **Note**
>
> The IServiceProvider passed to the constructor may be null.

The top-level factory

ASP.NET Core 2.x

The **AlgorithmConfiguration** class represents a type which knows how to create IAuthenticatedEncryptorDescriptor instances. It exposes a single API.

- CreateNewDescriptor() : IAuthenticatedEncryptorDescriptor

Think of AlgorithmConfiguration as the top-level factory. The configuration serves as a template. It wraps algorithmic information (for example this configuration produces descriptors with an AES-128-GCM master key), but it's not yet associated with a specific key.

When CreateNewDescriptor is called, fresh key material is created solely for this call, and a new IAuthenticatedEncryptorDescriptor is produced which wraps this key

material and the algorithmic information required to consume the material. The key material could be created in software (and held in memory), it could be created and held within an HSM, and so on. The crucial point is that any two calls to CreateNewDescriptor should never create equivalent IAuthenticatedEncryptorDescriptor instances.

The AlgorithmConfiguration type serves as the entry point for key creation routines such as automatic key rolling. To change the implementation for all future keys, set the AuthenticatedEncryptorConfiguration property in KeyManagementOptions.

Key management extensibility in ASP.NET Core

Article • 06/03/2022

Read the key management section before reading this section, as it explains some of the fundamental concepts behind these APIs.

Warning: Types that implement any of the following interfaces should be thread-safe for multiple callers.

Key

The `IKey` interface is the basic representation of a key in cryptosystem. The term key is used here in the abstract sense, not in the literal sense of "cryptographic key material". A key has the following properties:

- Activation, creation, and expiration dates
- Revocation status
- Key identifier (a GUID)

Additionally, `IKey` exposes a `CreateEncryptor` method which can be used to create an IAuthenticatedEncryptor instance tied to this key.

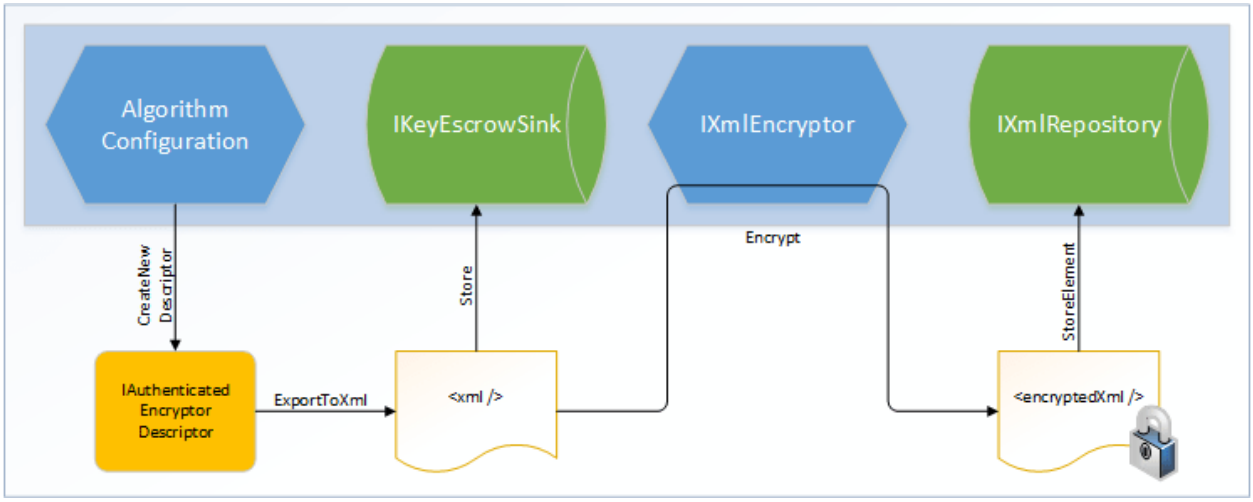
> **Note**
>
> There's no API to retrieve the raw cryptographic material from an `IKey` instance.

IKeyManager

The `IKeyManager` interface represents an object responsible for general key storage, retrieval, and manipulation. It exposes three high-level operations:

- Create a new key and persist it to storage.
- Get all keys from storage.
- Revoke one or more keys and persist the revocation information to storage.

> ⚠ **Warning**
>
> Writing an `IKeyManager` is a very advanced task, and the majority of developers shouldn't attempt it. Instead, most developers should take advantage of the facilities offered by the **XmlKeyManager** class.

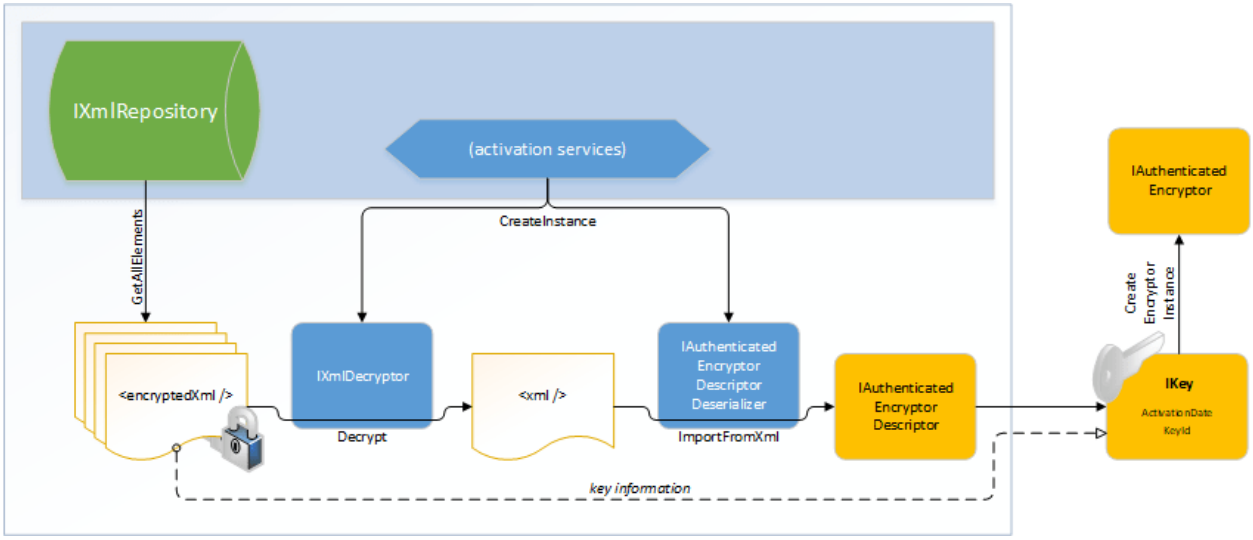


XmlKeyManager

The `XmlKeyManager` type is the in-box concrete implementation of `IKeyManager`. It provides several useful facilities, including key escrow and encryption of keys at rest. Keys in this system are represented as XML elements (specifically, XElement).

`XmlKeyManager` depends on several other components in the course of fulfilling its tasks:

- `AlgorithmConfiguration`, which dictates the algorithms used by new keys.
- `IXmlRepository`, which controls where keys are persisted in storage.
- `IXmlEncryptor` [optional], which allows encrypting keys at rest.
- `IKeyEscrowSink` [optional], which provides key escrow services.



Below are high-level diagrams which indicate how these components are wired together within `XmlKeyManager`.

Key Creation / CreateNewKey

In the implementation of `CreateNewKey`, the `AlgorithmConfiguration` component is used to create a unique `IAuthenticatedEncryptorDescriptor`, which is then serialized as XML. If a key escrow sink is present, the raw (unencrypted) XML is provided to the sink for long-term storage. The unencrypted XML is then run through an `IXmlEncryptor` (if

required) to generate the encrypted XML document. This encrypted document is persisted to long-term storage via the `IXmlRepository`. (If no `IXmlEncryptor` is configured, the unencrypted document is persisted in the `IXmlRepository`.)

Key Retrieval / GetAllKeys

In the implementation of `GetAllKeys`, the XML documents representing keys and revocations are read from the underlying `IXmlRepository`. If these documents are encrypted, the system will automatically decrypt them. `XmlKeyManager` creates the appropriate `IAuthenticatedEncryptorDescriptorDeserializer` instances to deserialize the documents back into `IAuthenticatedEncryptorDescriptor` instances, which are then wrapped in individual `IKey` instances. This collection of `IKey` instances is returned to the caller.

Further information on the particular XML elements can be found in the key storage format document.

IXmlRepository

The `IXmlRepository` interface represents a type that can persist XML to and retrieve XML from a backing store. It exposes two APIs:

- `GetAllElements` : `IReadOnlyCollection<XElement>`
- `StoreElement(XElement element, string friendlyName)`

Implementations of `IXmlRepository` don't need to parse the XML passing through them. They should treat the XML documents as opaque and let higher layers worry about generating and parsing the documents.

There are four built-in concrete types which implement `IXmlRepository`:

- FileSystemXmlRepository
- RegistryXmlRepository
- AzureStorage.AzureBlobXmlRepository
- RedisXmlRepository

See the key storage providers document for more information.

Registering a custom `IXmlRepository` is appropriate when using a different backing store (for example, Azure Table Storage).

To change the default repository application-wide, register a custom `IXmlRepository` instance:

```
C#

services.Configure<KeyManagementOptions>(options => options.XmlRepository =
new MyCustomXmlRepository());
```

IXmlEncryptor

The `IXmlEncryptor` interface represents a type that can encrypt a plaintext XML element. It exposes a single API:

- Encrypt(XElement plaintextElement) : EncryptedXmlInfo

If a serialized `IAuthenticatedEncryptorDescriptor` contains any elements marked as "requires encryption", then `XmlKeyManager` will run those elements through the configured `IXmlEncryptor`'s `Encrypt` method, and it will persist the enciphered element rather than the plaintext element to the `IXmlRepository`. The output of the `Encrypt` method is an `EncryptedXmlInfo` object. This object is a wrapper which contains both the resultant enciphered `XElement` and the Type which represents an `IXmlDecryptor` which can be used to decipher the corresponding element.

There are four built-in concrete types which implement `IXmlEncryptor`:

- CertificateXmlEncryptor
- DpapiNGXmlEncryptor
- DpapiXmlEncryptor
- NullXmlEncryptor

See the key encryption at rest document for more information.

To change the default key-encryption-at-rest mechanism application-wide, register a custom `IXmlEncryptor` instance:

```
C#

services.Configure<KeyManagementOptions>(options => options.XmlEncryptor =
new MyCustomXmlEncryptor());
```

IXmlDecryptor

The `IXmlDecryptor` interface represents a type that knows how to decrypt an `XElement` that was enciphered via an `IXmlEncryptor`. It exposes a single API:

- Decrypt(XElement encryptedElement) : XElement

The `Decrypt` method undoes the encryption performed by `IXmlEncryptor.Encrypt`. Generally, each concrete `IXmlEncryptor` implementation will have a corresponding concrete `IXmlDecryptor` implementation.

Types which implement `IXmlDecryptor` should have one of the following two public constructors:

- .ctor(IServiceProvider)
- .ctor()

> ⓘ **Note**
>
> The `IServiceProvider` passed to the constructor may be null.

IKeyEscrowSink

The `IKeyEscrowSink` interface represents a type that can perform escrow of sensitive information. Recall that serialized descriptors might contain sensitive information (such as cryptographic material), and this is what led to the introduction of the IXmlEncryptor type in the first place. However, accidents happen, and key rings can be deleted or become corrupted.

The escrow interface provides an emergency escape hatch, allowing access to the raw serialized XML before it's transformed by any configured IXmlEncryptor. The interface exposes a single API:

- Store(Guid keyId, XElement element)

It's up to the `IKeyEscrowSink` implementation to handle the provided element in a secure manner consistent with business policy. One possible implementation could be for the escrow sink to encrypt the XML element using a known corporate X.509 certificate where the certificate's private key has been escrowed; the `CertificateXmlEncryptor` type can assist with this. The `IKeyEscrowSink` implementation is also responsible for persisting the provided element appropriately.

By default no escrow mechanism is enabled, though server administrators can configure this globally. It can also be configured programmatically via the `IDataProtectionBuilder.AddKeyEscrowSink` method as shown in the sample below. The `AddKeyEscrowSink` method overloads mirror the `IServiceCollection.AddSingleton` and `IServiceCollection.AddInstance` overloads, as `IKeyEscrowSink` instances are intended to be singletons. If multiple `IKeyEscrowSink` instances are registered, each one will be called during key generation, so keys can be escrowed to multiple mechanisms simultaneously.

There's no API to read material from an `IKeyEscrowSink` instance. This is consistent with the design theory of the escrow mechanism: it's intended to make the key material accessible to a trusted authority, and since the application is itself not a trusted authority, it shouldn't have access to its own escrowed material.

The following sample code demonstrates creating and registering an `IKeyEscrowSink` where keys are escrowed such that only members of "CONTOSODomain Admins" can recover them.

> **Note**
>
> To run this sample, you must be on a domain-joined Windows 8 / Windows Server 2012 machine, and the domain controller must be Windows Server 2012 or later.

C#

```
using System;
using System.IO;
using System.Xml.Linq;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.AspNetCore.DataProtection.KeyManagement;
using Microsoft.AspNetCore.DataProtection.XmlEncryption;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Logging;

public class Program
```

```
{
    public static void Main(string[] args)
    {
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection()
            .PersistKeysToFileSystem(new DirectoryInfo(@"c:\temp-keys"))
            .ProtectKeysWithDpapi()
            .AddKeyEscrowSink(sp => new MyKeyEscrowSink(sp));
        var services = serviceCollection.BuildServiceProvider();

        // get a reference to the key manager and force a new key to be
generated
        Console.WriteLine("Generating new key...");
        var keyManager = services.GetService<IKeyManager>();
        keyManager.CreateNewKey(
            activationDate: DateTimeOffset.Now,
            expirationDate: DateTimeOffset.Now.AddDays(7));
    }

    // A key escrow sink where keys are escrowed such that they
    // can be read by members of the CONTOSO\Domain Admins group.
    private class MyKeyEscrowSink : IKeyEscrowSink
    {
        private readonly IXmlEncryptor _escrowEncryptor;

        public MyKeyEscrowSink(IServiceProvider services)
        {
            // Assuming I'm on a machine that's a member of the CONTOSO
            // domain, I can use the Domain Admins SID to generate an
            // encrypted payload that only they can read. Sample SID from
            // https://technet.microsoft.com/library/cc778824(v=ws.10).aspx.
            _escrowEncryptor = new DpapiNGXmlEncryptor(
                "SID=S-1-5-21-1004336348-1177238915-682003330-512",
                DpapiNGProtectionDescriptorFlags.None,
                new LoggerFactory());
        }

        public void Store(Guid keyId, XElement element)
        {
            // Encrypt the key element to the escrow encryptor.
            var encryptedXmlInfo = _escrowEncryptor.Encrypt(element);

            // A real implementation would save the escrowed key to a
            // write-only file share or some other stable storage, but
            // in this sample we'll just write it out to the console.
            Console.WriteLine($"Escrowing key {keyId}");
            Console.WriteLine(encryptedXmlInfo.EncryptedElement);

            // Note: We cannot read the escrowed key material ourselves.
            // We need to get a member of CONTOSO\Domain Admins to read
            // it for us in the event we need to recover it.
        }
    }
}
```

Miscellaneous ASP.NET Core Data Protection APIs

Article • 06/03/2022

> ⚠ **Warning**
>
> Types that implement any of the following interfaces should be thread-safe for multiple callers.

ISecret

The `ISecret` interface represents a secret value, such as cryptographic key material. It contains the following API surface:

- `Length`: `int`
- `Dispose()`: `void`
- `WriteSecretIntoBuffer(ArraySegment<byte> buffer)`: `void`

The `WriteSecretIntoBuffer` method populates the supplied buffer with the raw secret value. The reason this API takes the buffer as a parameter rather than returning a `byte[]` directly is that this gives the caller the opportunity to pin the buffer object, limiting secret exposure to the managed garbage collector.

The `Secret` type is a concrete implementation of `ISecret` where the secret value is stored in in-process memory. On Windows platforms, the secret value is encrypted via CryptProtectMemory.

Authenticated encryption details in ASP.NET Core

Article • 10/21/2024

Calls to IDataProtector.Protect are authenticated encryption operations. The Protect method offers both confidentiality and authenticity, and it's tied to the purpose chain that was used to derive this particular IDataProtector instance from its root IDataProtectionProvider.

IDataProtector.Protect takes a byte[] plaintext parameter and produces a byte[] protected payload, whose format is described below. (There's also an extension method overload which takes a string plaintext parameter and returns a string protected payload. If this API is used the protected payload format will still have the below structure, but it will be base64url-encoded.)

Protected payload format

The protected payload format consists of three primary components:

- A 32-bit magic header that identifies the version of the data protection system.
- A 128-bit key id that identifies the key used to protect this particular payload.
- The remainder of the protected payload is specific to the encryptor encapsulated by this key. In the example below, the key represents an AES-256-CBC + HMACSHA256 encryptor, and the payload is further subdivided as follows:
  - A 128-bit key modifier.
  - A 128-bit initialization vector.
  - 48 bytes of AES-256-CBC output.
  - An HMACSHA256 authentication tag.

A sample protected payload is illustrated below.

```
09 F0 C9 F0 80 9C 81 0C 19 66 19 40 95 36 53 F8
AA FF EE 57 57 2F 40 4C 3F 7F CC 9D CC D9 32 3E
84 17 99 16 EC BA 1F 4A A1 18 45 1F 2D 13 7A 28
79 6B 86 9C F8 B7 84 F9 26 31 FC B1 86 0A F1 56
61 CF 14 58 D3 51 6F CF 36 50 85 82 08 2D 3F 73
5F B0 AD 9E 1A B2 AE 13 57 90 C8 F5 7C 95 4E 6A
8A AA 06 EF 43 CA 19 62 84 7C 11 B2 C8 71 9D AA
```

```
52 19 2E 5B 4C 1E 54 F0 55 BE 88 92 12 C1 4B 5E
52 C9 74 A0
```

From the payload format above the first 32 bits, or 4 bytes are the magic header identifying the version (09 F0 C9 F0)

The next 128 bits, or 16 bytes is the key identifier (80 9C 81 0C 19 66 19 40 95 36 53 F8 AA FF EE 57)

The remainder contains the payload and is specific to the format used.

> ⚠ **Warning**
>
> All payloads protected to a given key will begin with the same 20-byte (magic value, key id) header. Administrators can use this fact for diagnostic purposes to approximate when a payload was generated. For example, the payload above corresponds to key {aaaaaaaa-0b0b-1c1c-2d2d-333333333333}. If after checking the key repository you find that this specific key's activation date was 2015-01-01 and its expiration date was 2015-03-01, then it's reasonable to assume that the payload (if not tampered with) was generated within that window, give or take a small fudge factor on either side.

Subkey derivation and authenticated encryption in ASP.NET Core

Article • 01/04/2023

Most keys in the key ring will contain some form of entropy and will have algorithmic information stating "CBC-mode encryption + HMAC validation" or "GCM encryption + validation". In these cases, we refer to the embedded entropy as the master keying material (or KM) for this key, and we perform a key derivation function to derive the keys that will be used for the actual cryptographic operations.

> ⓘ **Note**
>
> Keys are abstract, and a custom implementation might not behave as below. If the key provides its own implementation of `IAuthenticatedEncryptor` rather than using one of our built-in factories, the mechanism described in this section no longer applies.

Additional authenticated data and subkey derivation

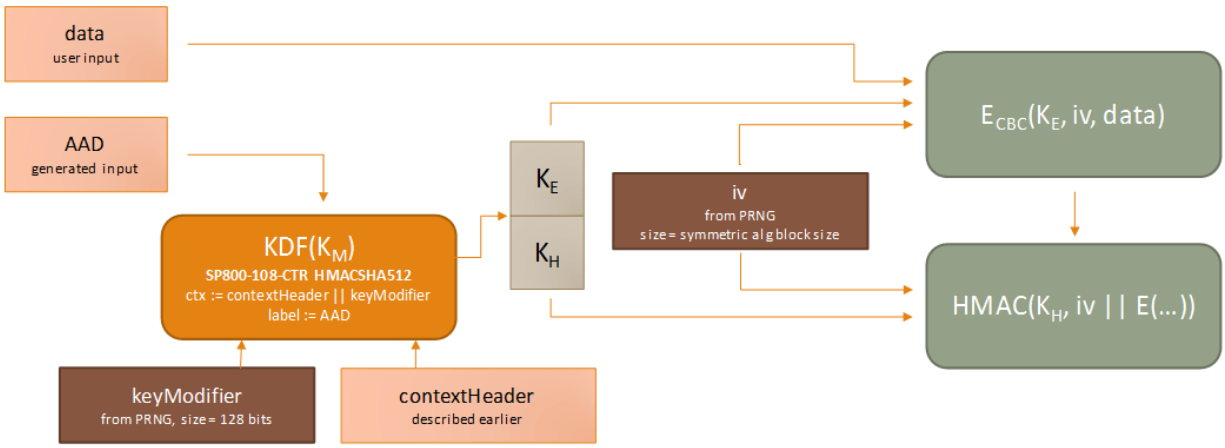
The `IAuthenticatedEncryptor` interface serves as the core interface for all authenticated encryption operations. Its `Encrypt` method takes two buffers: plaintext and additionalAuthenticatedData (AAD). The plaintext contents flow unchanged the call to `IDataProtector.Protect`, but the AAD is generated by the system and consists of three components:

1. The 32-bit magic header 09 F0 C9 F0 that identifies this version of the data protection system.
2. The 128-bit key id.
3. A variable-length string formed from the purpose chain that created the `IDataProtector` that's performing this operation.

Because the AAD is unique for the tuple of all three components, we can use it to derive new keys from KM instead of using KM itself in all of our cryptographic operations. For every call to `IAuthenticatedEncryptor.Encrypt`, the following key derivation process takes place:

```
( K_E, K_H ) = SP800_108_CTR_HMACSHA512(K_M, AAD, contextHeader || keyModifier)
```

Here, we're calling the NIST SP800-108 KDF in Counter Mode (see NIST SP800-108, Sec. 5.1) with the following parameters:



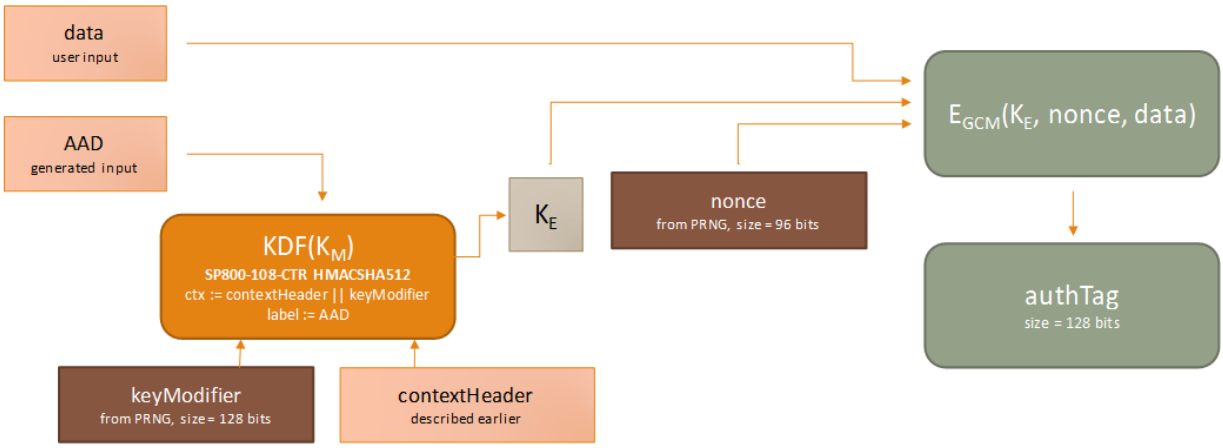
- Key derivation key (KDK) = `K_M`
- PRF = HMACSHA512
- label = additionalAuthenticatedData
- context = contextHeader || keyModifier

The context header is of variable length and essentially serves as a thumbprint of the algorithms for which we're deriving `K_E` and `K_H`. The key modifier is a 128-bit string randomly generated for each call to `Encrypt` and serves to ensure with overwhelming probability that KE and KH are unique for this specific authentication encryption operation, even if all other input to the KDF is constant.

For CBC-mode encryption + HMAC validation operations, `| K_E |` is the length of the symmetric block cipher key, and `| K_H |` is the digest size of the HMAC routine. For GCM encryption + validation operations, `| K_H | = 0`.

CBC-mode encryption + HMAC validation

Once `K_E` is generated via the above mechanism, we generate a random initialization vector and run the symmetric block cipher algorithm to encipher the plaintext. The initialization vector and ciphertext are then run through the HMAC routine initialized with the key `K_H` to produce the MAC. This process and the return value is represented graphically below.



`output:= keyModifier || iv || E_cbc (K_E,iv,data) || HMAC(K_H, iv || E_cbc (K_E,iv,data))`

> ⓘ Note
>
> The `IDataProtector.Protect` implementation will **prepend the magic header and key id** to output before returning it to the caller. Because the magic header and key id are implicitly part of **AAD**, and because the key modifier is fed as input to the KDF, this means that every single byte of the final returned payload is authenticated by the MAC.

Galois/Counter Mode encryption + validation

Once `K_E` is generated via the above mechanism, we generate a random 96-bit nonce and run the symmetric block cipher algorithm to encipher the plaintext and produce the 128-bit authentication tag.

`output := keyModifier || nonce || E_gcm (K_E,nonce,data) || authTag`

> ⓘ Note
>
> Even though GCM natively supports the concept of AAD, we're still feeding AAD only to the original KDF, opting to pass an empty string into GCM for its AAD parameter. The reason for this is two-fold. First, **to support agility** we never want to use `K_M` directly as the encryption key. Additionally, GCM imposes very strict uniqueness requirements on its inputs. The probability that the GCM encryption routine is ever invoked on two or more distinct sets of input data with the same (key, nonce) pair must not exceed 2^-32. If we fix `K_E` we cannot perform more than 2^32 encryption operations before we run afoul of the 2^-32 limit. This might

seem like a very large number of operations, but a high-traffic web server can go through 4 billion requests in mere days, well within the normal lifetime for these keys. To stay compliant of the 2^-32 probability limit, we continue to use a 128-bit key modifier and 96-bit nonce, which radically extends the usable operation count for any given `K_M`. For simplicity of design we share the KDF code path between CBC and GCM operations, and since AAD is already considered in the KDF there's no need to forward it to the GCM routine.

Context headers in ASP.NET Core

Article • 06/03/2022

Background and theory

In the data protection system, a "key" means an object that can provide authenticated encryption services. Each key is identified by a unique id (a GUID), and it carries with it algorithmic information and entropic material. It's intended that each key carry unique entropy, but the system cannot enforce that, and we also need to account for developers who might change the key ring manually by modifying the algorithmic information of an existing key in the key ring. To achieve our security requirements given these cases the data protection system has a concept of cryptographic agility, which allows securely using a single entropic value across multiple cryptographic algorithms.

Most systems which support cryptographic agility do so by including some identifying information about the algorithm inside the payload. The algorithm's OID is generally a good candidate for this. However, one problem that we ran into is that there are multiple ways to specify the same algorithm: "AES" (CNG) and the managed Aes, AesManaged, AesCryptoServiceProvider, AesCng, and RijndaelManaged (given specific parameters) classes are all actually the same thing, and we'd need to maintain a mapping of all of these to the correct OID. If a developer wanted to provide a custom algorithm (or even another implementation of AES!), they'd have to tell us its OID. This extra registration step makes system configuration particularly painful.

Stepping back, we decided that we were approaching the problem from the wrong direction. An OID tells you what the algorithm is, but we don't actually care about this. If we need to use a single entropic value securely in two different algorithms, it's not necessary for us to know what the algorithms actually are. What we actually care about is how they behave. Any decent symmetric block cipher algorithm is also a strong pseudorandom permutation (PRP): fix the inputs (key, chaining mode, IV, plaintext) and the ciphertext output will with overwhelming probability be distinct from any other symmetric block cipher algorithm given the same inputs. Similarly, any decent keyed hash function is also a strong pseudorandom function (PRF), and given a fixed input set its output will overwhelmingly be distinct from any other keyed hash function.

We use this concept of strong PRPs and PRFs to build up a context header. This context header essentially acts as a stable thumbprint over the algorithms in use for any given operation, and it provides the cryptographic agility needed by the data protection system. This header is reproducible and is used later as part of the subkey derivation

process. There are two different ways to build the context header depending on the modes of operation of the underlying algorithms.

CBC-mode encryption + HMAC authentication

The context header consists of the following components:

- [16 bits] The value 00 00, which is a marker meaning "CBC encryption + HMAC authentication".
- [32 bits] The key length (in bytes, big-endian) of the symmetric block cipher algorithm.
- [32 bits] The block size (in bytes, big-endian) of the symmetric block cipher algorithm.
- [32 bits] The key length (in bytes, big-endian) of the HMAC algorithm. (Currently the key size always matches the digest size.)
- [32 bits] The digest size (in bytes, big-endian) of the HMAC algorithm.
- `EncCBC(K_E, IV, "")`, which is the output of the symmetric block cipher algorithm given an empty string input and where IV is an all-zero vector. The construction of `K_E` is described below.
- `MAC(K_H, "")`, which is the output of the HMAC algorithm given an empty string input. The construction of `K_H` is described below.

Ideally, we could pass all-zero vectors for `K_E` and `K_H`. However, we want to avoid the situation where the underlying algorithm checks for the existence of weak keys before performing any operations (notably DES and 3DES), which precludes using a simple or repeatable pattern like an all-zero vector.

Instead, we use the NIST SP800-108 KDF in Counter Mode (see NIST SP800-108, Sec. 5.1) with a zero-length key, label, and context and HMACSHA512 as the underlying PRF. We derive `| K_E | + | K_H |` bytes of output, then decompose the result into `K_E` and `K_H` themselves. Mathematically, this is represented as follows.

```
( K_E || K_H ) = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")
```

Example: AES-192-CBC + HMACSHA256

As an example, consider the case where the symmetric block cipher algorithm is AES-192-CBC and the validation algorithm is HMACSHA256. The system would generate the context header using the following steps.

First, let `( K_E || K_H ) = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")`, where `| K_E | = 192 bits` and `| K_H | = 256 bits` per the specified algorithms. This leads to `K_E = 5BB6..21DD` and `K_H = A04A..00A9` in the example below:

```
5B B6 C9 83 13 78 22 1D 8E 10 73 CA CF 65 8E B0
61 62 42 71 CB 83 21 DD A0 4A 05 00 5B AB C0 A2
49 6F A5 61 E3 E2 49 87 AA 63 55 CD 74 0A DA C4
B7 92 3D BF 59 90 00 A9
```

Next, compute `Enc_CBC (K_E, IV, "")` for AES-192-CBC given `IV = 0*` and `K_E` as above.

`result := F474B1872B3B53E4721DE19C0841DB6F`

Next, compute `MAC(K_H, "")` for HMACSHA256 given `K_H` as above.

`result := D4791184B996092EE1202F36E8608FA8FBD98ABDFF5402F264B1D7211536220C`

This produces the full context header below:

```
00 00 00 00 00 18 00 00 00 10 00 00 00 20 00 00
00 20 F4 74 B1 87 2B 3B 53 E4 72 1D E1 9C 08 41
DB 6F D4 79 11 84 B9 96 09 2E E1 20 2F 36 E8 60
8F A8 FB D9 8A BD FF 54 02 F2 64 B1 D7 21 15 36
22 0C
```

This context header is the thumbprint of the authenticated encryption algorithm pair (AES-192-CBC encryption + HMACSHA256 validation). The components, as described above are:

- the marker `(00 00)`
- the block cipher key length `(00 00 00 18)`
- the block cipher block size `(00 00 00 10)`
- the HMAC key length `(00 00 00 20)`

- the HMAC digest size `(00 00 00 20)`
- the block cipher PRP output `(F4 74 - DB 6F)` and
- the HMAC PRF output `(D4 79 - end)`.

> ⓘ **Note**
>
> The CBC-mode encryption + HMAC authentication context header is built the same way regardless of whether the algorithms implementations are provided by Windows CNG or by managed SymmetricAlgorithm and KeyedHashAlgorithm types. This allows applications running on different operating systems to reliably produce the same context header even though the implementations of the algorithms differ between OSes. (In practice, the KeyedHashAlgorithm doesn't have to be a proper HMAC. It can be any keyed hash algorithm type.)

Example: 3DES-192-CBC + HMACSHA1

First, let `( K_E || K_H ) = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")`, where `| K_E | = 192 bits` and `| K_H | = 160 bits` per the specified algorithms. This leads to `K_E = A219..E2BB` and `K_H = DC4A..B464` in the example below:

```
A2 19 60 2F 83 A9 13 EA B0 61 3A 39 B8 A6 7E 22
61 D9 F8 6C 10 51 E2 BB DC 4A 00 D7 03 A2 48 3E
D1 F7 5A 34 EB 28 3E D7 D4 67 B4 64
```

Next, compute `Enc_CBC (K_E, IV, "")` for 3DES-192-CBC given `IV = 0*` and `K_E` as above.

`result := ABB100F81E53E10E`

Next, compute `MAC(K_H, "")` for HMACSHA1 given `K_H` as above.

`result := 76EB189B35CF03461DDF877CD9F4B1B4D63A7555`

This produces the full context header which is a thumbprint of the authenticated encryption algorithm pair (3DES-192-CBC encryption + HMACSHA1 validation), shown below:

```
00 00 00 00 00 18 00 00 00 08 00 00 00 14 00 00
00 14 AB B1 00 F8 1E 53 E1 0E 76 EB 18 9B 35 CF
03 46 1D DF 87 7C D9 F4 B1 B4 D6 3A 75 55
```

The components break down as follows:

- the marker `(00 00)`
- the block cipher key length `(00 00 00 18)`
- the block cipher block size `(00 00 00 08)`
- the HMAC key length `(00 00 00 14)`
- the HMAC digest size `(00 00 00 14)`
- the block cipher PRP output `(AB B1 - E1 0E)` and
- the HMAC PRF output `(76 EB - end)`.

Galois/Counter Mode encryption + authentication

The context header consists of the following components:

- [16 bits] The value 00 01, which is a marker meaning "GCM encryption + authentication".
- [32 bits] The key length (in bytes, big-endian) of the symmetric block cipher algorithm.
- [32 bits] The nonce size (in bytes, big-endian) used during authenticated encryption operations. (For our system, this is fixed at nonce size = 96 bits.)
- [32 bits] The block size (in bytes, big-endian) of the symmetric block cipher algorithm. (For GCM, this is fixed at block size = 128 bits.)
- [32 bits] The authentication tag size (in bytes, big-endian) produced by the authenticated encryption function. (For our system, this is fixed at tag size = 128 bits.)
- [128 bits] The tag of `Enc_GCM (K_E, nonce, "")`, which is the output of the symmetric block cipher algorithm given an empty string input and where nonce is a 96-bit all-zero vector.

`K_E` is derived using the same mechanism as in the CBC encryption + HMAC authentication scenario. However, since there's no `K_H` in play here, we essentially have `| K_H | = 0`, and the algorithm collapses to the below form.

```
K_E = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")
```

Example: AES-256-GCM

First, let `K_E = SP800_108_CTR(prf = HMACSHA512, key = "", label = "", context = "")`, where `| K_E | = 256 bits`.

```
K_E := 22BC6F1B171C08C4AE2F27444AF8FC8B3087A90006CAEA91FDCFB47C1B8733B8
```

Next, compute the authentication tag of `Enc_GCM (K_E, nonce, "")` for AES-256-GCM given `nonce = 096` and `K_E` as above.

```
result := E7DCCE66DF855A323A6BB7BD7A59BE45
```

This produces the full context header below:

```

00 01 00 00 00 20 00 00 00 0C 00 00 00 10 00 00
00 10 E7 DC CE 66 DF 85 5A 32 3A 6B B7 BD 7A 59
BE 45
```

The components break down as follows:

- the marker `(00 01)`
- the block cipher key length `(00 00 00 20)`
- the nonce size `(00 00 00 0C)`
- the block cipher block size `(00 00 00 10)`
- the authentication tag size `(00 00 00 10)` and
- the authentication tag from running the block cipher `(E7 DC - end)`.

Key management in ASP.NET Core

Article • 09/27/2024

The data protection system automatically manages the lifetime of master keys used to protect and unprotect payloads. Each key can exist in one of four stages:

- Created - the key exists in the key ring but has not yet been activated. The key shouldn't be used for new Protect operations until sufficient time has elapsed that the key has had a chance to propagate to all machines that are consuming this key ring.
- Active - the key exists in the key ring and should be used for all new Protect operations.
- Expired - the key has run its natural lifetime and should no longer be used for new Protect operations.
- Revoked - the key is compromised and must not be used for new Protect operations.

Created, active, and expired keys may all be used to unprotect incoming payloads. Revoked keys by default may not be used to unprotect payloads, but the application developer can override this behavior if necessary.

> ⚠ **Warning**
>
> The developer might be tempted to delete a key from the key ring (for example by deleting the corresponding file from the file system). At that point, all data protected by the key is permanently undecipherable, and there's no emergency override like there's with revoked keys. Deleting a key is truly destructive behavior.

Default key selection

When the data protection system reads the key ring from the backing repository, it will attempt to locate a "default" key from the key ring. The default key is used for new Protect operations.

The general heuristic is that the data protection system chooses the key with the most recent activation date as the default key. (There's a small fudge factor to allow for server-to-server clock skew.) If the key is expired or revoked, and if the application has

not disabled automatic key generation, then a new key will be generated with immediate activation per the key expiration and rolling policy below.

The reason the data protection system generates a new key immediately rather than falling back to a different key is that new key generation should be treated as an implicit expiration of all keys that were activated prior to the new key. The general idea is that new keys may have been configured with different algorithms or encryption-at-rest mechanisms than old keys, and the system should prefer the current configuration over falling back.

There's an exception. If the application developer has disabled automatic key generation, then the data protection system must choose something as the default key. In this fallback scenario, the system will choose the non-revoked key with the most recent activation date, with preference given to keys that have had time to propagate to other machines in the cluster. The fallback system may end up choosing an expired default key as a result. The fallback system will never choose a revoked key as the default key, and if the key ring is empty or every key has been revoked then the system will produce an error upon initialization.

Key expiration and rolling

When a key is created, it's automatically given an activation date of { now + 2 days } and an expiration date of { now + 90 days }. The 2-day delay before activation gives the key time to propagate through the system. That is, it allows other applications pointing at the backing store to observe the key at their next auto-refresh period, thus maximizing the chances that when the key ring does become active it has propagated to all applications that might need to use it.

If the default key will expire within 2 days and if the key ring doesn't already have a key that will be active upon expiration of the default key, then the data protection system will automatically persist a new key to the key ring. This new key has an activation date of { default key's expiration date } and an expiration date of { now + 90 days }. This allows the system to automatically roll keys on a regular basis with no interruption of service.

There might be circumstances where a key will be created with immediate activation. One example would be when the application hasn't run for a time and all keys in the key ring are expired. When this happens, the key is given an activation date of { now } without the normal 2-day activation delay.

The default key lifetime is 90 days, though this is configurable as in the following example.

C#

```
services.AddDataProtection()
       // use 14-day lifetime instead of 90-day lifetime
       .SetDefaultKeyLifetime(TimeSpan.FromDays(14));
```

An administrator can also change the default system-wide, though an explicit call to `SetDefaultKeyLifetime` will override any system-wide policy. The default key lifetime cannot be shorter than 7 days.

Automatic key ring refresh

When the data protection system initializes, it reads the key ring from the underlying repository and caches it in memory. This cache allows Protect and Unprotect operations to proceed without hitting the backing store. The system will automatically check the backing store for changes approximately every 24 hours or when the current default key expires, whichever comes first.

> ⚠ **Warning**
>
> Developers should very rarely (if ever) need to use the key management APIs directly. The data protection system will perform automatic key management as described above.

The data protection system exposes an interface `IKeyManager` that can be used to inspect and make changes to the key ring. The DI system that provided the instance of `IDataProtectionProvider` can also provide an instance of `IKeyManager` for your consumption. Alternatively, you can pull the `IKeyManager` straight from the `IServiceProvider` as in the example below.

Any operation which modifies the key ring (creating a new key explicitly or performing a revocation) will invalidate the in-memory cache. The next call to `Protect` or `Unprotect` will cause the data protection system to reread the key ring and recreate the cache.

The sample below demonstrates using the `IKeyManager` interface to inspect and manipulate the key ring, including revoking existing keys and generating a new key manually.

C#

```
using System;
using System.IO;
```

```
using System.Threading;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.AspNetCore.DataProtection.KeyManagement;
using Microsoft.Extensions.DependencyInjection;

public class Program
{
    public static void Main(string[] args)
    {
        var serviceCollection = new ServiceCollection();
        serviceCollection.AddDataProtection()
            // point at a specific folder and use DPAPI to encrypt keys
            .PersistKeysToFileSystem(new DirectoryInfo(@"c:\temp-keys"))
            .ProtectKeysWithDpapi();
        var services = serviceCollection.BuildServiceProvider();

        // perform a protect operation to force the system to put at least
        // one key in the key ring

services.GetDataProtector("Sample.KeyManager.v1").Protect("payload");
        Console.WriteLine("Performed a protect operation.");
        Thread.Sleep(2000);

        // get a reference to the key manager
        var keyManager = services.GetService<IKeyManager>();

        // list all keys in the key ring
        var allKeys = keyManager.GetAllKeys();
        Console.WriteLine($"The key ring contains {allKeys.Count} key(s).");
        foreach (var key in allKeys)
        {
            Console.WriteLine($"Key {key.KeyId:B}: Created =
{key.CreationDate:u}, IsRevoked = {key.IsRevoked}");
        }

        // revoke all keys in the key ring
        keyManager.RevokeAllKeys(DateTimeOffset.Now, reason: "Revocation
reason here.");
        Console.WriteLine("Revoked all existing keys.");

        // add a new key to the key ring with immediate activation and a 1-
month expiration
        keyManager.CreateNewKey(
            activationDate: DateTimeOffset.Now,
            expirationDate: DateTimeOffset.Now.AddMonths(1));
        Console.WriteLine("Added a new key.");

        // list all keys in the key ring
        allKeys = keyManager.GetAllKeys();
        Console.WriteLine($"The key ring contains {allKeys.Count} key(s).");
        foreach (var key in allKeys)
        {
            Console.WriteLine($"Key {key.KeyId:B}: Created =
{key.CreationDate:u}, IsRevoked = {key.IsRevoked}");
        }
```

```
    }
}

/*
 * SAMPLE OUTPUT
 *
 * Performed a protect operation.
 * The key ring contains 1 key(s).
 * Key {1b948618-be1f-440b-b204-64ff5a152552}: Created = 2015-03-18
22:20:49Z, IsRevoked = False
 * Revoked all existing keys.
 * Added a new key.
 * The key ring contains 2 key(s).
 * Key {1b948618-be1f-440b-b204-64ff5a152552}: Created = 2015-03-18
22:20:49Z, IsRevoked = True
 * Key {2266fc40-e2fb-48c6-8ce2-5fde6b1493f7}: Created = 2015-03-18
22:20:51Z, IsRevoked = False
 */
```

Key storage

The data protection system has a heuristic whereby it attempts to deduce an appropriate key storage location and encryption-at-rest mechanism automatically. The key persistence mechanism is also configurable by the app developer. The following documents discuss the in-box implementations of these mechanisms:

- Key storage providers in ASP.NET Core
- Key encryption at rest in Windows and Azure using ASP.NET Core

Key storage providers in ASP.NET Core

Article • 10/30/2024

The data protection system employs a discovery mechanism by default to determine where cryptographic keys should be persisted. The developer can override the default discovery mechanism and manually specify the location.

> ⚠ **Warning**
>
> If you specify an explicit key persistence location, the data protection system deregisters the default key encryption at rest mechanism, so keys are no longer encrypted at rest. It's recommended that you additionally specify an explicit key encryption mechanism for production deployments.

File system

To configure a file system-based key repository, call the PersistKeysToFileSystem configuration routine as shown below. Provide a DirectoryInfo pointing to the repository where keys should be stored:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToFileSystem(new DirectoryInfo(@"c:\temp-keys\"));
}
```

The `DirectoryInfo` can point to a directory on the local machine, or it can point to a folder on a network share. If pointing to a directory on the local machine (and the scenario is that only apps on the local machine require access to use this repository), consider using Windows DPAPI (on Windows) to encrypt the keys at rest. Otherwise, consider using an X.509 certificate to encrypt keys at rest.

Azure Storage

The Azure.Extensions.AspNetCore.DataProtection.Blobs package allows storing data protection keys in Azure Blob Storage. Keys can be shared across several instances of a web app. Apps can share authentication cookies or CSRF protection across multiple servers.

To configure the Azure Blob Storage provider, call one of the PersistKeysToAzureBlobStorage overloads.

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToAzureBlobStorage(new Uri("<blob URI including SAS
token>"));
}
```

If the web app is running as an Azure service, connection string can be used to authenticate to Azure storage by using Azure.Storage.Blobs.

> ⚠ **Warning**
>
> This article shows the use of connection strings. With a local database the user doesn't have to be authenticated, but in production, connection strings sometimes include a password to authenticate. A resource owner password credential (ROPC) is a security risk that should be avoided in production databases. Production apps should use the most secure authentication flow available. For more information on authentication for apps deployed to test or production environments, see Secure authentication flows.

C#

```
string connectionString = "<connection_string>";
string containerName = "my-key-container";
string blobName = "keys.xml";
BlobContainerClient container = new BlobContainerClient(connectionString,
containerName);

// optional - provision the container automatically
await container.CreateIfNotExistsAsync();

BlobClient blobClient = container.GetBlobClient(blobName);

services.AddDataProtection()
    .PersistKeysToAzureBlobStorage(blobClient);
```

> ⓘ **Note**
>
> The connection string to your storage account can be found in the Azure Portal under the "Access Keys" section or by running the following CLI command:

Bash

```
az storage account show-connection-string --name <account_name> --
resource-group <resource_group>
```

Redis

The Microsoft.AspNetCore.DataProtection.StackExchangeRedis package allows storing data protection keys in a Redis cache. Keys can be shared across several instances of a web app. Apps can share authentication cookies or CSRF protection across multiple servers.

To configure on Redis, call one of the PersistKeysToStackExchangeRedis overloads:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    var redis = ConnectionMultiplexer.Connect("<URI>");
    services.AddDataProtection()
        .PersistKeysToStackExchangeRedis(redis, "DataProtection-Keys");
}
```

For more information, see the following topics:

- StackExchange.Redis ConnectionMultiplexer
- Azure Redis Cache
- ASP.NET Core DataProtection samples

Registry

Only applies to Windows deployments.

Sometimes the app might not have write access to the file system. Consider a scenario where an app is running as a virtual service account (such as *w3wp.exe*'s app pool identity). In these cases, the administrator can provision a registry key that's accessible by the service account identity. Call the PersistKeysToRegistry extension method as shown below. Provide a RegistryKey pointing to the location where cryptographic keys should be stored:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()

.PersistKeysToRegistry(Registry.CurrentUser.OpenSubKey(@"SOFTWARE\Sample\keys", true));
}
```

> **ⓘ Important**
>
> We recommend using **Windows DPAPI** to encrypt the keys at rest.

Entity Framework Core

The Microsoft.AspNetCore.DataProtection.EntityFrameworkCore package provides a mechanism for storing data protection keys to a database using Entity Framework Core. The `Microsoft.AspNetCore.DataProtection.EntityFrameworkCore` NuGet package must be added to the project file, it's not part of the Microsoft.AspNetCore.App metapackage.

With this package, keys can be shared across multiple instances of a web app.

To configure the EF Core provider, call the PersistKeysToDbContext method:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));

    // Add a DbContext to store your Database Keys
    services.AddDbContext<MyKeysContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("MyKeysConnection")));

    // using Microsoft.AspNetCore.DataProtection;
    services.AddDataProtection()
        .PersistKeysToDbContext<MyKeysContext>();

    services.AddDefaultIdentity<IdentityUser>()
```

```
        .AddDefaultUI(UIFramework.Bootstrap4)
        .AddEntityFrameworkStores<ApplicationDbContext>();

services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

The generic parameter, `TContext`, must inherit from DbContext and implement IDataProtectionKeyContext:

C#

```
using Microsoft.AspNetCore.DataProtection.EntityFrameworkCore;
using Microsoft.EntityFrameworkCore;
using WebApp1.Data;

namespace WebApp1
{
    class MyKeysContext : DbContext, IDataProtectionKeyContext
    {
        // A recommended constructor overload when using EF Core
        // with dependency injection.
        public MyKeysContext(DbContextOptions<MyKeysContext> options)
            : base(options) { }

        // This maps to the table that stores keys.
        public DbSet<DataProtectionKey> DataProtectionKeys { get; set; }
    }
}
```

Create the `DataProtectionKeys` table.

Visual Studio

Execute the following commands in the **Package Manager Console** (PMC) window:

PowerShell

```
Add-Migration AddDataProtectionKeys -Context MyKeysContext
Update-Database -Context MyKeysContext
```

`MyKeysContext` is the `DbContext` defined in the preceding code sample. If you're using a `DbContext` with a different name, substitute your `DbContext` name for `MyKeysContext`.

The `DataProtectionKeys` class/entity adopts the structure shown in the following table.

Expand table

Property/Field	CLR Type	SQL Type
`Id`	`int`	`int`, PK, `IDENTITY(1,1)`, not null
`FriendlyName`	`string`	`nvarchar(MAX)`, null
`Xml`	`string`	`nvarchar(MAX)`, null

Custom key repository

If the in-box mechanisms aren't appropriate, the developer can specify their own key persistence mechanism by providing a custom IXmlRepository.

Key encryption at rest in Windows and Azure using ASP.NET Core

Article • 03/17/2023

The data protection system employs a discovery mechanism by default to determine how cryptographic keys should be encrypted at rest. The developer can override the discovery mechanism and manually specify how keys should be encrypted at rest.

> ⚠ **Warning**
>
> If you specify an explicit **key persistence location**, the data protection system deregisters the default key encryption at rest mechanism. Consequently, keys are no longer encrypted at rest. We recommend that you **specify an explicit key encryption mechanism** for production deployments. The encryption-at-rest mechanism options are described in this topic.

Azure Key Vault

To store keys in Azure Key Vault, configure the system with ProtectKeysWithAzureKeyVault in the `Startup` class:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()
        .PersistKeysToAzureBlobStorage(new Uri("<blobUriWithSasToken>"))
        .ProtectKeysWithAzureKeyVault("<keyIdentifier>", "<clientId>", "
<clientSecret>");
}
```

For more information, see Configure ASP.NET Core Data Protection: ProtectKeysWithAzureKeyVault.

Windows DPAPI

Only applies to Windows deployments.

When Windows DPAPI is used, key material is encrypted with CryptProtectData before being persisted to storage. DPAPI is an appropriate encryption mechanism for data

that's never read outside of the current machine (though it's possible to back these keys up to Active Directory). To configure DPAPI key-at-rest encryption, call one of the ProtectKeysWithDpapi) extension methods:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    // Only the local user account can decrypt the keys
    services.AddDataProtection()
        .ProtectKeysWithDpapi();
}
```

If `ProtectKeysWithDpapi` is called with no parameters, only the current Windows user account can decipher the persisted key ring. You can optionally specify that any user account on the machine (not just the current user account) be able to decipher the key ring:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    // All user accounts on the machine can decrypt the keys
    services.AddDataProtection()
        .ProtectKeysWithDpapi(protectToLocalMachine: true);
}
```

X.509 certificate

If the app is spread across multiple machines, it may be convenient to distribute a shared X.509 certificate across the machines and configure the hosted apps to use the certificate for encryption of keys at rest:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()

.ProtectKeysWithCertificate("3BCE558E2AD3E0E34A7743EAB5AEA2A9BD2575A0");
}
```

Due to .NET Framework limitations, only certificates with CAPI private keys are supported. See the content below for possible workarounds to these limitations.

Windows DPAPI-NG

This mechanism is available only on Windows 8/Windows Server 2012 or later.

Beginning with Windows 8, Windows OS supports DPAPI-NG (also called CNG DPAPI). For more information, see About CNG DPAPI.

The principal is encoded as a protection descriptor rule. In the following example that calls ProtectKeysWithDpapiNG, only the domain-joined user with the specified SID can decrypt the key ring:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    // Uses the descriptor rule "SID=S-1-5-21-..."
    services.AddDataProtection()
        .ProtectKeysWithDpapiNG("SID=S-1-5-21-...",
        flags: DpapiNGProtectionDescriptorFlags.None);
}
```

There's also a parameterless overload of `ProtectKeysWithDpapiNG`. Use this convenience method to specify the rule "SID={CURRENT_ACCOUNT_SID}", where *CURRENT_ACCOUNT_SID* is the SID of the current Windows user account:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    // Use the descriptor rule "SID={current account SID}"
    services.AddDataProtection()
        .ProtectKeysWithDpapiNG();
}
```

In this scenario, the AD domain controller is responsible for distributing the encryption keys used by the DPAPI-NG operations. The target user can decipher the encrypted payload from any domain-joined machine (provided that the process is running under their identity).

Certificate-based encryption with Windows DPAPI-NG

If the app is running on Windows 8.1/Windows Server 2012 R2 or later, you can use Windows DPAPI-NG to perform certificate-based encryption. Use the rule descriptor

string "CERTIFICATE=HashId:THUMBPRINT", where *THUMBPRINT* is the hex-encoded SHA1 thumbprint of the certificate:

```
C#
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDataProtection()

.ProtectKeysWithDpapiNG("CERTIFICATE=HashId:3BCE558E2...B5AEA2A9BD2575A0",
            flags: DpapiNGProtectionDescriptorFlags.None);
}
```

Any app pointed at this repository must be running on Windows 8.1/Windows Server 2012 R2 or later to decipher the keys.

Custom key encryption

If the in-box mechanisms aren't appropriate, the developer can specify their own key encryption mechanism by providing a custom IXmlEncryptor.

Key immutability and key settings in ASP.NET Core

Article • 06/03/2022

Once an object is persisted to the backing store, its representation is forever fixed. New data can be added to the backing store, but existing data can never be mutated. The primary purpose of this behavior is to prevent data corruption.

One consequence of this behavior is that once a key is written to the backing store, it's immutable. Its creation, activation, and expiration dates can never be changed, though it can revoked by using `IKeyManager`. Additionally, its underlying algorithmic information, master keying material, and encryption at rest properties are also immutable.

If the developer changes any setting that affects key persistence, those changes won't go into effect until the next time a key is generated, either via an explicit call to `IKeyManager.CreateNewKey` or via the data protection system's own automatic key generation behavior. The settings that affect key persistence are as follows:

- The default key lifetime
- The key encryption at rest mechanism
- The algorithmic information contained within the key

If you need these settings to kick in earlier than the next automatic key rolling time, consider making an explicit call to `IKeyManager.CreateNewKey` to force the creation of a new key. Remember to provide an explicit activation date ({ now + 2 days } is a good rule of thumb to allow time for the change to propagate) and expiration date in the call.

> **Tip**
>
> All applications touching the repository should specify the same settings with the `IDataProtectionBuilder` extension methods. Otherwise, the properties of the persisted key will be dependent on the particular application that invoked the key generation routines.

Key storage format in ASP.NET Core

Article • 10/21/2024

Objects are stored at rest in XML representation. The default directory for key storage is:

- Windows: *%LOCALAPPDATA%\ASP.NET\DataProtection-Keys*
- macOS / Linux: *$HOME/.aspnet/DataProtection-Keys*

The <key> element

Keys exist as top-level objects in the key repository. By convention keys have the filename `key-{guid}.xml`, where {guid} is the id of the key. Each such file contains a single key. The format of the file is as follows.

XML

```xml
<?xml version="1.0" encoding="utf-8"?>
<key id="aaaaaaaa-0b0b-1c1c-2d2d-333333333333" version="1">
  <creationDate>2015-03-19T23:32:02.3949887Z</creationDate>
  <activationDate>2015-03-19T23:32:02.3839429Z</activationDate>
  <expirationDate>2015-06-17T23:32:02.3839429Z</expirationDate>
  <descriptor deserializerType="{deserializerType}">
    <descriptor>
      <encryption algorithm="AES_256_CBC" />
      <validation algorithm="HMACSHA256" />
      <enc:encryptedSecret decryptorType="{decryptorType}" xmlns:enc="...">
        <encryptedKey>
          <!-- This key is encrypted with Windows DPAPI. -->
          <value>AQAAANCM...8/zeP8lcwAg==</value>
        </encryptedKey>
      </enc:encryptedSecret>
    </descriptor>
  </descriptor>
</key>
```

The <key> element contains the following attributes and child elements:

- The key id. This value is treated as authoritative; the filename is simply a nicety for human readability.
- The version of the <key> element, currently fixed at 1.
- The key's creation, activation, and expiration dates.
- A <descriptor> element, which contains information on the authenticated encryption implementation contained within this key.

In the above example, the key's id is {aaaaaaaa-0b0b-1c1c-2d2d-333333333333}, it was created and activated on March 19, 2015, and it has a lifetime of 90 days. (Occasionally the activation date might be slightly before the creation date as in this example. This is due to a nit in how the APIs work and is harmless in practice.)

The <descriptor> element

The outer <descriptor> element contains an attribute deserializerType, which is the assembly-qualified name of a type which implements IAuthenticatedEncryptorDescriptorDeserializer. This type is responsible for reading the inner <descriptor> element and for parsing the information contained within.

The particular format of the <descriptor> element depends on the authenticated encryptor implementation encapsulated by the key, and each deserializer type expects a slightly different format for this. In general, though, this element will contain algorithmic information (names, types, OIDs, or similar) and secret key material. In the above example, the descriptor specifies that this key wraps AES-256-CBC encryption + HMACSHA256 validation.

The <encryptedSecret> element

An **<encryptedSecret>** element which contains the encrypted form of the secret key material may be present if encryption of secrets at rest is enabled. The attribute `decryptorType` is the assembly-qualified name of a type which implements IXmlDecryptor. This type is responsible for reading the inner **<encryptedKey>** element and decrypting it to recover the original plaintext.

As with `<descriptor>`, the particular format of the `<encryptedSecret>` element depends on the at-rest encryption mechanism in use. In the above example, the master key is encrypted using Windows DPAPI per the comment.

The <revocation> element

Revocations exist as top-level objects in the key repository. By convention revocations have the filename *`revocation-{timestamp}.xml`* (for revoking all keys before a specific date) or *`revocation-{guid}.xml`* (for revoking a specific key). Each file contains a single <revocation> element.

For revocations of individual keys, the file contents will be as below.

```
XML
```

```xml
<?xml version="1.0" encoding="utf-8"?>
<revocation version="1">
  <revocationDate>2015-03-20T22:45:30.2616742Z</revocationDate>
  <key id="bbbbbbbb-1c1c-2d2d-3e3e-444444444444" />
  <reason>human-readable reason</reason>
</revocation>
```

In this case, only the specified key is revoked. If the key id is "*", however, as in the below example, all keys whose creation date is prior to the specified revocation date are revoked.

XML

```xml
<?xml version="1.0" encoding="utf-8"?>
<revocation version="1">
  <revocationDate>2015-03-20T15:45:45.7366491-07:00</revocationDate>
  <!-- All keys created before the revocation date are revoked. -->
  <key id="*" />
  <reason>human-readable reason</reason>
</revocation>
```

The <reason> element is never read by the system. It's simply a convenient place to store a human-readable reason for revocation.

Ephemeral data protection providers in ASP.NET Core

Article • 02/28/2023

There are scenarios where an application needs a throwaway `IDataProtectionProvider`. For example, the developer might just be experimenting in a one-off console application, or the application itself is transient (it's scripted or a unit test project). To support these scenarios the Microsoft.AspNetCore.DataProtection package includes a type `EphemeralDataProtectionProvider`. This type provides a basic implementation of `IDataProtectionProvider` whose key repository is held solely in-memory and isn't written out to any backing store.

Each instance of `EphemeralDataProtectionProvider` uses its own unique primary key. Therefore, if an `IDataProtector` rooted at an `EphemeralDataProtectionProvider` generates a protected payload, that payload can only be unprotected by an equivalent `IDataProtector` (given the same purpose chain) rooted at the same `EphemeralDataProtectionProvider` instance.

The following sample demonstrates instantiating an `EphemeralDataProtectionProvider` and using it to protect and unprotect data.

C#

```
using System;
using Microsoft.AspNetCore.DataProtection;

public class Program
{
    public static void Main(string[] args)
    {
        const string purpose = "Ephemeral.App.v1";

        // create an ephemeral provider and demonstrate that it can round-
trip a payload
        var provider = new EphemeralDataProtectionProvider();
        var protector = provider.CreateProtector(purpose);
        Console.Write("Enter input: ");
        string input = Console.ReadLine();

        // protect the payload
        string protectedPayload = protector.Protect(input);
        Console.WriteLine($"Protect returned: {protectedPayload}");

        // unprotect the payload
        string unprotectedPayload = protector.Unprotect(protectedPayload);
```

```
        Console.WriteLine($"Unprotect returned: {unprotectedPayload}");

        // if I create a new ephemeral provider, it won't be able to
unprotect existing
        // payloads, even if I specify the same purpose
        provider = new EphemeralDataProtectionProvider();
        protector = provider.CreateProtector(purpose);
        unprotectedPayload = protector.Unprotect(protectedPayload); //
THROWS
    }
}

/*
* SAMPLE OUTPUT
*
* Enter input: Hello!
* Protect returned: CfDJ8AAAAAAAAAAAAAAAAAAA...uGoxWLjGKtm1SkNACQ
* Unprotect returned: Hello!
* << throws CryptographicException >>
*/
```

Compatibility in ASP.NET Core

Article • 06/03/2022

- Replacing ASP.NET <machineKey> in ASP.NET Core

Replace the ASP.NET machineKey in ASP.NET Core

Article • 06/03/2022

The implementation of the `<machineKey>` element in ASP.NET is replaceable. This allows most calls to ASP.NET cryptographic routines to be routed through a replacement data protection mechanism, including the new data protection system.

Package installation

> **Note**
>
> The new data protection system can only be installed into an existing ASP.NET application targeting .NET 4.5.1 or later. Installation will fail if the application targets .NET 4.5 or lower.

To install the new data protection system into an existing ASP.NET 4.5.1+ project, install the package Microsoft.AspNetCore.DataProtection.SystemWeb. This will instantiate the data protection system using the default configuration settings.

When you install the package, it inserts a line into *Web.config* that tells ASP.NET to use it for most cryptographic operations, including forms authentication, view state, and calls to MachineKey.Protect. It does not use the data protection API. The line that's inserted reads as follows.

XML

```xml
<machineKey compatibilityMode="Framework45" dataProtectorType="..." />
```

> **Tip**
>
> You can tell if the new data protection system is active by inspecting fields like `__VIEWSTATE`, which should begin with "CfDJ8" as in the example below. "CfDJ8" is the base64 representation of the magic "09 F0 C9 F0" header that identifies a payload protected by the data protection system.

HTML

```
<input type="hidden" name="__VIEWSTATE" id="__VIEWSTATE"
value="CfDJ8AWPr2EQPTBGs3L2GCZOpk...">
```

Package configuration

The data protection system is instantiated with a default zero-setup configuration. However, since by default keys are persisted to the local file system, this won't work for applications which are deployed in a farm. To resolve this, you can provide configuration by creating a type which subclasses DataProtectionStartup and overrides its ConfigureServices method.

Below is an example of a custom data protection startup type which configured both where keys are persisted and how they're encrypted at rest. It also overrides the default app isolation policy by providing its own application name.

C#

```
using System;
using System.IO;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.AspNetCore.DataProtection.SystemWeb;
using Microsoft.Extensions.DependencyInjection;

namespace DataProtectionDemo
{
    public class MyDataProtectionStartup : DataProtectionStartup
    {
        public override void ConfigureServices(IServiceCollection services)
        {
            services.AddDataProtection()
                .SetApplicationName("my-app")
                .PersistKeysToFileSystem(new
DirectoryInfo(@"\\server\share\myapp-keys\"))
                .ProtectKeysWithCertificate("thumbprint");
        }
    }
}
```

Tip

You can also use `<machineKey applicationName="my-app" ... />` in place of an explicit call to SetApplicationName. This is a convenience mechanism to avoid forcing the developer to create a DataProtectionStartup-derived type if all they wanted to configure was setting the application name.

To enable this custom configuration, go back to Web.config and look for the `<appSettings>` element that the package install added to the config file. It will look like the following markup:

XML

```
<appSettings>
  <!--
  If you want to customize the behavior of the ASP.NET Core Data Protection
stack, set the
  "aspnet:dataProtectionStartupType" switch below to be the fully-qualified
name of a
  type which subclasses
Microsoft.AspNetCore.DataProtection.SystemWeb.DataProtectionStartup.
  -->
  <add key="aspnet:dataProtectionStartupType" value="" />
</appSettings>
```

Fill in the blank value with the assembly-qualified name of the DataProtectionStartup-derived type you just created. If the name of the application is DataProtectionDemo, this would look like the below.

XML

```
<add key="aspnet:dataProtectionStartupType"
     value="DataProtectionDemo.MyDataProtectionStartup, DataProtectionDemo"
/>
```

The newly-configured data protection system is now ready for use inside the application.

Safe storage of app secrets in development in ASP.NET Core

Article • 10/29/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson and Kirk Larkin

View or download sample code (how to download)

This article explains how to manage sensitive data for an ASP.NET Core app on a development machine. Never store passwords or other sensitive data in source code or configuration files. Production secrets shouldn't be used for development or test. Secrets shouldn't be deployed with the app. Production secrets should be accessed through a controlled means like Azure Key Vault. Azure test and production secrets can be stored and protected with the Azure Key Vault configuration provider.

For more information on authentication for deployed test and production apps, see Secure authentication flows.

To use user secrets in a .NET console app, see this GitHub issue.

Environment variables

Environment variables are used to avoid storage of app secrets in code or in local configuration files. Environment variables override configuration values for all previously specified configuration sources.

Consider an ASP.NET Core web app in which **Individual User Accounts** security is enabled. A default database connection string is included in the project's `appsettings.json` file with the key `DefaultConnection`. The default connection string is for LocalDB, which runs in user mode and doesn't require a password. During app deployment, the `DefaultConnection` key value can be overridden with an environment

variable's value. The environment variable may store the complete connection string with sensitive credentials.

> ⚠ **Warning**
>
> Environment variables are generally stored in plain, unencrypted text. If the machine or process is compromised, environment variables can be accessed by untrusted parties. Additional measures to prevent disclosure of user secrets may be required.

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. For example, the `:` separator is not supported by Bash. The double underscore, `__`, is:

- Supported by all platforms.
- Automatically replaced by a colon, `:`.

Secret Manager

The Secret Manager tool stores sensitive data during application development. In this context, a piece of sensitive data is an app secret. App secrets are stored in a separate location from the project tree. The app secrets are associated with a specific project or shared across several projects. The app secrets aren't checked into source control.

> ⚠ **Warning**
>
> The Secret Manager tool doesn't encrypt the stored secrets and shouldn't be treated as a trusted store. It's for development purposes only. The keys and values are stored in a JSON configuration file in the user profile directory.

How the Secret Manager tool works

The Secret Manager tool hides implementation details, such as where and how the values are stored. You can use the tool without knowing these implementation details. The values are stored in a JSON file in the local machine's user profile folder:

Windows

File system path:

```
%APPDATA%\Microsoft\UserSecrets\<user_secrets_id>\secrets.json
```

In the preceding file paths, replace `<user_secrets_id>` with the `UserSecretsId` value specified in the project file.

Don't write code that depends on the location or format of data saved with the Secret Manager tool. These implementation details may change. For example, the secret values aren't encrypted.

Enable secret storage

The Secret Manager tool operates on project-specific configuration settings stored in your user profile.

Use the CLI

The Secret Manager tool includes an `init` command. To use user secrets, run the following command in the project directory:

.NET CLI

```
dotnet user-secrets init
```

The preceding command adds a `UserSecretsId` element within a `PropertyGroup` of the project file. By default, the inner text of `UserSecretsId` is a GUID. The inner text is arbitrary, but is unique to the project.

XML

```
<PropertyGroup>
  <TargetFramework>netcoreapp3.1</TargetFramework>
  <UserSecretsId>79a3edd0-2092-40a2-a04d-dcb46d5ca9ed</UserSecretsId>
</PropertyGroup>
```

Use Visual Studio

In Visual Studio, right-click the project in Solution Explorer, and select **Manage User Secrets** from the context menu. This gesture adds a `UserSecretsId` element, populated with a GUID, to the project file.

If `GenerateAssemblyInfo` is `false`

If the generation of assembly info attributes is disabled, manually add the UserSecretsIdAttribute in `AssemblyInfo.cs`. For example:

C#

```
[assembly: UserSecretsId("your_user_secrets_id")]
```

When manually adding the `UserSecretsId` attribute to `AssemblyInfo.cs`, the `UserSecretsId` value must match the value in the project file.

Set a secret

Define an app secret consisting of a key and its value. The secret is associated with the project's `UserSecretsId` value. For example, run the following command from the directory in which the project file exists:

.NET CLI

```
dotnet user-secrets set "Movies:ServiceApiKey" "12345"
```

In the preceding example, the colon denotes that `Movies` is an object literal with a `ServiceApiKey` property.

The Secret Manager tool can be used from other directories too. Use the `--project` option to supply the file system path at which the project file exists. For example:

.NET CLI

```
dotnet user-secrets set "Movies:ServiceApiKey" "12345" --project
"C:\apps\WebApp1\src\WebApp1"
```

JSON structure flattening in Visual Studio

Visual Studio's **Manage User Secrets** gesture opens a `secrets.json` file in the text editor. Replace the contents of `secrets.json` with the key-value pairs to be stored. For example:

JSON

```
{
  "Movies": {
    "ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
    "ServiceApiKey": "12345"
  }
}
```

The JSON structure is flattened after modifications via `dotnet user-secrets remove` or `dotnet user-secrets set`. For example, running `dotnet user-secrets remove "Movies:ConnectionString"` collapses the `Movies` object literal. The modified file resembles the following JSON:

JSON

```
{
  "Movies:ServiceApiKey": "12345"
}
```

Set multiple secrets

A batch of secrets can be set by piping JSON to the `set` command. In the following example, the `input.json` file's contents are piped to the `set` command.

Windows

Open a command shell, and execute the following command:

.NET CLI

```
type .\input.json | dotnet user-secrets set
```

Access a secret

To access a secret, complete the following steps:

1. Register the user secrets configuration source
2. Read the secret via the Configuration API

Register the user secrets configuration source

The user secrets configuration provider registers the appropriate configuration source with the .NET Configuration API.

ASP.NET Core web apps created with dotnet new or Visual Studio generate the following code:

```
C#

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

WebApplication.CreateBuilder initializes a new instance of the WebApplicationBuilder class with preconfigured defaults. The initialized `WebApplicationBuilder` (`builder`) provides default configuration and calls AddUserSecrets when the EnvironmentName is Development:

Read the secret via the Configuration API

Consider the following examples of reading the `Movies:ServiceApiKey` key:

Program.cs file:

```
C#

var builder = WebApplication.CreateBuilder(args);
var movieApiKey = builder.Configuration["Movies:ServiceApiKey"];

var app = builder.Build();

app.MapGet("/", () => movieApiKey);

app.Run();
```

Razor Pages page model:

```
C#

public class IndexModel : PageModel
{
    private readonly IConfiguration _config;

    public IndexModel(IConfiguration config)
    {
```

```
        _config = config;
    }

    public void OnGet()
    {
        var moviesApiKey = _config["Movies:ServiceApiKey"];

        // call Movies service with the API key
    }
}
```

For more information, see Configuration in ASP.NET Core.

Map secrets to a POCO

Mapping an entire object literal to a POCO (a simple .NET class with properties) is useful for aggregating related properties.

Assume the app's `secrets.json` file contains the following two secrets:

JSON

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

To map the preceding secrets to a POCO, use the .NET Configuration API's object graph binding feature. The following code binds to a custom `MovieSettings` POCO and accesses the `ServiceApiKey` property value:

C#

```
var moviesConfig =
    Configuration.GetSection("Movies").Get<MovieSettings>();
_moviesApiKey = moviesConfig.ServiceApiKey;
```

The `Movies:ConnectionString` and `Movies:ServiceApiKey` secrets are mapped to the respective properties in `MovieSettings`:

C#

```
public class MovieSettings
{
    public string ConnectionString { get; set; }
```

```
    public string ServiceApiKey { get; set; }
}
```

String replacement with secrets

Storing passwords in plain text is insecure. For example, a database connection string stored in `appsettings.json` may include a password for the specified user:

JSON

```
{
  "ConnectionStrings": {
    "Movies": "Server=(localdb)\\mssqllocaldb;Database=Movie-1;User
Id=johndoe;Password=pass123;MultipleActiveResultSets=true"
  }
}
```

A more secure approach is to store the password as a secret. For example:

.NET CLI

```
dotnet user-secrets set "DbPassword" "pass123"
```

Remove the `Password` key-value pair from the connection string in `appsettings.json`. For example:

JSON

```
{
  "ConnectionStrings": {
    "Movies": "Server=(localdb)\\mssqllocaldb;Database=Movie-1;User
Id=johndoe;MultipleActiveResultSets=true"
  }
}
```

The secret's value can be set on a SqlConnectionStringBuilder object's Password property to complete the connection string:

C#

```
using System.Data.SqlClient;

var builder = WebApplication.CreateBuilder(args);
```

```
var conStrBuilder = new SqlConnectionStringBuilder(
        builder.Configuration.GetConnectionString("Movies"));
conStrBuilder.Password = builder.Configuration["DbPassword"];
var connection = conStrBuilder.ConnectionString;

var app = builder.Build();

app.MapGet("/", () => connection);

app.Run();
```

List the secrets

Assume the app's `secrets.json` file contains the following two secrets:

JSON

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

Run the following command from the directory in which the project file exists:

.NET CLI

```
dotnet user-secrets list
```

The following output appears:

Console

```
Movies:ConnectionString = Server=(localdb)\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true
Movies:ServiceApiKey = 12345
```

In the preceding example, a colon in the key names denotes the object hierarchy within `secrets.json`.

Remove a single secret

Assume the app's `secrets.json` file contains the following two secrets:

```
```

JSON

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

Run the following command from the directory in which the project file exists:

.NET CLI

```
dotnet user-secrets remove "Movies:ConnectionString"
```

The app's `secrets.json` file was modified to remove the key-value pair associated with the `Movies:ConnectionString` key:

JSON

```
{
  "Movies": {
    "ServiceApiKey": "12345"
  }
}
```

`dotnet user-secrets list` displays the following message:

Console

```
Movies:ServiceApiKey = 12345
```

Remove all secrets

Assume the app's `secrets.json` file contains the following two secrets:

JSON

```
{
  "Movies:ConnectionString": "Server=(localdb)\\mssqllocaldb;Database=Movie-
1;Trusted_Connection=True;MultipleActiveResultSets=true",
  "Movies:ServiceApiKey": "12345"
}
```

Run the following command from the directory in which the project file exists:

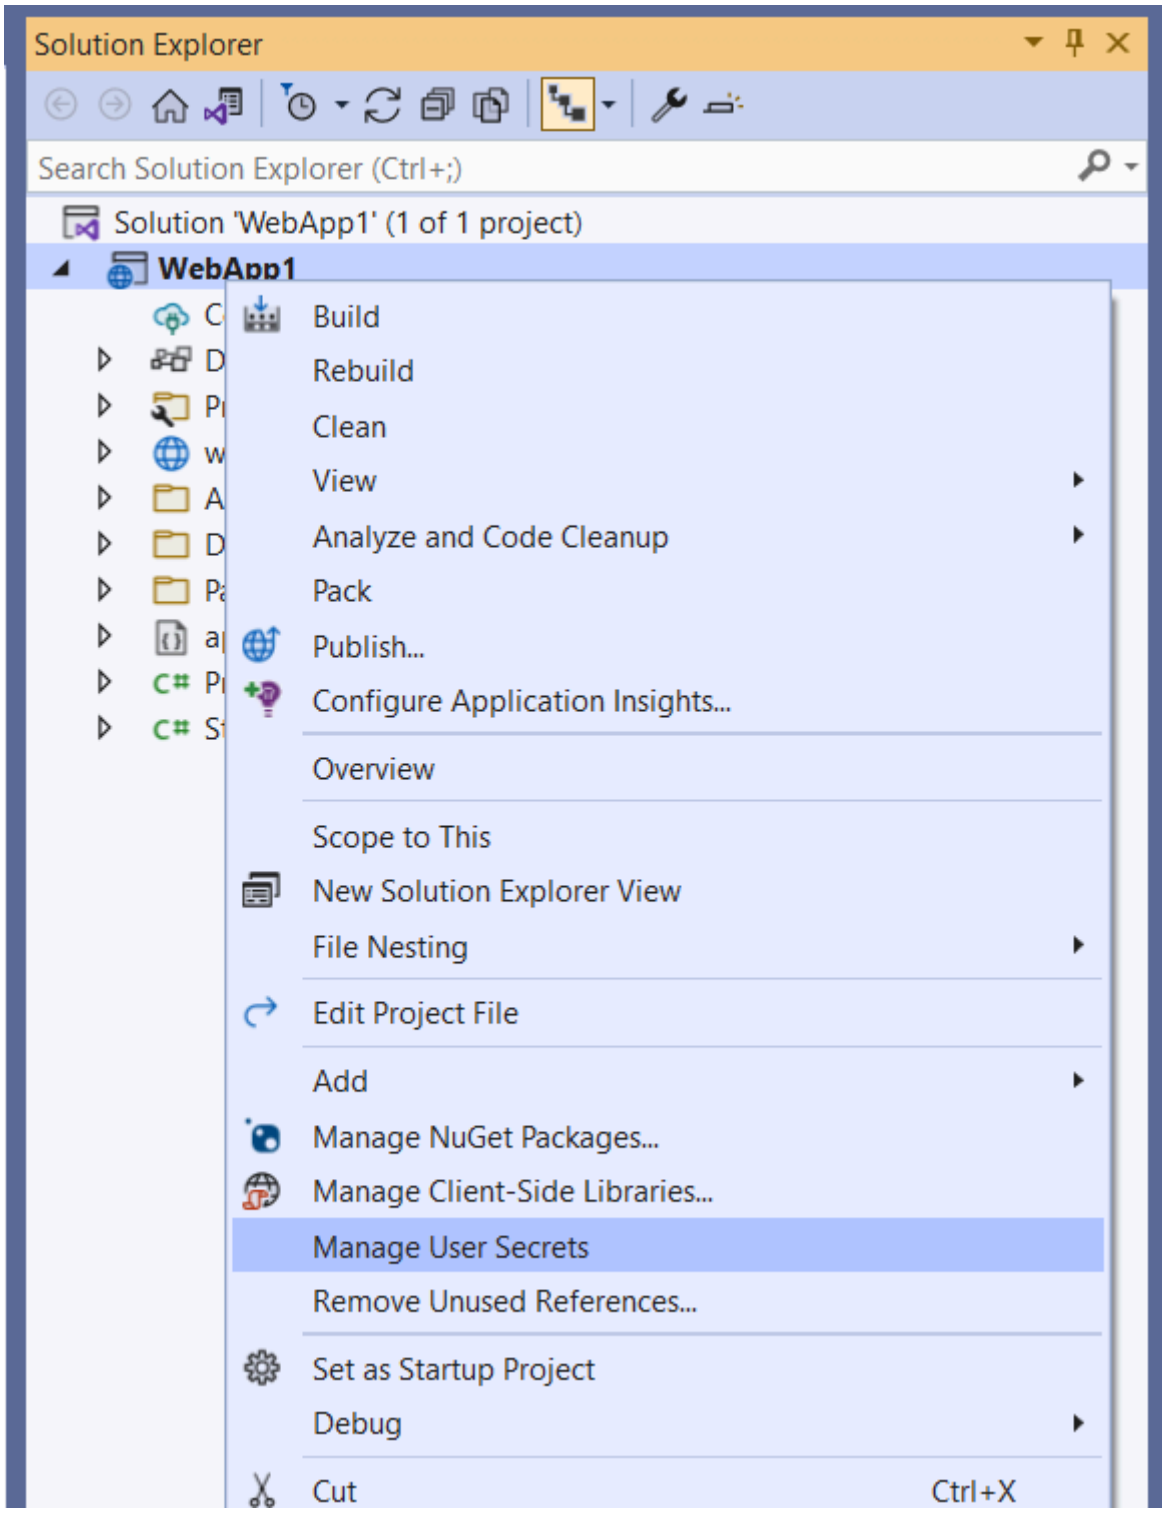
.NET CLI

```
dotnet user-secrets clear
```

All user secrets for the app have been deleted from the `secrets.json` file:

JSON

```
{}
```



Running `dotnet user-secrets list` displays the following message:

Console

```
No secrets configured for this application.
```

Manage user secrets with Visual Studio

To manage user secrets in Visual Studio, right click the project in solution explorer and select **Manage User Secrets**:

Migrating User Secrets from ASP.NET Framework to ASP.NET Core

See this GitHub issue.

User secrets in non-web applications

Projects that target `Microsoft.NET.Sdk.Web` automatically include support for user secrets. For projects that target `Microsoft.NET.Sdk`, such as console applications, install

the configuration extension and user secrets NuGet packages explicitly.

Using PowerShell:

PowerShell

```
Install-Package Microsoft.Extensions.Configuration
Install-Package Microsoft.Extensions.Configuration.UserSecrets
```

Using the .NET CLI:

.NET CLI

```
dotnet add package Microsoft.Extensions.Configuration
dotnet add package Microsoft.Extensions.Configuration.UserSecrets
```

Once the packages are installed, initialize the project and set secrets the same way as for a web app. The following example shows a console application that retrieves the value of a secret that was set with the key "AppSecret":

C#

```
using Microsoft.Extensions.Configuration;

namespace ConsoleApp;

class Program
{
    static void Main(string[] args)
    {
        IConfigurationRoot config = new ConfigurationBuilder()
            .AddUserSecrets<Program>()
            .Build();

        Console.WriteLine(config["AppSecret"]);
    }
}
```

Additional resources

Manage JSON Web Tokens in development with dotnet user-jwts

Article • 09/27/2024

By Rick Anderson

The `dotnet user-jwts` command line tool can create and manage app specific local JSON Web Tokens (JWTs).

Synopsis

.NET CLI

```
dotnet user-jwts [<PROJECT>] [command]
dotnet user-jwts [command] -h|--help
```

Description

Creates and manages project specific local JSON Web Tokens.

Arguments

`PROJECT | SOLUTION`

The MSBuild project to apply a command on. If a project is not specified, MSBuild searches the current working directory for a file that has a file extension that ends in *proj* and uses that file.

Commands

Expand table

Command	Description
clear	Delete all issued JWTs for a project.
create	Issue a new JSON Web Token.
remove	Delete a given JWT.

Command	Description
key	Display or reset the signing key used to issue JWTs.
list	Lists the JWTs issued for the project.
print	Display the details of a given JWT.

Create

Usage: `dotnet user-jwts create [options]`

Expand table

Option	Description
-p | --project	The path of the project to operate on. Defaults to the project in the current directory.
--scheme	The scheme name to use for the generated token. Defaults to 'Bearer'.
-n | --name	The name of the user to create the JWT for. Defaults to the current environment user.
--audience	The audiences to create the JWT for. Defaults to the URLs configured in the project's launchSettings.json.
--issuer	The issuer of the JWT. Defaults to 'dotnet-user-jwts'.
--scope	A scope claim to add to the JWT. Specify once for each scope.
--role	A role claim to add to the JWT. Specify once for each role.
--claim	Claims to add to the JWT. Specify once for each claim in the format "name=value".
--not-before	The UTC date & time the JWT should not be valid before in the format 'yyyy-MM-dd [[HH:mm[[:ss]]]]'. Defaults to the date & time the JWT is created.
--expires-on	The UTC date & time the JWT should expire in the format 'yyyy-MM-dd [[[[HH:mm]]:ss]]'. Defaults to 6 months after the --not-before date. Do not use this option in conjunction with the --valid-for option.
--valid-for	The period the JWT should expire after. Specify using a number followed by duration type like 'd' for days, 'h' for hours, 'm' for minutes, and 's' for seconds, for example 365d'. Do not use this option in conjunction with the --expires-on option.
-o | --output	The format to use for displaying output from the command. Can be one of 'default', 'token', or 'json'.
-h | --help	Show help information

Examples

Run the following commands to create an empty web project and add the Microsoft.AspNetCore.Authentication.JwtBearer NuGet package:

.NET CLI

```
dotnet new web -o MyJWT
cd MyJWT
dotnet add package Microsoft.AspNetCore.Authentication.JwtBearer
```

Replace the contents of `Program.cs` with the following code:

C#

```
using System.Security.Claims;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization();
builder.Services.AddAuthentication("Bearer").AddJwtBearer();

var app = builder.Build();

app.UseAuthorization();

app.MapGet("/", () => "Hello, World!");
app.MapGet("/secret", (ClaimsPrincipal user) => $"Hello
{user.Identity?.Name}. My secret")
    .RequireAuthorization();

app.Run();
```

In the preceding code, a GET request to `/secret` returns an `401 Unauthorized` error. A production app might get the JWT from a Security token service (STS), perhaps in response to logging in via a set of credentials. For the purpose of working with the API during local development, the `dotnet user-jwts` command line tool can be used to create and manage app-specific local JWTs.

The `user-jwts` tool is similar in concept to the user-secrets tool, it can be used to manage values for the app that are only valid for the developer on the local machine. In fact, the user-jwts tool utilizes the `user-secrets` infrastructure to manage the key that the JWTs are signed with, ensuring it's stored safely in the user profile.

The `user-jwts` tool hides implementation details, such as where and how the values are stored. The tool can be used without knowing the implementation details. The values

are stored in a JSON file in the local machine's user profile folder:

Windows

File system path:

`%APPDATA%\Microsoft\UserSecrets\<secrets_GUID>\user-jwts.json`

Create a JWT

The following command creates a local JWT:

.NET CLI

```
dotnet user-jwts create
```

The preceding command creates a JWT and updates the project's `appsettings.Development.json` file with JSON similar to the following:

C#

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "Authentication": {
    "Schemes": {
      "Bearer": {
        "ValidAudiences": [
          "http://localhost:8401",
          "https://localhost:44308",
          "http://localhost:5182",
          "https://localhost:7076"
        ],
        "ValidIssuer": "dotnet-user-jwts"
      }
    }
  }
}
```

Copy the JWT and the `ID` created in the preceding command. Use a tool like Curl to test `/secret`:

.NET CLI

```
curl -i -H "Authorization: Bearer {token}" https://localhost:{port}/secret
```

Where `{token}` is the previously generated JWT.

Display JWT security information

The following command displays the JWT security information, including expiration, scopes, roles, token header and payload, and the compact token:

.NET CLI

```
dotnet user-jwts print {ID} --show-all
```

Create a token for a specific user and scope

See Create in this topic for supported create options.

The following command creates a JWT for a user named `MyTestUser`:

.NET CLI

```
dotnet user-jwts create --name MyTestUser --scope "myapi:secrets"
```

The preceding command has output similar to the following:

.NET CLI

```
New JWT saved with ID '43e0b748'.
Name: MyTestUser
Scopes: myapi:secrets

Token: eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9.{Remaining token deleted}
```

The preceding token can be used to test the `/secret2` endpoint in the following code:

C#

```
using System.Security.Claims;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization();
```

```
builder.Services.AddAuthentication("Bearer").AddJwtBearer();

var app = builder.Build();

app.MapGet("/", () => "Hello, World!");
app.MapGet("/secret", (ClaimsPrincipal user) => $"Hello
{user.Identity?.Name}. My secret")
    .RequireAuthorization();
app.MapGet("/secret2", () => "This is a different secret!")
    .RequireAuthorization(p => p.RequireClaim("scope", "myapi:secrets"));

app.Run();
```

Azure Key Vault configuration provider in ASP.NET Core

Article • 10/29/2024

This article explains how to use the Azure Key Vault configuration provider to load app configuration values from Azure Key Vault secrets. Azure Key Vault is a cloud-based service that helps safeguard cryptographic keys and secrets used by apps and services. Common scenarios for using Azure Key Vault with ASP.NET Core apps include:

- Controlling access to sensitive configuration data.
- Meeting the requirement for FIPS 140-2 Level 2 validated Hardware Security Modules (HSMs) when storing configuration data.

Packages

Add package references for the following packages:

- Azure.Extensions.AspNetCore.Configuration.Secrets
- Azure.Identity

Sample app

The sample app runs in either of two modes determined by the `#define` preprocessor directive at the top of `Program.cs`:

- `Certificate`: Demonstrates using an Azure Key Vault Client ID and X.509 certificate to access secrets stored in Azure Key Vault. This sample can be run from any location, whether deployed to Azure App Service or any host that can serve an ASP.NET Core app.
- `Managed`: Demonstrates how to use Managed identities for Azure resources. The managed identity authenticates the app to Azure Key Vault with Managed identities for Azure resources without storing credentials in the app's code or configuration. The `Managed` version of the sample must be deployed to Azure. Follow the guidance in the Use the managed identities for Azure resources section.

For more information configuring a sample app using preprocessor directives (`#define`), see Overview of ASP.NET Core.

View or download sample code (how to download)

Secret storage in the Development environment

Set secrets locally using Secret Manager. When the sample app runs on the local machine in the Development environment, secrets are loaded from the local user secrets store.

Secret Manager requires a `<UserSecretsId>` property in the app's project file. Set the property value (`{GUID}`) to any unique GUID:

XML

```
<PropertyGroup>
  <UserSecretsId>{GUID}</UserSecretsId>
</PropertyGroup>
```

Secrets are created as name-value pairs. Hierarchical values (configuration sections) use a `:` (colon) as a separator in ASP.NET Core configuration key names.

Secret Manager is used from a command shell opened to the project's content root, where `{SECRET NAME}` is the name and `{SECRET VALUE}` is the value:

.NET CLI

```
dotnet user-secrets set "{SECRET NAME}" "{SECRET VALUE}"
```

Execute the following commands in a command shell from the project's content root to set the secrets for the sample app:

.NET CLI

```
dotnet user-secrets set "SecretName" "secret_value_1_dev"
dotnet user-secrets set "Section:SecretName" "secret_value_2_dev"
```

When these secrets are stored in Azure Key Vault in the Secret storage in the Production environment with Azure Key Vault section, the `_dev` suffix is changed to `_prod`. The suffix provides a visual cue in the app's output indicating the source of the configuration values.

Secret storage in the Production environment with Azure Key Vault

Complete the following steps to create an Azure Key Vault and store the sample app's secrets in it. For more information, see Quickstart: Set and retrieve a secret from Azure Key Vault using Azure CLI.

1. Open Azure Cloud Shell using any one of the following methods in the Azure portal:

   - Select **Try It** in the upper-right corner of a code block. Use the search string "Azure CLI" in the text box.
   - Open Cloud Shell in your browser with the **Launch Cloud Shell** button.
   - Select the **Cloud Shell** button on the menu in the upper-right corner of the Azure portal.

   For more information, see Azure CLI and Overview of Azure Cloud Shell.

2. If you aren't already authenticated, sign in with the `az login` command.

3. Create a resource group with the following command, where `{RESOURCE GROUP NAME}` is the new resource group's name and `{LOCATION}` is the Azure region:

   Azure CLI

   ```
   az group create --name "{RESOURCE GROUP NAME}" --location {LOCATION}
   ```

4. Create a Key Vault in the resource group with the following command, where `{KEY VAULT NAME}` is the new vault's name and `{LOCATION}` is the Azure region:

   Azure CLI

   ```
   az keyvault create --name {KEY VAULT NAME} --resource-group "{RESOURCE GROUP NAME}" --location {LOCATION}
   ```

5. Create secrets in the vault as name-value pairs.

   Azure Key Vault secret names are limited to alphanumeric characters and dashes. Hierarchical values (configuration sections) use `--` (two dashes) as a delimiter, as colons aren't allowed in Key Vault secret names. Colons delimit a section from a subkey in ASP.NET Core configuration. The two-dash sequence is replaced with a colon when the secrets are loaded into the app's configuration.

   The following secrets are for use with the sample app. The values include a `_prod` suffix to distinguish them from the `_dev` suffix values loaded in the Development

environment from Secret Manager. Replace `{KEY VAULT NAME}` with the name of the Key Vault you created in the prior step:

Azure CLI

```
az keyvault secret set --vault-name {KEY VAULT NAME} --name
"SecretName" --value "secret_value_1_prod"
az keyvault secret set --vault-name {KEY VAULT NAME} --name "Section--
SecretName" --value "secret_value_2_prod"
```

Use Application ID and X.509 certificate for non-Azure-hosted apps

Configure Azure Key Vault and the app to use an Microsoft Entra ID Application ID and X.509 certificate to authenticate to a vault **when the app is hosted outside of Azure**. For more information, see About keys, secrets, and certificates.

> **Note**
>
> Although using an Application ID and X.509 certificate is supported for apps hosted in Azure, it's not recommended. Instead, use Managed identities for Azure resources when hosting an app in Azure. Managed identities don't require storing a certificate in the app or in the development environment.

The sample app uses an Application ID and X.509 certificate when the `#define` preprocessor directive at the top of `Program.cs` is set to `Certificate`.

1. Create a PKCS#12 archive (*.pfx*) certificate. Options for creating certificates include New-SelfSignedCertificate on Windows and OpenSSL.
2. Install the certificate into the current user's personal certificate store. Marking the key as exportable is optional. Note the certificate's thumbprint, which is used later in this process.
3. Export the PKCS#12 archive (*.pfx*) certificate as a DER-encoded certificate (*.cer*).
4. Register the app with Microsoft Entra ID (**App registrations**).
5. Upload the DER-encoded certificate (*.cer*) to Microsoft Entra ID:
   a. Select the app in Microsoft Entra ID.
   b. Navigate to **Certificates & secrets**.
   c. Select **Upload certificate** to upload the certificate, which contains the public key. A *.cer*, *.pem*, or *.crt* certificate is acceptable.

6. Store the Key Vault name, Application ID, and certificate thumbprint in the app's `appsettings.json` file.
7. Navigate to **Key Vaults** in the Azure portal.
8. Select the Key Vault you created in the Secret storage in the Production environment with Azure Key Vault section.
9. Select **Access policies**.
10. Select **Add Access Policy**.
11. Open **Secret permissions** and provide the app with **Get** and **List** permissions.
12. Select **Select principal** and select the registered app by name. Select the **Select** button.
13. Select **OK**.
14. Select **Save**.
15. Deploy the app.

The `Certificate` sample app obtains its configuration values from IConfigurationRoot with the same name as the secret name:

- Non-hierarchical values: The value for `SecretName` is obtained with `config["SecretName"]`.
- Hierarchical values (sections): Use `:` (colon) notation or the GetSection method. Use either of these approaches to obtain the configuration value:
  - `config["Section:SecretName"]`
  - `config.GetSection("Section")["SecretName"]`

The X.509 certificate is managed by the OS. The app calls AddAzureKeyVault with values supplied by the `appsettings.json` file:

C#

```
using System.Security.Cryptography.X509Certificates;
using Azure.Identity;

var builder = WebApplication.CreateBuilder(args);

if (builder.Environment.IsProduction())
{
    using var x509Store = new X509Store(StoreLocation.CurrentUser);

    x509Store.Open(OpenFlags.ReadOnly);

    var x509Certificate = x509Store.Certificates
        .Find(
            X509FindType.FindByThumbprint,
            builder.Configuration["AzureADCertThumbprint"],
            validOnly: false)
```

```
        .OfType<X509Certificate2>()
        .Single();

    builder.Configuration.AddAzureKeyVault(
        new
Uri($"https://{builder.Configuration["KeyVaultName"]}.vault.azure.net/"),
        new ClientCertificateCredential(
            builder.Configuration["AzureADDirectoryId"],
            builder.Configuration["AzureADApplicationId"],
            x509Certificate));
}

var app = builder.Build();
```

Example values:

- Key Vault name: `contosovault`
- Application ID: `00001111-aaaa-2222-bbbb-3333cccc4444`
- Certificate thumbprint: `fe14593dd66b2406c5269d742d04b6e1ab03adb1`

`appsettings.json`:

JSON

```
{
  "KeyVaultName": "Key Vault Name",
  "AzureADApplicationId": "Azure AD Application ID",
  "AzureADCertThumbprint": "Azure AD Certificate Thumbprint",
  "AzureADDirectoryId": "Azure AD Directory ID"
}
```

When you run the app, a webpage shows the loaded secret values. In the Development environment, secret values load with the `_dev` suffix. In the Production environment, the values load with the `_prod` suffix.

Use managed identities for Azure resources

An app deployed to Azure can take advantage of Managed identities for Azure resources. A managed identity allows the app to authenticate with Azure Key Vault using Microsoft Entra ID authentication without storing credentials in the app's code or configuration.

The sample app uses a system-assigned managed identity when the `#define` preprocessor directive at the top of `Program.cs` is set to `Managed`. To create a managed identity for an Azure App Service app, see How to use managed identities for App

Service and Azure Functions. Once the managed identity has been created, note the app's Object ID shown in the Azure portal on the **Identity** panel of the App Service.

Enter the vault name into the app's `appsettings.json` file. The sample app doesn't require an Application ID and Password (Client Secret) when set to the `Managed` version, so you can ignore those configuration entries. The app is deployed to Azure, and Azure authenticates the app to access Azure Key Vault only using the vault name stored in the `appsettings.json` file.

Deploy the sample app to Azure App Service.

Using Azure CLI and the app's Object ID, provide the app with `list` and `get` permissions to access the vault:

Azure CLI

```
az keyvault set-policy --name {KEY VAULT NAME} --object-id {OBJECT ID} --
secret-permissions get list
```

Restart the app using Azure CLI, PowerShell, or the Azure portal.

The sample app creates an instance of the DefaultAzureCredential class. The credential attempts to obtain an access token from environment for Azure resources:

C#

```
using Azure.Identity;

var builder = WebApplication.CreateBuilder(args);

if (builder.Environment.IsProduction())
{
    builder.Configuration.AddAzureKeyVault(
        new
Uri($"https://{builder.Configuration["KeyVaultName"]}.vault.azure.net/"),
        new DefaultAzureCredential());
}
```

Key Vault name example value: `contosovault`

`appsettings.json`:

JSON

```
{
  "KeyVaultName": "Key Vault Name"
```

```
}
```

For apps that use a user-assigned managed identity, configure the managed identity's Client ID using one of the following approaches:

1. Set the `AZURE_CLIENT_ID` environment variable.
2. Set the DefaultAzureCredentialOptions.ManagedIdentityClientId property when calling `AddAzureKeyVault`:

   C#

   ```
   builder.Configuration.AddAzureKeyVault(
       new
   Uri($"https://{builder.Configuration["KeyVaultName"]}.vault.azure.net/"
   ),
       new DefaultAzureCredential(new DefaultAzureCredentialOptions
       {
           ManagedIdentityClientId =
   builder.Configuration["AzureADManagedIdentityClientId"]
       }));
   ```

When you run the app, a webpage shows the loaded secret values. In the Development environment, secret values have the `_dev` suffix because they're provided by Secret Manager. In the Production environment, the values load with the `_prod` suffix because they're provided by Azure Key Vault.

If you receive an `Access denied` error, confirm that the app is registered with Microsoft Entra ID and provided access to the vault. Confirm that you've restarted the service in Azure.

For information on using the provider with a managed identity and Azure Pipelines, see Create an Azure Resource Manager service connection to a VM with a managed service identity.

Configuration options

`AddAzureKeyVault` can accept an AzureKeyVaultConfigurationOptions object:

C#

```
// using Azure.Extensions.AspNetCore.Configuration.Secrets;

builder.Configuration.AddAzureKeyVault(
    new
```

```
Uri($"https://{builder.Configuration["KeyVaultName"]}.vault.azure.net/"),
    new DefaultAzureCredential(),
    new AzureKeyVaultConfigurationOptions
    {
        // ...
    });
```

The `AzureKeyVaultConfigurationOptions` object contains the following properties:

Expand table

Property	Description
Manager	KeyVaultSecretManager instance used to control secret loading.
ReloadInterval	`TimeSpan` to wait between attempts at polling the vault for changes. The default value is `null` (configuration isn't reloaded).

Use a key name prefix

`AddAzureKeyVault` provides an overload that accepts an implementation of KeyVaultSecretManager, which allows you to control how Key Vault secrets are converted into configuration keys. For example, you can implement the interface to load secret values based on a prefix value you provide at app startup. This technique allows you, for example, to load secrets based on the version of the app.

> ⚠ **Warning**
>
> Don't use prefixes on Key Vault secrets to:
>
> - Place secrets for multiple apps into the same vault.
> - Place environmental secrets (for example, *development* versus *production* secrets) into the same vault.
>
> Different apps and development/production environments should use separate Key Vaults to isolate app environments for the highest level of security.

In the following example, a secret is established in Key Vault (and using Secret Manager for the Development environment) for `5000-AppSecret` (periods aren't allowed in Key Vault secret names). This secret represents an app secret for version 5.0.0.0 of the app. For another version of the app, 5.1.0.0, a secret is added to the vault (and using Secret

Manager) for `5100-AppSecret`. Each app version loads its versioned secret value into its configuration as `AppSecret`, removing the version as it loads the secret.

`AddAzureKeyVault` is called with a custom `KeyVaultSecretManager` implementation:

C#

```
// using Azure.Extensions.AspNetCore.Configuration.Secrets;

builder.Configuration.AddAzureKeyVault(
    new
Uri($"https://{builder.Configuration["KeyVaultName"]}.vault.azure.net/"),
    new DefaultAzureCredential(),
    new SamplePrefixKeyVaultSecretManager("5000"));
```

The implementation reacts to the version prefixes of secrets to load the proper secret into configuration:

- `Load` loads a secret when its name starts with the prefix. Other secrets aren't loaded.
- `GetKey`:
  - Removes the prefix from the secret name.
  - Replaces two dashes in any name with the `KeyDelimiter`, which is the delimiter used in configuration (usually a colon). Azure Key Vault doesn't allow a colon in secret names.

C#

```
public class SamplePrefixKeyVaultSecretManager : KeyVaultSecretManager
{
    private readonly string _prefix;

    public SamplePrefixKeyVaultSecretManager(string prefix)
        => _prefix = $"{prefix}-";

    public override bool Load(SecretProperties properties)
        => properties.Name.StartsWith(_prefix);

    public override string GetKey(KeyVaultSecret secret)
        => secret.Name[_prefix.Length..].Replace("--",
ConfigurationPath.KeyDelimiter);
}
```

The `Load` method is called by a provider algorithm that iterates through the vault secrets to find the version-prefixed secrets. When a version prefix is found with `Load`, the algorithm uses the `GetKey` method to return the configuration name of the secret

name. It removes the version prefix from the secret's name. The rest of the secret name is returned for loading into the app's configuration name-value pairs.

When this approach is implemented:

1. The app's version specified in the app's project file. In the following example, the app's version is set to `5.0.0.0`:

   XML

   ```xml
   <PropertyGroup>
     <Version>5.0.0.0</Version>
   </PropertyGroup>
   ```

2. Confirm that a `<UserSecretsId>` property is present in the app's project file, where `{GUID}` is a user-supplied GUID:

   XML

   ```xml
   <PropertyGroup>
     <UserSecretsId>{GUID}</UserSecretsId>
   </PropertyGroup>
   ```

   Save the following secrets locally with Secret Manager:

   .NET CLI

   ```
   dotnet user-secrets set "5000-AppSecret" "5.0.0.0_secret_value_dev"
   dotnet user-secrets set "5100-AppSecret" "5.1.0.0_secret_value_dev"
   ```

3. Secrets are saved in Azure Key Vault using the following Azure CLI commands:

   Azure CLI

   ```
   az keyvault secret set --vault-name {KEY VAULT NAME} --name "5000-
   AppSecret" --value "5.0.0.0_secret_value_prod"
   az keyvault secret set --vault-name {KEY VAULT NAME} --name "5100-
   AppSecret" --value "5.1.0.0_secret_value_prod"
   ```

4. When the app is run, the Key Vault secrets are loaded. The string secret for `5000-AppSecret` is matched to the app's version specified in the app's project file (`5.0.0.0`).

5. The version, `5000` (with the dash), is stripped from the key name. Throughout the app, reading configuration with the key `AppSecret` loads the secret value.

6. If the app's version is changed in the project file to `5.1.0.0` and the app is run again, the secret value returned is `5.1.0.0_secret_value_dev` in the Development environment and `5.1.0.0_secret_value_prod` in Production.

> **Note**
>
> You can also provide your own SecretClient implementation to `AddAzureKeyVault`. A custom client permits sharing a single instance of the client across the app.

Bind an array to a class

The provider can read configuration values into an array for binding to a POCO array.

When reading from a configuration source that allows keys to contain colon (`:`) separators, a numeric key segment is used to distinguish the keys that make up an array (`:0:`, `:1:`, ... `:{n}:`). For more information, see Configuration: Bind an array to a class.

Azure Key Vault keys can't use a colon as a separator. The approach described in this article uses double dashes (`--`) as a separator for hierarchical values (sections). Array keys are stored in Azure Key Vault with double dashes and numeric key segments (`--0--`, `--1--`, ... `--{n}--`).

Examine the following Serilog logging provider configuration provided by a JSON file. There are two object literals defined in the `WriteTo` array that reflect two Serilog *sinks*, which describe destinations for logging output:

JSON

```
"Serilog": {
  "WriteTo": [
    {
      "Name": "AzureTableStorage",
      "Args": {
        "storageTableName": "logs",
        "connectionString": "DefaultEnd...ountKey=Eby8...GMGw=="
      }
    },
    {
      "Name": "AzureDocumentDB",
      "Args": {
        "endpointUrl": "https://contoso.documents.azure.com:443",
        "authorizationKey": "Eby8...GMGw=="
      }
    }
```

```
  ]
}
```

The configuration shown in the preceding JSON file is stored in Azure Key Vault using double dash (`--`) notation and numeric segments:

Expand table

Key	Value
`Serilog--WriteTo--0--Name`	`AzureTableStorage`
`Serilog--WriteTo--0--Args--storageTableName`	`logs`
`Serilog--WriteTo--0--Args--connectionString`	`DefaultEnd...ountKey=Eby8...GMGw==`
`Serilog--WriteTo--1--Name`	`AzureDocumentDB`
`Serilog--WriteTo--1--Args--endpointUrl`	`https://contoso.documents.azure.com:443`
`Serilog--WriteTo--1--Args--authorizationKey`	`Eby8...GMGw==`

Reload secrets

By default, secrets are cached by the configuration provider for the app's lifetime. Secrets that have been subsequently disabled or updated in the vault are ignored by the app.

To reload secrets, call IConfigurationRoot.Reload:

C#

```
config.Reload();
```

To reload secrets periodically, at a specified interval, set the AzureKeyVaultConfigurationOptions.ReloadInterval property. For more information, see Configuration options.

Disabled and expired secrets

Expired secrets are included by default in the configuration provider. To exclude values for these secrets in app configuration, update the expired secret or provide the configuration using a custom configuration provider:

C#

```
class SampleKeyVaultSecretManager : KeyVaultSecretManager
{
  public override bool Load(SecretProperties properties) =>
    properties.ExpiresOn.HasValue &&
    properties.ExpiresOn.Value > DateTimeOffset.Now;
}
```

Pass this custom `KeyVaultSecretManager` to `AddAzureKeyVault`:

C#

```
// using Azure.Extensions.AspNetCore.Configuration.Secrets;

builder.Configuration.AddAzureKeyVault(
    new
Uri($"https://{builder.Configuration["KeyVaultName"]}.vault.azure.net/"),
    new DefaultAzureCredential(),
    new SampleKeyVaultSecretManager());
```

Disabled secrets cannot be retrieved from Key Vault and are never included.

Troubleshoot

When the app fails to load configuration using the provider, an error message is written to the ASP.NET Core Logging infrastructure. The following conditions will prevent configuration from loading:

- The app or certificate isn't configured correctly in Microsoft Entra ID.
- The vault doesn't exist in Azure Key Vault.
- The app isn't authorized to access the vault.
- The access policy doesn't include `Get` and `List` permissions.
- In the vault, the configuration data (name-value pair) is incorrectly named, missing, or disabled.
- The app has the wrong Key Vault name (`KeyVaultName`), Microsoft Entra ID Application ID (`AzureADApplicationId`), or Microsoft Entra ID certificate thumbprint (`AzureADCertThumbprint`), or Microsoft Entra ID Directory ID (`AzureADDirectoryId`).
- When adding the Key Vault access policy for the app, the policy was created, but the **Save** button wasn't selected in the **Access policies** UI.

Enforce HTTPS in ASP.NET Core

Article • 10/24/2024

By David Galvan and Rick Anderson

this article shows how to:

- Require HTTPS for all requests.
- Redirect all HTTP requests to HTTPS.

No API can prevent a client from sending sensitive data on the first request.

⚠ **Warning**

API projects

Do **not** use RequireHttpsAttribute on Web APIs that receive sensitive information. `RequireHttpsAttribute` uses HTTP status codes to redirect browsers from HTTP to HTTPS. API clients may not understand or obey redirects from HTTP to HTTPS. Such clients may send information over HTTP. Web APIs should either:

- Not listen on HTTP.
- Close the connection with status code 400 (Bad Request) and not serve the request.

To disable HTTP redirection in an API, set the `ASPNETCORE_URLS` environment variable or use the `--urls` command line flag. For more information, see Use multiple environments in ASP.NET Core and 8 ways to set the URLs for an ASP.NET Core app by Andrew Lock.

HSTS and API projects

The default API projects don't include HSTS because HSTS is generally a browser only instruction. Other callers, such as phone or desktop apps, do **not** obey the instruction. Even within browsers, a single authenticated call to an API over HTTP has risks on insecure networks. The secure approach is to configure API projects to only listen to and respond over HTTPS.

HTTP redirection to HTTPS causes ERR_INVALID_REDIRECT on the CORS preflight request

Requests to an endpoint using HTTP that are redirected to HTTPS by UseHttpsRedirection fail with `ERR_INVALID_REDIRECT` on the CORS preflight request.

API projects can reject HTTP requests rather than use `UseHttpsRedirection` to redirect requests to HTTPS.

Require HTTPS

We recommend that production ASP.NET Core web apps use:

- HTTPS Redirection Middleware (UseHttpsRedirection) to redirect HTTP requests to HTTPS.
- HSTS Middleware (UseHsts) to send HTTP Strict Transport Security Protocol (HSTS) headers to clients.

> **Note**
>
> Apps deployed in a reverse proxy configuration allow the proxy to handle connection security (HTTPS). If the proxy also handles HTTPS redirection, there's no need to use HTTPS Redirection Middleware. If the proxy server also handles writing HSTS headers (for example, native HSTS support in IIS 10.0 (1709) or later), HSTS Middleware isn't required by the app. For more information, see Opt-out of HTTPS/HSTS on project creation.

UseHttpsRedirection

The following code calls UseHttpsRedirection in the `Program.cs` file:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
```

```
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The preceding highlighted code:

- Uses the default HttpsRedirectionOptions.RedirectStatusCode (Status307TemporaryRedirect).
- Uses the default HttpsRedirectionOptions.HttpsPort (null) unless overridden by the `ASPNETCORE_HTTPS_PORT` environment variable or IServerAddressesFeature.

We recommend using temporary redirects rather than permanent redirects. Link caching can cause unstable behavior in development environments. If you prefer to send a permanent redirect status code when the app is in a non-Development environment, see the Configure permanent redirects in production section. We recommend using HSTS to signal to clients that only secure resource requests should be sent to the app (only in production).

Port configuration

A port must be available for the middleware to redirect an insecure request to HTTPS. If no port is available:

- Redirection to HTTPS doesn't occur.
- The middleware logs the warning "Failed to determine the https port for redirect."

Specify the HTTPS port using any of the following approaches:

- Set HttpsRedirectionOptions.HttpsPort.
- Set the `https_port` host setting:
  - In host configuration.
  - By setting the `ASPNETCORE_HTTPS_PORT` environment variable.
  - By adding a top-level entry in `appsettings.json`:

JSON

```
{
  "https_port": 443,
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*"
}
```

- Indicate a port with the secure scheme using the ASPNETCORE_URLS environment variable. The environment variable configures the server. The middleware indirectly discovers the HTTPS port via IServerAddressesFeature. This approach doesn't work in reverse proxy deployments.
- The ASP.NET Core web templates set an HTTPS URL in `Properties/launchsettings.json` for both Kestrel and IIS Express. `launchsettings.json` is only used on the local machine.
- Configure an HTTPS URL endpoint for a public-facing edge deployment of Kestrel server or HTTP.sys server. Only **one HTTPS port** is used by the app. The middleware discovers the port via IServerAddressesFeature.

> **Note**
>
> When an app is run in a reverse proxy configuration, IServerAddressesFeature isn't available. Set the port using one of the other approaches described in this section.

Edge deployments

When Kestrel or HTTP.sys is used as a public-facing edge server, Kestrel or HTTP.sys must be configured to listen on both:

- The secure port where the client is redirected (typically, 443 in production and 5001 in development).
- The insecure port (typically, 80 in production and 5000 in development).

The insecure port must be accessible by the client in order for the app to receive an insecure request and redirect the client to the secure port.

For more information, see Kestrel endpoint configuration or HTTP.sys web server implementation in ASP.NET Core.

Deployment scenarios

Any firewall between the client and server must also have communication ports open for traffic.

If requests are forwarded in a reverse proxy configuration, use Forwarded Headers Middleware before calling HTTPS Redirection Middleware. Forwarded Headers Middleware updates the `Request.Scheme`, using the `X-Forwarded-Proto` header. The middleware permits redirect URIs and other security policies to work correctly. When Forwarded Headers Middleware isn't used, the backend app might not receive the correct scheme and end up in a redirect loop. A common end user error message is that too many redirects have occurred.

When deploying to Azure App Service, follow the guidance in Tutorial: Bind an existing custom SSL certificate to Azure Web Apps.

Options

The following highlighted code calls AddHttpsRedirection to configure middleware options:

C#

```
using static Microsoft.AspNetCore.Http.StatusCodes;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddHsts(options =>
{
    options.Preload = true;
    options.IncludeSubDomains = true;
    options.MaxAge = TimeSpan.FromDays(60);
    options.ExcludedHosts.Add("example.com");
    options.ExcludedHosts.Add("www.example.com");
});

builder.Services.AddHttpsRedirection(options =>
{
    options.RedirectStatusCode = Status307TemporaryRedirect;
    options.HttpsPort = 5001;
});
```

```
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Calling `AddHttpsRedirection` is only necessary to change the values of `HttpsPort` or `RedirectStatusCode`.

The preceding highlighted code:

- Sets HttpsRedirectionOptions.RedirectStatusCode to Status307TemporaryRedirect, which is the default value. Use the fields of the StatusCodes class for assignments to `RedirectStatusCode`.
- Sets the HTTPS port to 5001.

Configure permanent redirects in production

The middleware defaults to sending a Status307TemporaryRedirect with all redirects. If you prefer to send a permanent redirect status code when the app is in a non-Development environment, wrap the middleware options configuration in a conditional check for a non-Development environment.

When configuring services in `Program.cs`:

C#

```
using static Microsoft.AspNetCore.Http.StatusCodes;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
```

```
if (!builder.Environment.IsDevelopment())
{
    builder.Services.AddHttpsRedirection(options =>
    {
        options.RedirectStatusCode = Status308PermanentRedirect;
        options.HttpsPort = 443;
    });
}

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");

    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

HTTPS Redirection Middleware alternative approach

An alternative to using HTTPS Redirection Middleware (`UseHttpsRedirection`) is to use URL Rewriting Middleware (`AddRedirectToHttps`). `AddRedirectToHttps` can also set the status code and port when the redirect is executed. For more information, see URL Rewriting Middleware.

When redirecting to HTTPS without the requirement for additional redirect rules, we recommend using HTTPS Redirection Middleware (`UseHttpsRedirection`) described in this article.

HTTP Strict Transport Security Protocol (HSTS)

Per OWASP, HTTP Strict Transport Security (HSTS) is an opt-in security enhancement that's specified by a web app through the use of a response header. When a browser that supports HSTS receives this header:

- The browser stores configuration for the domain that prevents sending any communication over HTTP. The browser forces all communication over HTTPS.
- The browser prevents the user from using untrusted or invalid certificates. The browser disables prompts that allow a user to temporarily trust such a certificate.

Because HSTS is enforced by the client, it has some limitations:

- The client must support HSTS.
- HSTS requires at least one successful HTTPS request to establish the HSTS policy.
- The application must check every HTTP request and redirect or reject the HTTP request.

ASP.NET Core implements HSTS with the UseHsts extension method. The following code calls `UseHsts` when the app isn't in development mode:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

`UseHsts` isn't recommended in development because the HSTS settings are highly cacheable by browsers. By default, `UseHsts` excludes the local loopback address.

For production environments that are implementing HTTPS for the first time, set the initial HstsOptions.MaxAge to a small value using one of the TimeSpan methods. Set the value from hours to no more than a single day in case you need to revert the HTTPS infrastructure to HTTP. After you're confident in the sustainability of the HTTPS configuration, increase the HSTS `max-age` value; a commonly used value is one year.

The following highlighted code:

C#

```
using static Microsoft.AspNetCore.Http.StatusCodes;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddHsts(options =>
{
    options.Preload = true;
    options.IncludeSubDomains = true;
    options.MaxAge = TimeSpan.FromDays(60);
    options.ExcludedHosts.Add("example.com");
    options.ExcludedHosts.Add("www.example.com");
});

builder.Services.AddHttpsRedirection(options =>
{
    options.RedirectStatusCode = Status307TemporaryRedirect;
    options.HttpsPort = 5001;
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

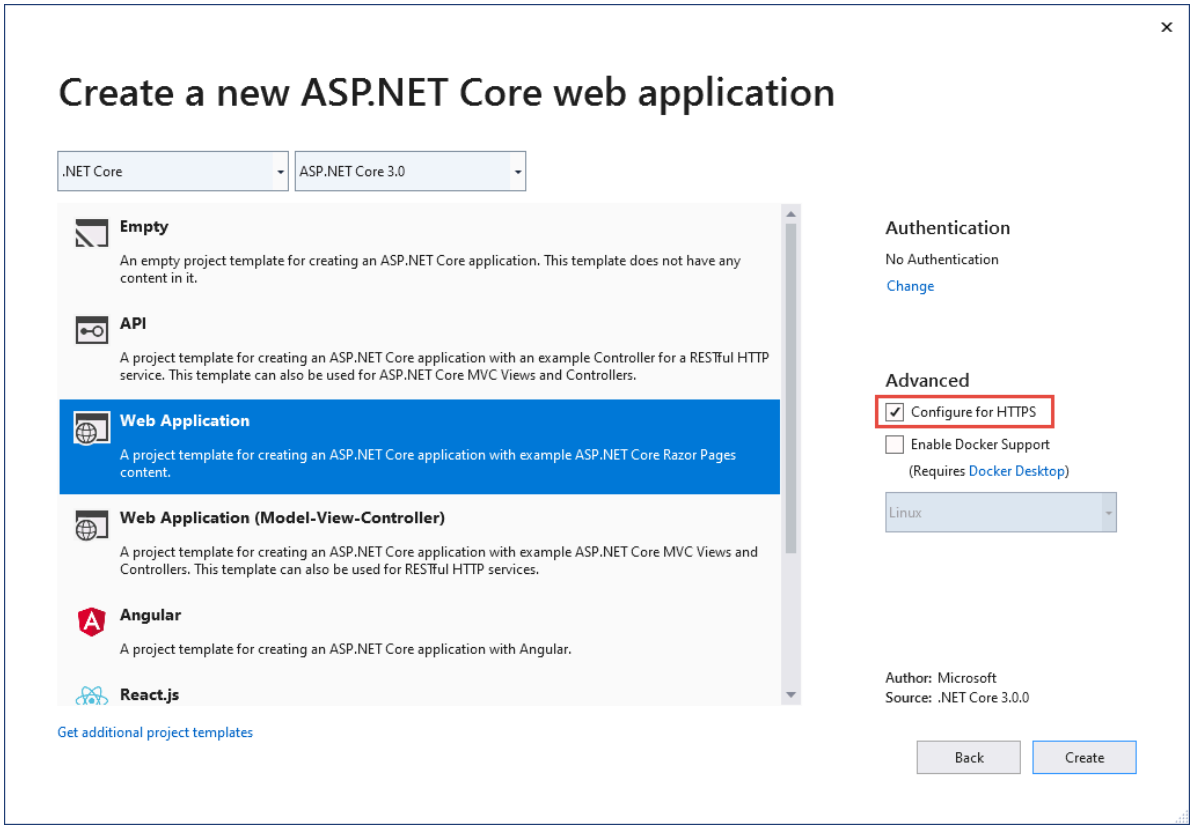
app.Run();
```

- Sets the preload parameter of the `Strict-Transport-Security` header. Preload isn't part of the RFC HSTS specification, but is supported by web browsers to preload HSTS sites on fresh install. For more information, see https://hstspreload.org/.
- Enables includeSubDomain, which applies the HSTS policy to Host subdomains.
- Explicitly sets the `max-age` parameter of the `Strict-Transport-Security` header to 60 days. If not set, defaults to 30 days. For more information, see the max-age directive.

- Adds `example.com` to the list of hosts to exclude.

`UseHsts` excludes the following loopback hosts:

- `localhost` : The IPv4 loopback address.
- `127.0.0.1` : The IPv4 loopback address.
- `[::1]` : The IPv6 loopback address.



Opt-out of HTTPS/HSTS on project creation

In some backend service scenarios where connection security is handled at the public-facing edge of the network, configuring connection security at each node isn't required. Web apps that are generated from the templates in Visual Studio or from the dotnet new command enable HTTPS redirection and HSTS. For deployments that don't require these scenarios, you can opt-out of HTTPS/HSTS when the app is created from the template.

To opt-out of HTTPS/HSTS:

Visual Studio

Uncheck the **Configure for HTTPS** checkbox.

Trust the ASP.NET Core HTTPS development certificate

The .NET Core SDK includes an HTTPS development certificate. The certificate is installed as part of the first-run experience. For example, `dotnet --info` produces a variation of the following output:

cli

```
ASP.NET Core
------------
Successfully installed the ASP.NET Core HTTPS Development Certificate.
To trust the certificate run 'dotnet dev-certs https --trust' (Windows and
macOS only).
For establishing trust on other platforms refer to the platform specific
documentation.
For more information on configuring HTTPS see
https://go.microsoft.com/fwlink/?linkid=848054.
```

Installing the .NET Core SDK installs the ASP.NET Core HTTPS development certificate to the local user certificate store. The certificate has been installed, but it's not trusted. To trust the certificate, perform the one-time step to run the `dotnet dev-certs` tool:

.NET CLI

```
dotnet dev-certs https --trust
```

The following command provides help on the `dotnet dev-certs` tool:

.NET CLI

```
dotnet dev-certs https --help
```

> ⚠ **Warning**
>
> Do not create a development certificate in an environment that will be redistributed, such as a container image or virtual machine. Doing so can lead to spoofing and elevation of privilege. To help prevent this, set the `DOTNET_GENERATE_ASPNET_CERTIFICATE` environment variable to `false` prior to calling the .NET CLI for the first time. This will skip the automatic generation of the ASP.NET Core development certificate during the CLI's first-run experience.

How to set up a developer certificate for Docker

See this GitHub issue.

Linux-specific considerations

Linux distros differ substantially in how they mark certificates as trusted. While `dotnet dev-certs` is expected to be broadly applicable it is only officially supported on Ubuntu and Fedora and specifically aims to ensure trust in Firefox and Chromium-based browsers (Edge, Chrome, and Chromium).

Dependencies

To establish OpenSSL trust, the `openssl` tool must be on the path.

To establish browser trust (for example in Edge or Firefox), the `certutil` tool must be on the path.

OpenSSL trust

When the ASP.NET Core development certificate is trusted, it is exported to a folder in the current user's home directory. To have OpenSSL (and clients that consume it) pick up this folder, you need to set the `SSL_CERT_DIR` environment variable. You can either do this in a single session by running a command like `export SSL_CERT_DIR=$HOME/.aspnet/dev-certs/trust:/usr/lib/ssl/certs` (the exact value will be in the output when `--verbose` is passed) or by adding it your (distro- and shell-specific) configuration file (for example `.profile`).

This is required to make tools like `curl` trust the development certificate. Or, alternatively, you can pass `-CAfile` or `-CApath` to each individual `curl` invocation.

Note that this requires 1.1.1h or later or 3.0.0 or later, depending on which major version you're using.

If OpenSSL trust gets into a bad state (for example if `dotnet dev-certs https --clean` fails to remove it), it is frequently possible to set things right using the c_rehash tool.

Overrides

If you're using another browser with its own Network Security Services (NSS) store, you can use the `DOTNET_DEV_CERTS_NSSDB_PATHS` environment variable to specify a colon-delimited list of NSS directories (for example, the directory containing `cert9.db`) to which to add the development certificate.

If you store the certificates you want OpenSSL to trust in a specific directory, you can use the `DOTNET_DEV_CERTS_OPENSSL_CERTIFICATE_DIRECTORY` environment variable to indicate where that is.

> ⚠ **Warning**
>
> If you set either of these variables, it is important that they are set to the same values each time trust is updated. If they change, the tool won't know about certificates in the former locations (for example to clean them up).

Using sudo

As on other platforms, development certificates are stored and trusted separately for each user. As a result, if you run `dotnet dev-certs` as a different user (for example by using `sudo`), it is *that* user (for example `root`) that will trust the development certificate.

Trust HTTPS certificate on Linux with linux-dev-certs

linux-dev-certs is an open-source, community-supported, .NET global tool that provides a convenient way to create and trust a developer certificate on Linux. The tool is not maintained or supported by Microsoft.

The following commands install the tool and create a trusted developer certificate:

cli

```
dotnet tool update -g linux-dev-certs
dotnet linux-dev-certs install
```

For more information or to report issues, see the linux-dev-certs GitHub repository.

SUSE Linux Enterprise Server

See this GitHub issue

Troubleshoot certificate problems such as certificate not trusted

This section provides help when the ASP.NET Core HTTPS development certificate has been installed and trusted, but you still have browser warnings that the certificate is not trusted. The ASP.NET Core HTTPS development certificate is used by Kestrel.

To repair the IIS Express certificate, see this Stackoverflow issue.

All platforms - certificate not trusted

Run the following commands:

.NET CLI

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

Close any browser instances open. Open a new browser window to app. Certificate trust is cached by browsers.

dotnet dev-certs https --clean Fails

The preceding commands solve most browser trust issues. If the browser is still not trusting the certificate, follow the platform-specific suggestions that follow.

Docker - certificate not trusted

- Delete the *C:\Users{USER}\AppData\Roaming\ASP.NET\Https* folder.
- Clean the solution. Delete the *bin* and *obj* folders.
- Restart the development tool. For example, Visual Studio or Visual Studio Code.

Windows - certificate not trusted

- Check the certificates in the certificate store. There should be a `localhost` certificate with the `ASP.NET Core HTTPS development certificate` friendly name both under `Current User > Personal > Certificates` and `Current User > Trusted root certification authorities > Certificates`
- Remove all the found certificates from both Personal and Trusted root certification authorities. Do **not** remove the IIS Express localhost certificate.

- Run the following commands:

.NET CLI

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

Close any browser instances open. Open a new browser window to app.

OS X - certificate not trusted

- Open KeyChain Access.
- Select the System keychain.
- Check for the presence of a localhost certificate.
- Check that it contains a `+` symbol on the icon to indicate it's trusted for all users.
- Remove the certificate from the system keychain.
- Run the following commands:

.NET CLI

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

Close any browser instances open. Open a new browser window to app.

See HTTPS Error using IIS Express (dotnet/AspNetCore #16892) for troubleshooting certificate issues with Visual Studio.

Linux certificate not trusted

Check that the certificate being configured for trust is the user HTTPS developer certificate that will be used by the Kestrel server.

Check the current user default HTTPS developer Kestrel certificate at the following location:

```
ls -la ~/.dotnet/corefx/cryptography/x509stores/my
```

The HTTPS developer Kestrel certificate file is the SHA1 thumbprint. When the file is deleted via `dotnet dev-certs https --clean`, it's regenerated when needed with a

different thumbprint. Check the thumbprint of the exported certificate matches with the following command:

```
openssl x509 -noout -fingerprint -sha1 -inform pem -in /usr/local/share/ca-certificates/aspnet/https.crt
```

If the certificate doesn't match, it could be one of the following:

- An old certificate.
- An exported a developer certificate for the root user. For this case, export the certificate.

The root user certificate can be checked at:

```
ls -la /root/.dotnet/corefx/cryptography/x509stores/my
```

IIS Express SSL certificate used with Visual Studio

To fix problems with the IIS Express certificate, select **Repair** from the Visual Studio installer. For more information, see this GitHub issue.

Group policy prevents self-signed certificates from being trusted

In some cases, group policy may prevent self-signed certificates from being trusted. For more information, see this GitHub issue.

Hosting ASP.NET Core images with Docker over HTTPS

Article • 09/07/2024

By Rick Anderson

ASP.NET Core uses HTTPS by default. HTTPS relies on certificates for trust, identity, and encryption.

This document explains how to run pre-built container images with HTTPS using the .NET command-line interface (CLI). For instructions on how to run Docker in development with Visual Studio, see Developing ASP.NET Core Applications with Docker over HTTPS.

This sample requires Docker 17.06 or later of the Docker client.

Prerequisites

The current .NET SDK.

Certificates

A certificate from a certificate authority is required for production hosting for a domain. Let's Encrypt is a certificate authority that offers free certificates.

This document uses self-signed development certificates for hosting pre-built images over `localhost`. The instructions are similar to using production certificates. The certificate generated by `dotnet dev-certs` is for use with `localhost` only and should ***not*** be used in an environment like Kubernetes. To support HTTPS within a Kubernetes cluster, use the tools provided by Manage TLS Certificates in a Cluster to setup TLS within pods.

Use dotnet dev-certs to create self-signed certificates for development and testing.

For production certs:

- The `dotnet dev-certs` tool is not required.
- Certificates do not need to be stored in the location used in the instructions. Any location should work, although storing certs within your site directory is not recommended.

The instructions contained in the following section volume mount certificates into containers using Docker's `-v` command-line option. You could add certificates into container images with a `COPY` command in a *Dockerfile*, but it's not recommended. Copying certificates into an image isn't recommended for the following reasons:

- It's difficult to use the same image for testing with developer certificates.
- It's difficult to use the same image for Hosting with production certificates.
- There is significant risk of certificate disclosure.

Running pre-built container images with HTTPS

Use the following instructions for your operating system configuration.

Windows using Linux containers

Generate a certificate and configure the local machine:

.NET CLI

```
dotnet dev-certs https -ep %USERPROFILE%\.aspnet\https\aspnetapp.pfx -p
<CREDENTIAL_PLACEHOLDER>
dotnet dev-certs https --trust
```

In the preceding commands, replace `<CREDENTIAL_PLACEHOLDER>` with a password.

Run the container image with ASP.NET Core configured for HTTPS in a command shell:

Console

```
docker pull mcr.microsoft.com/dotnet/samples:aspnetapp
docker run --rm -it -p 8000:80 -p 8001:443 -e
ASPNETCORE_URLS="https://+;http://+" -e ASPNETCORE_HTTPS_PORTS=8001 -e
ASPNETCORE_Kestrel__Certificates__Default__Password="
<CREDENTIAL_PLACEHOLDER>" -e
ASPNETCORE_Kestrel__Certificates__Default__Path=/https/aspnetapp.pfx -v
%USERPROFILE%\.aspnet\https:/https/
mcr.microsoft.com/dotnet/samples:aspnetapp
```

In the preceding code, replace `<CREDENTIAL_PLACEHOLDER>` with the password. The password must match the password used for the certificate.

When using PowerShell, replace `%USERPROFILE%` with `$env:USERPROFILE`.

Note: The certificate in this case must be a `.pfx` file. Utilizing a `.crt` or `.key` file with or without the password isn't supported with the sample container. For example, when specifying a `.crt` file, the container may return error messages such as 'The server mode SSL must use a certificate with the associated private key.'. When using WSL, validate the mount path to ensure that the certificate loads correctly.

macOS or Linux

Generate certificate and configure local machine:

.NET CLI

```
dotnet dev-certs https -ep ${HOME}/.aspnet/https/aspnetapp.pfx -p
<CREDENTIAL_PLACEHOLDER>
dotnet dev-certs https --trust
```

On Linux, `dotnet dev-certs https --trust` requires .NET 9 SDK or later. For Linux on .NET 8.0.401 SDK and earlier, see your Linux distribution's documentation for trusting a certificate.

In the preceding commands, replace `<CREDENTIAL_PLACEHOLDER>` with a password.

Run the container image with ASP.NET Core configured for HTTPS:

Console

```
docker pull mcr.microsoft.com/dotnet/samples:aspnetapp
docker run --rm -it -p 8000:80 -p 8001:443 -e
ASPNETCORE_URLS="https://+;http://+" -e ASPNETCORE_HTTPS_PORTS=8001 -e
ASPNETCORE_Kestrel__Certificates__Default__Password="
<CREDENTIAL_PLACEHOLDER>" -e
ASPNETCORE_Kestrel__Certificates__Default__Path=/https/aspnetapp.pfx -v
${HOME}/.aspnet/https:/https/ mcr.microsoft.com/dotnet/samples:aspnetapp
```

In the preceding code, replace `<CREDENTIAL_PLACEHOLDER>` with the password. The password must match the password used for the certificate.

Windows using Windows containers

Generate certificate and configure local machine:

.NET CLI

```
dotnet dev-certs https -ep %USERPROFILE%\.aspnet\https\aspnetapp.pfx -p
<CREDENTIAL_PLACEHOLDER>
```

```
dotnet dev-certs https --trust
```

In the preceding commands, replace `<CREDENTIAL_PLACEHOLDER>` with a password. When using PowerShell, replace `%USERPROFILE%` with `$env:USERPROFILE`.

Run the container image with ASP.NET Core configured for HTTPS:

Console

```
docker pull mcr.microsoft.com/dotnet/samples:aspnetapp
docker run --rm -it -p 8000:80 -p 8001:443 -e
ASPNETCORE_URLS="https://+;http://+" -e ASPNETCORE_HTTPS_PORTS=8001 -e
ASPNETCORE_Kestrel__Certificates__Default__Password="
<CREDENTIAL_PLACEHOLDER>" -e
ASPNETCORE_Kestrel__Certificates__Default__Path=c:\https\aspnetapp.pfx -v
%USERPROFILE%\.aspnet\https:C:\https\ --user ContainerAdministrator
mcr.microsoft.com/dotnet/samples:aspnetapp
```

NOTE: `<CREDENTIAL_PLACEHOLDER>` is a placeholder for the Kestrel certificates default password.

The password must match the password used for the certificate. When using PowerShell, replace `%USERPROFILE%` with `$env:USERPROFILE`.

Developing ASP.NET Core Applications with Docker over HTTPS

Hosting ASP.NET Core images with Docker Compose over HTTPS

Article • 09/07/2024

ASP.NET Core uses HTTPS by default. HTTPS relies on certificates for trust, identity, and encryption.

This document explains how to run pre-built container images with HTTPS.

See Developing ASP.NET Core Applications with Docker over HTTPS for development scenarios.

This sample requires Docker 17.06 or later of the Docker client.

Prerequisites

The .NET Core 2.2 SDK or later is required for some of the instructions in this document.

Certificates

A certificate from a certificate authority is required for production hosting for a domain. Let's Encrypt is a certificate authority that offers free certificates.

This document uses self-signed development certificates for hosting pre-built images over `localhost`. The instructions are similar to using production certificates.

For production certificates:

- The `dotnet dev-certs` tool is not required.
- Certificates don't need to be stored in the location used in the instructions. Store the certificates in any location outside the site directory.

The instructions contained in the following section volume mount certificates into containers using the `volumes` property in *docker-compose.yml*. You could add certificates into container images with a `COPY` command in a *Dockerfile*, but it's not recommended. Copying certificates into an image isn't recommended for the following reasons:

- It makes it difficult to use the same image for testing with developer certificates.
- It makes it difficult to use the same image for Hosting with production certificates.
- There is significant risk of certificate disclosure.

Starting a container with https support using docker compose

Use the following instructions for your operating system configuration.

Windows using Linux containers

Generate certificate and configure local machine:

PowerShell

```
dotnet dev-certs https -ep "$env:USERPROFILE\.aspnet\https\aspnetapp.pfx"  -
p $CREDENTIAL_PLACEHOLDER$
dotnet dev-certs https --trust
```

The previous command using the .NET CLI:

.NET CLI

```
dotnet dev-certs https -ep %USERPROFILE%\.aspnet\https\aspnetapp.pfx -p
$CREDENTIAL_PLACEHOLDER$
dotnet dev-certs https --trust
```

In the preceding commands, replace `$CREDENTIAL_PLACEHOLDER$` with a password.

Create a *docker-compose.debug.yml* file with the following content:

YAML

```
version: '3.4'

services:
  webapp:
    image: mcr.microsoft.com/dotnet/samples:aspnetapp
    ports:
      - 80
      - 443
    environment:
      - ASPNETCORE_ENVIRONMENT=Development
      - ASPNETCORE_URLS=https://+:443;http://+:80
      - ASPNETCORE_Kestrel__Certificates__Default__Password=password
      - ASPNETCORE_Kestrel__Certificates__Default__Path=/https/aspnetapp.pfx
    volumes:
      - ~/.aspnet/https:/https:ro
```

The password specified in the docker compose file must match the password used for the certificate.

Start the container with ASP.NET Core configured for HTTPS:

Console

```
docker-compose -f "docker-compose.debug.yml" up -d
```

macOS or Linux

Generate certificate and configure local machine:

.NET CLI

```
dotnet dev-certs https -ep ${HOME}/.aspnet/https/aspnetapp.pfx -p
$CREDENTIAL_PLACEHOLDER$
dotnet dev-certs https --trust
```

On Linux, `dotnet dev-certs https --trust` requires .NET 9 SDK or later. For Linux on .NET 8.0.401 SDK and earlier, see your Linux distribution's documentation for trusting a certificate.

In the preceding commands, replace `$CREDENTIAL_PLACEHOLDER$` with a password.

Create a *docker-compose.debug.yml* file with the following content:

YAML

```
version: '3.4'

services:
  webapp:
    image: mcr.microsoft.com/dotnet/samples:aspnetapp
    ports:
      - 80
      - 443
    environment:
      - ASPNETCORE_ENVIRONMENT=Development
      - ASPNETCORE_URLS=https://+:443;http://+:80
      - ASPNETCORE_Kestrel__Certificates__Default__Password=password
      - ASPNETCORE_Kestrel__Certificates__Default__Path=/https/aspnetapp.pfx
    volumes:
      - ~/.aspnet/https:/https:ro
```

The password specified in the docker compose file must match the password used for the certificate.

Start the container with ASP.NET Core configured for HTTPS:

Console

```
docker-compose -f "docker-compose.debug.yml" up -d
```

Windows using Windows containers

Generate certificate and configure local machine:

.NET CLI

```
dotnet dev-certs https -ep %USERPROFILE%\.aspnet\https\aspnetapp.pfx -p
$CREDENTIAL_PLACEHOLDER$
dotnet dev-certs https --trust
```

In the preceding commands, replace `$CREDENTIAL_PLACEHOLDER$` with a password.

Create a *docker-compose.debug.yml* file with the following content:

YAML

```
version: '3.4'

services:
  webapp:
    image: mcr.microsoft.com/dotnet/samples:aspnetapp
    ports:
      - 80
      - 443
    environment:
      - ASPNETCORE_ENVIRONMENT=Development
      - ASPNETCORE_URLS=https://+:443;http://+:80
      - ASPNETCORE_Kestrel__Certificates__Default__Password=password
      -
ASPNETCORE_Kestrel__Certificates__Default__Path=C:\https\aspnetapp.pfx
    volumes:
      - ${USERPROFILE}\.aspnet\https:C:\https:ro
```

The password specified in the docker compose file must match the password used for the certificate.

Start the container with ASP.NET Core configured for HTTPS:

Console

```
docker-compose -f "docker-compose.debug.yml" up -d
```

EU General Data Protection Regulation (GDPR) support in ASP.NET Core

Article • 06/17/2024

By Rick Anderson

ASP.NET Core provides APIs and templates to help meet some of the EU General Data Protection Regulation (GDPR) requirements:

- The project templates include extension points and stubbed markup that you can replace with your privacy and cookie use policy.
- The `Pages/Privacy.cshtml` page or `Views/Home/Privacy.cshtml` view provides a page to detail your site's privacy policy.

To enable the default cookie consent feature like that found in the ASP.NET Core 2.2 templates in a current ASP.NET Core template generated app, add the following highlighted code to `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.Configure<CookiePolicyOptions>(options =>
{
    // This lambda determines whether user consent for non-essential
    // cookies is needed for a given request.
    options.CheckConsentNeeded = context => true;

    options.MinimumSameSitePolicy = SameSiteMode.None;
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseCookiePolicy();

app.UseRouting();

app.UseAuthorization();
```

```
app.MapRazorPages();

app.Run();
```

In the preceding code, CookiePolicyOptions and UseCookiePolicy are used.

- Add the cookie consent partial to the `_Layout.cshtml` file:

CSHTML

```
            @*Previous markup removed for brevity*@
    </header>
    <div class="container">
        <partial name="_CookieConsentPartial" />
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2022 - WebGDPR - <a asp-area="" asp-
page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.min.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.min.js">
</script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```

- Add the `_CookieConsentPartial.cshtml` file to the project:

CSHTML

```
@using Microsoft.AspNetCore.Http.Features

@{
    var consentFeature = Context.Features.Get<ITrackingConsentFeature>
();
    var showBanner = !consentFeature?.CanTrack ?? false;
    var cookieString = consentFeature?.CreateConsentCookie();
}

@if (showBanner)
{
```

```
    <div id="cookieConsent" class="alert alert-info alert-dismissible
fade show" role="alert">
        Use this space to summarize your privacy and cookie use policy.
<a asp-page="/Privacy">Learn More</a>.
        <button type="button" class="accept-policy close" data-bs-
dismiss="alert" aria-label="Close" data-cookie-string="@cookieString">
            <span aria-hidden="true">Accept</span>
        </button>
    </div>
    <script>
        (function () {
            var button = document.querySelector("#cookieConsent
button[data-cookie-string]");
            button.addEventListener("click", function (event) {
                document.cookie = button.dataset.cookieString;
            }, false);
        })();
    </script>
}
```

- Select the ASP.NET Core 2.2 version of this article to read about the cookie consent feature.

Customize the cookie consent value

Specify the value used to track if the user consented to the cookie use policy using the CookiePolicyOptions.ConsentCookieValue property:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.Configure<CookiePolicyOptions>(options =>
{
    options.CheckConsentNeeded = context => true;
    options.MinimumSameSitePolicy = SameSiteMode.None;
    options.ConsentCookieValue = "true";
});

var app = builder.Build();
```

Encryption at rest

Some databases and storage mechanisms allow for encryption at rest. Encryption at rest:

- Encrypts stored data automatically.

- Encrypts without configuration, programming, or other work for the software that accesses the data.
- Is the easiest and safest option.
- Allows the database to manage keys and encryption.

For example:

- Microsoft SQL and Azure SQL provide Transparent Data Encryption (TDE).
- SQL Azure encrypts the database by default
- Azure Blobs, Files, Table, and Queue Storage are encrypted by default.

For databases that don't provide built-in encryption at rest, you may be able to use disk encryption to provide the same protection. For example:

- BitLocker for Windows Server
- Linux:
  - eCryptfs
  - EncFS.

Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core

Article • 10/21/2024

By Fiyaz Hasan and Rick Anderson

Cross-site request forgery is an attack against web-hosted apps whereby a malicious web app can influence the interaction between a client browser and a web app that trusts that browser. These attacks are possible because web browsers send some types of authentication tokens automatically with every request to a website. This form of exploit is also known as a *one-click attack* or *session riding* because the attack takes advantage of the user's previously authenticated session. Cross-site request forgery is also known as XSRF or CSRF.

An example of a CSRF attack:

1. A user signs into `www.good-banking-site.example.com` using forms authentication. The server authenticates the user and issues a response that includes an authentication cookie. The site is vulnerable to attack because it trusts any request that it receives with a valid authentication cookie.

2. The user visits a malicious site, `www.bad-crook-site.example.com`.

   The malicious site, `www.bad-crook-site.example.com`, contains an HTML form similar to the following example:

   HTML

   ```
   <h1>Congratulations! You're a Winner!</h1>
   <form action="https://good-banking-site.com/api/account" method="post">
       <input type="hidden" name="Transaction" value="withdraw" />
       <input type="hidden" name="Amount" value="1000000" />
       <input type="submit" value="Click to collect your prize!" />
   </form>
   ```

   Notice that the form's `action` posts to the vulnerable site, not to the malicious site. This is the "cross-site" part of CSRF.

3. The user selects the submit button. The browser makes the request and automatically includes the authentication cookie for the requested domain, `www.good-banking-site.example.com`.

4. The request runs on the `www.good-banking-site.example.com` server with the user's authentication context and can perform any action that an authenticated user is allowed to perform.

In addition to the scenario where the user selects the button to submit the form, the malicious site could:

- Run a script that automatically submits the form.
- Send the form submission as an AJAX request.
- Hide the form using CSS.

These alternative scenarios don't require any action or input from the user other than initially visiting the malicious site.

Using HTTPS doesn't prevent a CSRF attack. The malicious site can send an `https://www.good-banking-site.com/` request as easily as it can send an insecure request.

Some attacks target endpoints that respond to GET requests, in which case an image tag can be used to perform the action. This form of attack is common on forum sites that permit images but block JavaScript. Apps that change state on GET requests, where variables or resources are altered, are vulnerable to malicious attacks. **GET requests that change state are insecure. A best practice is to never change state on a GET request.**

CSRF attacks are possible against web apps that use cookies for authentication because:

- Browsers store cookies issued by a web app.
- Stored cookies include session cookies for authenticated users.
- Browsers send all of the cookies associated with a domain to the web app every request regardless of how the request to app was generated within the browser.

However, CSRF attacks aren't limited to exploiting cookies. For example, Basic and Digest authentication are also vulnerable. After a user signs in with Basic or Digest authentication, the browser automatically sends the credentials until the session ends.

In this context, *session* refers to the client-side session during which the user is authenticated. It's unrelated to server-side sessions or ASP.NET Core Session Middleware.

Users can protect against CSRF vulnerabilities by taking precautions:

- Sign out of web apps when finished using them.
- Clear browser cookies periodically.

However, CSRF vulnerabilities are fundamentally a problem with the web app, not the end user.

Authentication fundamentals

Cookie-based authentication is a popular form of authentication. Token-based authentication systems are growing in popularity, especially for Single Page Applications (SPAs).

Cookie-based authentication

When a user authenticates using their username and password they're issued a token containing an authentication ticket. The token can be used for authentication and authorization. The token is stored as a cookie that's sent with every request the client makes. Generating and validating this cookie is performed with the Cookie Authentication Middleware. The middleware serializes a user principal into an encrypted cookie. On subsequent requests, the middleware validates the cookie, recreates the principal, and assigns the principal to the HttpContext.User property.

Token-based authentication

When a user is authenticated, they're issued a token (not an antiforgery token). The token contains user information in the form of claims or a reference token that points the app to user state maintained in the app. When a user attempts to access a resource that requires authentication, the token is sent to the app with an extra authorization header in the form of a Bearer token. This approach makes the app stateless. In each subsequent request, the token is passed in the request for server-side validation. This token isn't *encrypted*; it's *encoded*. On the server, the token is decoded to access its information. To send the token on subsequent requests, store the token in the browser's local storage. Placing a token in the browser local storage and retrieving it and using it as a bearer token provides protection against CSRF attacks. However, should the app be vulnerable to script injection via XSS or a compromised external JavaScript file, a cyberattacker could retrieve any value from local storage and send it to themselves. ASP.NET Core encodes all server side output from variables by default, reducing the risk of XSS. If you override this behavior by using Html.Raw or custom code with untrusted input then you may increase the risk of XSS.

Don't be concerned about CSRF vulnerability if the token is stored in the browser's local storage. CSRF is a concern when the token is stored in a cookie. For more information, see the GitHub issue SPA code sample adds two cookies.

Multiple apps hosted at one domain

Shared hosting environments are vulnerable to session hijacking, sign-in CSRF, and other attacks.

Although `example1.contoso.net` and `example2.contoso.net` are different hosts, there's an implicit trust relationship between hosts under the `*.contoso.net` domain. This implicit trust relationship allows potentially untrusted hosts to affect each other's cookies (the same-origin policies that govern AJAX requests don't necessarily apply to HTTP cookies).

Attacks that exploit trusted cookies between apps hosted on the same domain can be prevented by not sharing domains. When each app is hosted on its own domain, there's no implicit cookie trust relationship to exploit.

Antiforgery in ASP.NET Core

> ⚠ **Warning**
>
> ASP.NET Core implements antiforgery using ASP.NET Core Data Protection. The data protection stack must be configured to work in a server farm. For more information, see Configuring data protection.

Antiforgery middleware is added to the Dependency injection container when one of the following APIs is called in `Program.cs`:

- AddMvc
- MapRazorPages
- MapControllerRoute
- AddRazorComponents

For more information, see Antiforgery with Minimal APIs.

The FormTagHelper injects antiforgery tokens into HTML form elements. The following markup in a Razor file automatically generates antiforgery tokens:

CSHTML

```
<form method="post">
    <!-- ... -->
</form>
```

Similarly, IHtmlHelper.BeginForm generates antiforgery tokens by default if the form's method isn't GET.

The automatic generation of antiforgery tokens for HTML form elements happens when the `<form>` tag contains the `method="post"` attribute and either of the following are true:

- The action attribute is empty (`action=""`).
- The action attribute isn't supplied (`<form method="post">`).

Automatic generation of antiforgery tokens for HTML form elements can be disabled:

- Explicitly disable antiforgery tokens with the `asp-antiforgery` attribute:

  CSHTML

  ```
  <form method="post" asp-antiforgery="false">
      <!-- ... -->
  </form>
  ```

- The form element is opted-out of Tag Helpers by using the Tag Helper ! opt-out symbol:

  CSHTML

  ```
  <!form method="post">
      <!-- ... -->
  </!form>
  ```

- Remove the `FormTagHelper` from the view. The `FormTagHelper` can be removed from a view by adding the following directive to the Razor view:

  CSHTML

  ```
  @removeTagHelper Microsoft.AspNetCore.Mvc.TagHelpers.FormTagHelper,
  Microsoft.AspNetCore.Mvc.TagHelpers
  ```

> ⓘ Note
>
> Razor Pages are automatically protected from XSRF/CSRF. For more information, see XSRF/CSRF and Razor Pages.

The most common approach to protecting against CSRF attacks is to use the *Synchronizer Token Pattern* (STP). STP is used when the user requests a page with form data:

1. The server sends a token associated with the current user's identity to the client.
2. The client sends back the token to the server for verification.
3. If the server receives a token that doesn't match the authenticated user's identity, the request is rejected.

The token is unique and unpredictable. The token can also be used to ensure proper sequencing of a series of requests (for example, ensuring the request sequence of: page 1 > page 2 > page 3). All of the forms in ASP.NET Core MVC and Razor Pages templates generate antiforgery tokens. The following pair of view examples generates antiforgery tokens:

CSHTML

```
<form asp-action="Index" asp-controller="Home" method="post">
    <!-- ... -->
</form>

@using (Html.BeginForm("Index", "Home"))
{
    <!-- ... -->
}
```

Explicitly add an antiforgery token to a `<form>` element without using Tag Helpers with the HTML helper @Html.AntiForgeryToken:

CSHTML

```
<form asp-action="Index" asp-controller="Home" method="post">
    @Html.AntiForgeryToken()

    <!-- ... -->
</form>
```

In each of the preceding cases, ASP.NET Core adds a hidden form field similar to the following example:

HTML

```
<input name="__RequestVerificationToken" type="hidden" value="CfDJ8NrAkS ...
s2-m9Yw">
```

ASP.NET Core includes three filters for working with antiforgery tokens:

- ValidateAntiForgeryToken
- AutoValidateAntiforgeryToken

- IgnoreAntiforgeryToken

Antiforgery with `AddControllers`

Calling AddControllers does ***not*** enable antiforgery tokens. AddControllersWithViews must be called to have built-in antiforgery token support.

Multiple browser tabs and the Synchronizer Token Pattern

With the Synchronizer Token Pattern, only the most recently loaded page contains a valid antiforgery token. Using multiple tabs can be problematic. For example, if a user opens multiple tabs:

- Only the most recently loaded tab contains a valid antiforgery token.
- Requests made from previously loaded tabs fail with an error: `Antiforgery token validation failed. The antiforgery cookie token and request token do not match`

Consider alternative CSRF protection patterns if this poses an issue.

Configure antiforgery with `AntiforgeryOptions`

Customize AntiforgeryOptions in `Program.cs`:

C#

```
builder.Services.AddAntiforgery(options =>
{
    // Set Cookie properties using CookieBuilder properties†.
    options.FormFieldName = "AntiforgeryFieldname";
    options.HeaderName = "X-CSRF-TOKEN-HEADERNAME";
    options.SuppressXFrameOptionsHeader = false;
});
```

Set the antiforgery `Cookie` properties using the properties of the CookieBuilder class, as shown in the following table.

Expand table

Option	Description
Cookie	Determines the settings used to create the antiforgery cookies.

Option	Description
FormFieldName	The name of the hidden form field used by the antiforgery system to render antiforgery tokens in views.
HeaderName	The name of the header used by the antiforgery system. If `null`, the system considers only form data.
SuppressXFrameOptionsHeader	Specifies whether to suppress generation of the `X-Frame-Options` header. By default, the header is generated with a value of "SAMEORIGIN". Defaults to `false`.

For more information, see CookieAuthenticationOptions.

Generate antiforgery tokens with `IAntiforgery`

IAntiforgery provides the API to configure antiforgery features. `IAntiforgery` can be requested in `Program.cs` using WebApplication.Services. The following example uses middleware from the app's home page to generate an antiforgery token and send it in the response as a cookie:

C#

```
app.UseRouting();

app.UseAuthorization();

var antiforgery = app.Services.GetRequiredService<IAntiforgery>();

app.Use((context, next) =>
{
    var requestPath = context.Request.Path.Value;

    if (string.Equals(requestPath, "/", StringComparison.OrdinalIgnoreCase)
        || string.Equals(requestPath, "/index.html",
StringComparison.OrdinalIgnoreCase))
    {
        var tokenSet = antiforgery.GetAndStoreTokens(context);
        context.Response.Cookies.Append("XSRF-TOKEN",
tokenSet.RequestToken!,
            new CookieOptions { HttpOnly = false });
    }

    return next(context);
});
```

The preceding example sets a cookie named `XSRF-TOKEN`. The client can read this cookie and provide its value as a header attached to AJAX requests. For example, Angular

includes built-in XSRF protection that reads a cookie named `XSRF-TOKEN` by default.

Require antiforgery validation

The ValidateAntiForgeryToken action filter can be applied to an individual action, a controller, or globally. Requests made to actions that have this filter applied are blocked unless the request includes a valid antiforgery token:

```
C#

[HttpPost]
[ValidateAntiForgeryToken]
public IActionResult Index()
{
    // ...

    return RedirectToAction();
}
```

The `ValidateAntiForgeryToken` attribute requires a token for requests to the action methods it marks, including HTTP GET requests. If the `ValidateAntiForgeryToken` attribute is applied across the app's controllers, it can be overridden with the `IgnoreAntiforgeryToken` attribute.

Automatically validate antiforgery tokens for unsafe HTTP methods only

Instead of broadly applying the `ValidateAntiForgeryToken` attribute and then overriding it with `IgnoreAntiforgeryToken` attributes, the AutoValidateAntiforgeryToken attribute can be used. This attribute works identically to the `ValidateAntiForgeryToken` attribute, except that it doesn't require tokens for requests made using the following HTTP methods:

- GET
- HEAD
- OPTIONS
- TRACE

We recommend use of `AutoValidateAntiforgeryToken` broadly for non-API scenarios. This attribute ensures POST actions are protected by default. The alternative is to ignore antiforgery tokens by default, unless `ValidateAntiForgeryToken` is applied to individual action methods. It's more likely in this scenario for a POST action method to be left

unprotected by mistake, leaving the app vulnerable to CSRF attacks. All POSTs should send the antiforgery token.

APIs don't have an automatic mechanism for sending the non-cookie part of the token. The implementation probably depends on the client code implementation. Some examples are shown below:

Class-level example:

```
C#

[AutoValidateAntiforgeryToken]
public class HomeController : Controller
```

Global example:

```
C#

builder.Services.AddControllersWithViews(options =>
{
    options.Filters.Add(new AutoValidateAntiforgeryTokenAttribute());
});
```

Override global or controller antiforgery attributes

The IgnoreAntiforgeryToken filter is used to eliminate the need for an antiforgery token for a given action (or controller). When applied, this filter overrides `ValidateAntiForgeryToken` and `AutoValidateAntiforgeryToken` filters specified at a higher level (globally or on a controller).

```
C#

[IgnoreAntiforgeryToken]
public IActionResult IndexOverride()
{
    // ...

    return RedirectToAction();
}
```

Refresh tokens after authentication

Tokens should be refreshed after the user is authenticated by redirecting the user to a view or Razor Pages page.

JavaScript, AJAX, and SPAs

In traditional HTML-based apps, antiforgery tokens are passed to the server using hidden form fields. In modern JavaScript-based apps and SPAs, many requests are made programmatically. These AJAX requests may use other techniques, such as request headers or cookies, to send the token.

If cookies are used to store authentication tokens and to authenticate API requests on the server, CSRF is a potential problem. If local storage is used to store the token, CSRF vulnerability might be mitigated because values from local storage aren't sent automatically to the server with every request. Using local storage to store the antiforgery token on the client and sending the token as a request header is a recommended approach.

Blazor

For more information, see ASP.NET Core Blazor authentication and authorization.

JavaScript

Using JavaScript with views, the token can be created using a service from within the view. Inject the IAntiforgery service into the view and call GetAndStoreTokens:

CSHTML

```
@inject Microsoft.AspNetCore.Antiforgery.IAntiforgery Antiforgery

@{
    ViewData["Title"] = "JavaScript";

    var requestToken = Antiforgery.GetAndStoreTokens(Context).RequestToken;
}

<input id="RequestVerificationToken" type="hidden" value="@requestToken" />

<button id="button" class="btn btn-primary">Submit with Token</button>
<div id="result" class="mt-2"></div>

@section Scripts {
<script>
    document.addEventListener("DOMContentLoaded", () => {
        const resultElement = document.getElementById("result");

        document.getElementById("button").addEventListener("click", async ()
=> {

            const response = await fetch("@Url.Action("FetchEndpoint")", {
```

```
                method: "POST",
                headers: {
                    RequestVerificationToken:

document.getElementById("RequestVerificationToken").value
                }
            });

            if (response.ok) {
                resultElement.innerText = await response.text();
            } else {
                resultElement.innerText = `Request Failed:
${response.status}`
            }
        });
    });
</script>
}
```

The preceding example uses JavaScript to read the hidden field value for the AJAX POST header.

This approach eliminates the need to deal directly with setting cookies from the server or reading them from the client. However, when injecting the IAntiforgery service isn't possible, use JavaScript to access tokens in cookies:

- Access tokens in an additional request to the server, typically usually `same-origin`.
- Use the cookie's contents to create a header with the token's value.

Assuming the script sends the token in a request header called `X-XSRF-TOKEN`, configure the antiforgery service to look for the `X-XSRF-TOKEN` header:

C#

```
builder.Services.AddAntiforgery(options => options.HeaderName = "X-XSRF-
TOKEN");
```

The following example adds a protected endpoint that writes the request token to a JavaScript-readable cookie:

C#

```
app.UseAuthorization();
app.MapGet("antiforgery/token", (IAntiforgery forgeryService, HttpContext
context) =>
{
    var tokens = forgeryService.GetAndStoreTokens(context);
    context.Response.Cookies.Append("XSRF-TOKEN", tokens.RequestToken!,
            new CookieOptions { HttpOnly = false });
```

```
    return Results.Ok();
}).RequireAuthorization();
```

The following example uses JavaScript to make an AJAX request to obtain the token and make another request with the appropriate header:

JavaScript

```
var response = await fetch("/antiforgery/token", {
    method: "GET",
    headers: { "Authorization": authorizationToken }
});

if (response.ok) {
    // https://developer.mozilla.org/docs/web/api/document/cookie
    const xsrfToken = document.cookie
        .split("; ")
        .find(row => row.startsWith("XSRF-TOKEN="))
        .split("=")[1];

    response = await fetch("/JavaScript/FetchEndpoint", {
        method: "POST",
        headers: { "X-XSRF-TOKEN": xsrfToken, "Authorization":
authorizationToken }
    });

    if (response.ok) {
        resultElement.innerText = await response.text();
    } else {
        resultElement.innerText = `Request Failed: ${response.status}`
    }
} else {
    resultElement.innerText = `Request Failed: ${response.status}`
}
```

> **Note**
>
> When the antiforgery token is provided in both the request header and in the form payload, only the token in the header is validated.

Antiforgery with Minimal APIs

Call AddAntiforgery and UseAntiforgery(IApplicationBuilder) to register antiforgery services in DI. Antiforgery tokens are used to mitigate cross-site request forgery attacks.

C#

```
var builder = WebApplication.CreateBuilder();

builder.Services.AddAntiforgery();

var app = builder.Build();

app.UseAntiforgery();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The antiforgery middleware:

- Does ***not*** short-circuit the execution of the rest of the request pipeline.
- Sets the IAntiforgeryValidationFeature in the HttpContext.Features of the current request.

The antiforgery token is only validated if:

- The endpoint contains metadata implementing IAntiforgeryMetadata where `RequiresValidation=true`.
- The HTTP method associated with the endpoint is a relevant HTTP method. The relevant methods are all HTTP methods except for TRACE, OPTIONS, HEAD, and GET.
- The request is associated with a valid endpoint.

Note: When enabled manually, the antiforgery middleware must run after the authentication and authorization middleware to prevent reading form data when the user is unauthenticated.

By default, minimal APIs that accept form data require antiforgery token validation.

Consider the following `GenerateForm` method:

C#

```
public static string GenerateForm(string action,
    AntiforgeryTokenSet token, bool UseToken=true)
{
    string tokenInput = "";
    if (UseToken)
    {
        tokenInput = $@"<input name=""{token.FormFieldName}""
                        type=""hidden"" value=""{token.RequestToken}"" />";
    }

    return $@"
```

```
    <html><body>
        <form action=""{action}"" method=""POST"" enctype=""multipart/form-
data"">
            {tokenInput}
            <input type=""text"" name=""name"" />
            <input type=""date"" name=""dueDate"" />
            <input type=""checkbox"" name=""isCompleted"" />
            <input type=""submit"" />
        </form>
    </body></html>
";
}
```

The preceding code has three arguments, the action, the antiforgery token, and a `bool` indicating whether the token should be used.

Consider the following sample:

C#

```
using Microsoft.AspNetCore.Antiforgery;
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAntiforgery();

var app = builder.Build();

app.UseAntiforgery();

// Pass token
app.MapGet("/", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    return Results.Content(MyHtml.GenerateForm("/todo", token),
"text/html");
});

// Don't pass a token, fails
app.MapGet("/SkipToken", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    return Results.Content(MyHtml.GenerateForm("/todo",token, false ),
"text/html");
});

// Post to /todo2. DisableAntiforgery on that endpoint so no token needed.
app.MapGet("/DisableAntiforgery", (HttpContext context, IAntiforgery
antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    return Results.Content(MyHtml.GenerateForm("/todo2", token, false),
```

```
"text/html");
});

app.MapPost("/todo", ([FromForm] Todo todo) => Results.Ok(todo));

app.MapPost("/todo2", ([FromForm] Todo todo) => Results.Ok(todo))
                                                    .DisableAntiforgery();

app.Run();

class Todo
{
    public required string Name { get; set; }
    public bool IsCompleted { get; set; }
    public DateTime DueDate { get; set; }
}

public static class MyHtml
{
    public static string GenerateForm(string action,
        AntiforgeryTokenSet token, bool UseToken=true)
    {
        string tokenInput = "";
        if (UseToken)
        {
            tokenInput = $@"<input name=""{token.FormFieldName}""
                                type=""hidden"" value=""{token.RequestToken}""
/>";
        }

        return $@"
        <html><body>
            <form action=""{action}"" method=""POST""
enctype=""multipart/form-data"">
                {tokenInput}
                <input type=""text"" name=""name"" />
                <input type=""date"" name=""dueDate"" />
                <input type=""checkbox"" name=""isCompleted"" />
                <input type=""submit"" />
            </form>
        </body></html>
    ";
    }
}
```

In the preceding code, posts to:

- `/todo` require a valid antiforgery token.
- `/todo2` do ***not*** require a valid antiforgery token because DisableAntiforgery is called.

C#

```
app.MapPost("/todo", ([FromForm] Todo todo) => Results.Ok(todo));

app.MapPost("/todo2", ([FromForm] Todo todo) => Results.Ok(todo))
                                                .DisableAntiforgery();
```

A POST to:

- `/todo` from the form generated by the `/` endpoint succeeds because the antiforgery token is valid.
- `/todo` from the form generated by the `/SkipToken` fails because the antiforgery is not included.
- `/todo2` from the form generated by the `/DisableAntiforgery` endpoint succeeds because the antiforgery is not required.

C#

```
app.MapPost("/todo", ([FromForm] Todo todo) => Results.Ok(todo));

app.MapPost("/todo2", ([FromForm] Todo todo) => Results.Ok(todo))
                                                .DisableAntiforgery();
```

When a form is submitted without a valid antiforgery token:

- In the development environment, an exception is thrown.
- In the production environment, a message is logged.

Windows authentication and antiforgery cookies

When using Windows Authentication, application endpoints must be protected against CSRF attacks in the same way as done for cookies. The browser implicitly sends the authentication context to the server and endpoints need to be protected against CSRF attacks.

Extend antiforgery

The IAntiforgeryAdditionalDataProvider type allows developers to extend the behavior of the anti-CSRF system by round-tripping additional data in each token. The GetAdditionalData method is called each time a field token is generated, and the return value is embedded within the generated token. An implementer could return a timestamp, a nonce, or any other value and then call ValidateAdditionalData to validate

this data when the token is validated. The client's username is already embedded in the generated tokens, so there's no need to include this information. If a token includes supplemental data but no `IAntiForgeryAdditionalDataProvider` is configured, the supplemental data isn't validated.

Prevent open redirect attacks in ASP.NET Core

Article • 09/27/2024

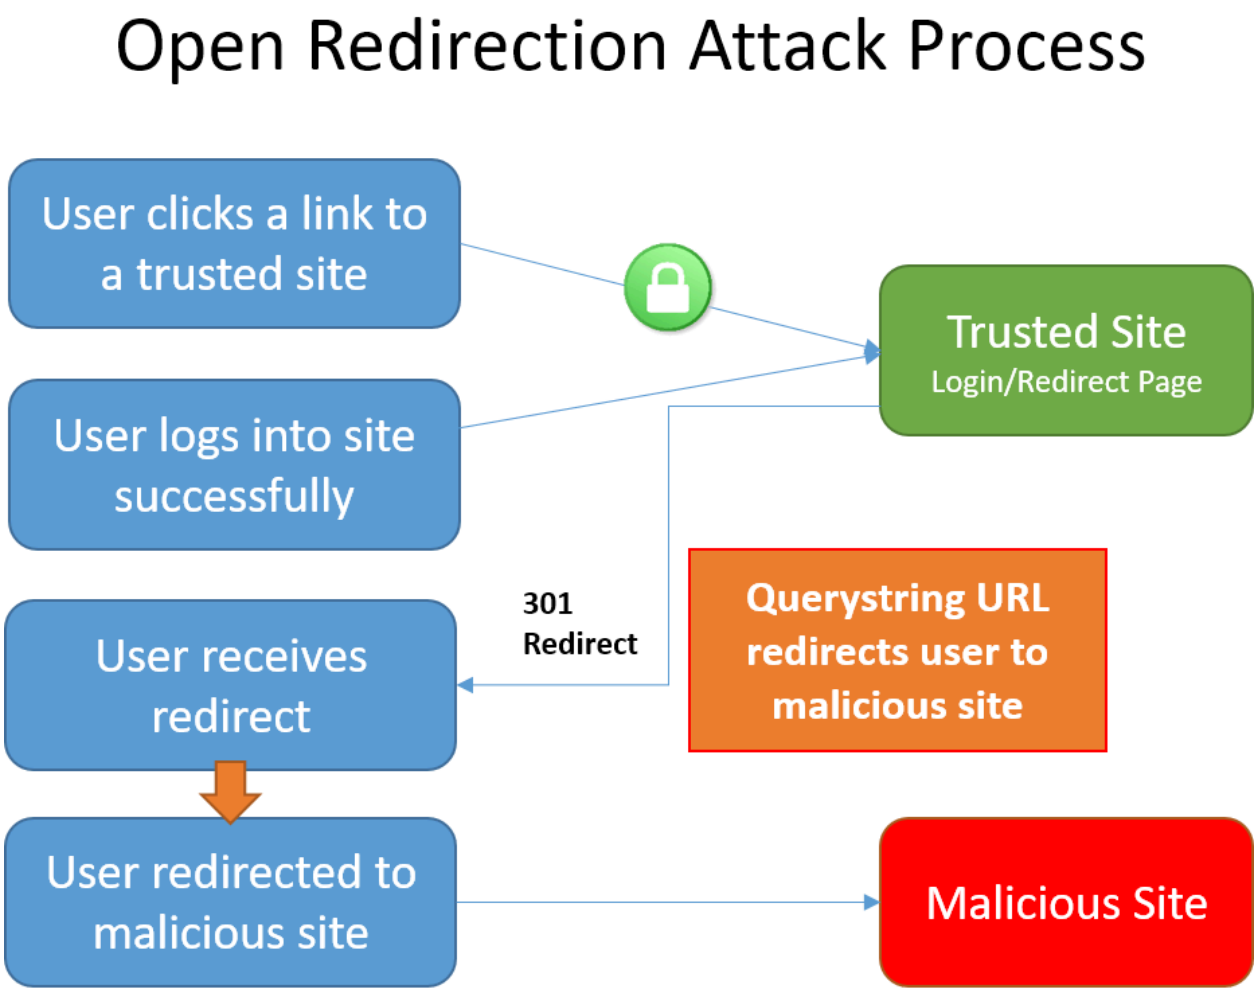
A web app that redirects to a URL that's specified via the request such as the querystring or form data can potentially be tampered with to redirect users to an external, malicious URL. This tampering is called an open redirection attack.

Whenever your application logic redirects to a specified URL, you must verify that the redirection URL hasn't been tampered with. ASP.NET Core has built-in functionality to help protect apps from open redirect (also known as open redirection) attacks.

What is an open redirect attack?

Web applications frequently redirect users to a login page when they access resources that require authentication. The redirection typically includes a `returnUrl` querystring parameter so that the user can be returned to the originally requested URL after they have successfully logged in. After the user authenticates, they're redirected to the URL they had originally requested.

Because the destination URL is specified in the querystring of the request, a malicious user could tamper with the querystring. A tampered querystring could allow the site to redirect the user to an external, malicious site. This technique is called an open redirect (or redirection) attack.



An example attack

A malicious user can develop an attack intended to allow the malicious user access to a user's credentials or sensitive information. To begin the attack, the malicious user convinces the user to click a link to your site's login page with a `returnUrl` querystring value added to the URL. For example, consider an app at `contoso.com` that includes a login page at `http://contoso.com/Account/LogOn?returnUrl=/Home/About`. The attack follows these steps:

1. The user clicks a malicious link to `http://contoso.com/Account/LogOn?returnUrl=http://contoso1.com/Account/LogOn` (the second URL is "contoso**1**.com", not "contoso.com").
2. The user logs in successfully.

3. The user is redirected (by the site) to `http://contoso1.com/Account/LogOn` (a malicious site that looks exactly like real site).
4. The user logs in again (giving malicious site their credentials) and is redirected back to the real site.

The user likely believes that their first attempt to log in failed and that their second attempt is successful. The user most likely remains unaware that their credentials are compromised.

In addition to login pages, some sites provide redirect pages or endpoints. Imagine your app has a page with an open redirect, `/Home/Redirect`. A cyberattacker could create, for example, a link in an email that goes to `[yoursite]/Home/Redirect?url=http://phishingsite.com/Home/Login`. A typical user will look at the URL and see it begins with your site name. Trusting that, they will click the link. The open redirect would then send the user to the phishing site, which looks identical to yours, and the user would likely login to what they believe is your site.

Protecting against open redirect attacks

When developing web applications, treat all user-provided data as untrustworthy. If your application has functionality that redirects the user based on the contents of the URL, ensure that such redirects are only done locally within your app (or to a known URL, not any URL that may be supplied in the querystring).

LocalRedirect

Use the `LocalRedirect` helper method from the base `Controller` class:

C#

```
public IActionResult SomeAction(string redirectUrl)
{
    return LocalRedirect(redirectUrl);
}
```

`LocalRedirect` will throw an exception if a non-local URL is specified. Otherwise, it behaves just like the `Redirect` method.

IsLocalUrl

Use the IsLocalUrl method to test URLs before redirecting:

The following example shows how to check whether a URL is local before redirecting.

C#

```
private IActionResult RedirectToLocal(string returnUrl)
{
    if (Url.IsLocalUrl(returnUrl))
    {
        return Redirect(returnUrl);
    }
    else
    {
        return RedirectToAction(nameof(HomeController.Index), "Home");
    }
}
```

The `IsLocalUrl` method protects users from being inadvertently redirected to a malicious site. You can log the details of the URL that was provided when a non-local URL is supplied in a situation where you expected a local URL. Logging redirect URLs may help in diagnosing redirection attacks.

Prevent Cross-Site Scripting (XSS) in ASP.NET Core

Article • 09/27/2024

By Rick Anderson

Cross-Site Scripting (XSS) is a security vulnerability that enables a cyberattacker to place client side scripts (usually JavaScript) into web pages. When other users load affected pages, the cyberattacker's scripts run, enabling the cyberattacker to steal cookies and session tokens, change the contents of the web page through DOM manipulation, or redirect the browser to another page. XSS vulnerabilities generally occur when an application takes user input and outputs it to a page without validating, encoding or escaping it.

This article applies primarily to ASP.NET Core MVC with views, Razor Pages, and other apps that return HTML that may be vulnerable to XSS. Web APIs that return data in the form of HTML, XML, or JSON can trigger XSS attacks in their client apps if they don't properly sanitize user input, depending on how much trust the client app places in the API. For example, if an API accepts user-generated content and returns it in an HTML response, a cyberattacker could inject malicious scripts into the content that executes when the response is rendered in the user's browser.

To prevent XSS attacks, web APIs should implement input validation and output encoding. Input validation ensures that user input meets expected criteria and doesn't include malicious code. Output encoding ensures that any data returned by the API is properly sanitized so that it can't be executed as code by the user's browser. For more information, see this GitHub issue.

Protecting your application against XSS

At a basic level, XSS works by tricking your application into inserting a `<script>` tag into your rendered page, or by inserting an `On*` event into an element. Developers should use the following prevention steps to avoid introducing XSS into their applications:

1. Never put untrusted data into your HTML input, unless you follow the rest of the steps below. Untrusted data is any data that may be controlled by a cyberattacker, such as HTML form inputs, query strings, HTTP headers, or even data sourced from a database, as a cyberattacker may be able to breach your database even if they can't breach your application.

2. Before putting untrusted data inside an HTML element, ensure it's HTML encoded. HTML encoding takes characters such as < and changes them into a safe form like <

3. Before putting untrusted data into an HTML attribute, ensure it's HTML encoded. HTML attribute encoding is a superset of HTML encoding and encodes additional characters such as " and ".

4. Before putting untrusted data into JavaScript, place the data in an HTML element whose contents you retrieve at runtime. If this isn't possible, then ensure the data is JavaScript encoded. JavaScript encoding takes dangerous characters for JavaScript and replaces them with their hex, for example, < would be encoded as `\u003C`.

5. Before putting untrusted data into a URL query string ensure it's URL encoded.

HTML Encoding using Razor

The Razor engine used in MVC automatically encodes all output sourced from variables, unless you work really hard to prevent it doing so. It uses HTML attribute encoding rules whenever you use the @ directive. As HTML attribute encoding is a superset of HTML encoding this means you don't have to concern yourself with whether you should use HTML encoding or HTML attribute encoding. You must ensure that you only use @ in an HTML context, not when attempting to insert untrusted input directly into JavaScript. Tag helpers will also encode input you use in tag parameters.

Take the following Razor view:

CSHTML

```
@{
    var untrustedInput = "<\"123\">";
}

@untrustedInput
```

This view outputs the contents of the *untrustedInput* variable. This variable includes some characters which are used in XSS attacks, namely <, " and >. Examining the source shows the rendered output encoded as:

HTML

```
&lt;&quot;123&quot;&gt;
```

> ⚠ **Warning**
>
> ASP.NET Core MVC provides an `HtmlString` class which isn't automatically encoded upon output. This should never be used in combination with untrusted input as this will expose an XSS vulnerability.

JavaScript Encoding using Razor

There may be times you want to insert a value into JavaScript to process in your view. There are two ways to do this. The safest way to insert values is to place the value in a data attribute of a tag and retrieve it in your JavaScript. For example:

CSHTML

```
@{
    var untrustedInput = "<script>alert(1)</script>";
}

<div id="injectedData"
     data-untrustedinput="@untrustedInput" />

<div id="scriptedWrite" />
<div id="scriptedWrite-html5" />

<script>
    var injectedData = document.getElementById("injectedData");

    // All clients
    var clientSideUntrustedInputOldStyle =
        injectedData.getAttribute("data-untrustedinput");

    // HTML 5 clients only
    var clientSideUntrustedInputHtml5 =
        injectedData.dataset.untrustedinput;

    // Put the injected, untrusted data into the scriptedWrite div tag.
    // Do NOT use document.write() on dynamically generated data as it
    // can lead to XSS.

    document.getElementById("scriptedWrite").innerText +=
clientSideUntrustedInputOldStyle;

    // Or you can use createElement() to dynamically create document
elements
    // This time we're using textContent to ensure the data is properly
encoded.
    var x = document.createElement("div");
    x.textContent = clientSideUntrustedInputHtml5;
    document.body.appendChild(x);
```

```
    // You can also use createTextNode on an element to ensure data is
properly encoded.
    var y = document.createElement("div");
    y.appendChild(document.createTextNode(clientSideUntrustedInputHtml5));
    document.body.appendChild(y);

</script>
```

The preceding markup generates the following HTML:

HTML

```
<div id="injectedData"
     data-untrustedinput="&lt;script&gt;alert(1)&lt;/script&gt;" />

<div id="scriptedWrite" />
<div id="scriptedWrite-html5" />

<script>
    var injectedData = document.getElementById("injectedData");

    // All clients
    var clientSideUntrustedInputOldStyle =
        injectedData.getAttribute("data-untrustedinput");

    // HTML 5 clients only
    var clientSideUntrustedInputHtml5 =
        injectedData.dataset.untrustedinput;

    // Put the injected, untrusted data into the scriptedWrite div tag.
    // Do NOT use document.write() on dynamically generated data as it can
    // lead to XSS.

    document.getElementById("scriptedWrite").innerText +=
clientSideUntrustedInputOldStyle;

    // Or you can use createElement() to dynamically create document
elements
    // This time we're using textContent to ensure the data is properly
encoded.
    var x = document.createElement("div");
    x.textContent = clientSideUntrustedInputHtml5;
    document.body.appendChild(x);

    // You can also use createTextNode on an element to ensure data is
properly encoded.
    var y = document.createElement("div");
    y.appendChild(document.createTextNode(clientSideUntrustedInputHtml5));
    document.body.appendChild(y);

</script>
```

The preceding code generates the following output:

```
<script>alert(1)</script>
<script>alert(1)</script>
<script>alert(1)</script>
```

> ⚠ **Warning**
>
> Do ***NOT*** concatenate untrusted input in JavaScript to create DOM elements or use `document.write()` on dynamically generated content.
>
> Use one of the following approaches to prevent code from being exposed to DOM-based XSS:
>
> - `createElement()` and assign property values with appropriate methods or properties such as `node.textContent=` or `node.InnerText=`.
> - `document.CreateTextNode()` and append it in the appropriate DOM location.
> - `element.SetAttribute()`
> - `element[attribute]=`

Accessing encoders in code

The HTML, JavaScript and URL encoders are available to your code in two ways:

- Inject them via dependency injection.
- Use the default encoders contained in the `System.Text.Encodings.Web` namespace.

When using the default encoders, then any customizations applied to character ranges to be treated as safe won't take effect. The default encoders use the safest encoding rules possible.

To use the configurable encoders via DI your constructors should take an *HtmlEncoder*, *JavaScriptEncoder* and *UrlEncoder* parameter as appropriate. For example;

C#

```
public class HomeController : Controller
{
    HtmlEncoder _htmlEncoder;
    JavaScriptEncoder _javaScriptEncoder;
    UrlEncoder _urlEncoder;
```

```
    public HomeController(HtmlEncoder htmlEncoder,
                          JavaScriptEncoder javascriptEncoder,
                          UrlEncoder urlEncoder)
    {
        _htmlEncoder = htmlEncoder;
        _javaScriptEncoder = javascriptEncoder;
        _urlEncoder = urlEncoder;
    }
}
```

Encoding URL Parameters

If you want to build a URL query string with untrusted input as a value use the `UrlEncoder` to encode the value. For example,

C#

```
var example = "\"Quoted Value with spaces and &\"";
var encodedValue = _urlEncoder.Encode(example);
```

After encoding the encodedValue variable contains `%22Quoted%20Value%20with%20spaces%20and%20%26%22`. Spaces, quotes, punctuation and other unsafe characters are percent encoded to their hexadecimal value, for example a space character will become %20.

> ⚠ **Warning**
>
> Don't use untrusted input as part of a URL path. Always pass untrusted input as a query string value.

Customizing the Encoders

By default encoders use a safe list limited to the Basic Latin Unicode range and encode all characters outside of that range as their character code equivalents. This behavior also affects Razor TagHelper and HtmlHelper rendering as it uses the encoders to output your strings.

The reasoning behind this is to protect against unknown or future browser bugs (previous browser bugs have tripped up parsing based on the processing of non-English characters). If your web site makes heavy use of non-Latin characters, such as Chinese, Cyrillic or others this is probably not the behavior you want.

The encoder safe lists can be customized to include Unicode ranges appropriate to the app during startup, in `Program.cs`:

For example, using the default configuration using a Razor HtmlHelper similar to the following:

HTML

```
<p>This link text is in Chinese: @Html.ActionLink("汉语/漢語", "Index")</p>
```

The preceding markup is rendered with Chinese text encoded:

HTML

```
<p>This link text is in Chinese: <a
href="/">&#x6C49;&#x8BED;/&#x6F22;&#x8A9E;</a></p>
```

To widen the characters treated as safe by the encoder, insert the following line into `Program.cs`.:

C#

```
builder.Services.AddSingleton<HtmlEncoder>(
     HtmlEncoder.Create(allowedRanges: new[] { UnicodeRanges.BasicLatin,

UnicodeRanges.CjkUnifiedIdeographs }));
```

This example widens the safe list to include the Unicode Range CjkUnifiedIdeographs. The rendered output would now become

HTML

```
<p>This link text is in Chinese: <a href="/">汉语/漢語</a></p>
```

Safe list ranges are specified as Unicode code charts, not languages. The Unicode standard has a list of code charts you can use to find the chart containing your characters. Each encoder, Html, JavaScript and Url, must be configured separately.

> **Note**
>
> Customization of the safe list only affects encoders sourced via DI. If you directly access an encoder via `System.Text.Encodings.Web.*Encoder.Default` then the default, Basic Latin only safelist will be used.

Where should encoding take place?

The general accepted practice is that encoding takes place at the point of output and encoded values should never be stored in a database. Encoding at the point of output allows you to change the use of data, for example, from HTML to a query string value. It also enables you to easily search your data without having to encode values before searching and allows you to take advantage of any changes or bug fixes made to encoders.

Validation as an XSS prevention technique

Validation can be a useful tool in limiting XSS attacks. For example, a numeric string containing only the characters 0-9 won't trigger an XSS attack. Validation becomes more complicated when accepting HTML in user input. Parsing HTML input is difficult, if not impossible. Markdown, coupled with a parser that strips embedded HTML, is a safer option for accepting rich input. Never rely on validation alone. Always encode untrusted input before output, no matter what validation or sanitization has been performed.

Enable Cross-Origin Requests (CORS) in ASP.NET Core

Article • 09/21/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Rick Anderson and Kirk Larkin

This article shows how **C**ross-**O**rigin **R**esource **S**haring (CORS) is enabled in an ASP.NET Core app.

Browser security prevents a web page from making requests to a different domain than the one that served the web page. This restriction is called the *same-origin policy*. The same-origin policy prevents a malicious site from reading sensitive data from another site. Sometimes, you might want to allow other sites to make cross-origin requests to your app. For more information, see the Mozilla CORS article.

Cross Origin Resource Sharing (CORS):

- Is a W3C standard that allows a server to relax the same-origin policy.
- Is **not** a security feature, CORS relaxes security. An API is not safer by allowing CORS. For more information, see How CORS works.
- Allows a server to explicitly allow some cross-origin requests while rejecting others.
- Is safer and more flexible than earlier techniques, such as JSONP.

View or download sample code (how to download)

Same origin

Two URLs have the same origin if they have identical schemes, hosts, and ports (RFC 6454).

These two URLs have the same origin:

- `https://example.com/foo.html`

- `https://example.com/bar.html`

These URLs have different origins than the previous two URLs:

- `https://example.net`: Different domain
- `https://contoso.example.com/foo.html`: Different subdomain
- `http://example.com/foo.html`: Different scheme
- `https://example.com:9000/foo.html`: Different port

Enable CORS

There are three ways to enable CORS:

- In middleware using a named policy or default policy.
- Using endpoint routing.
- With the [EnableCors] attribute.

Using the [EnableCors] attribute with a named policy provides the finest control in limiting endpoints that support CORS.

> ⚠ **Warning**
>
> UseCors must be called in the correct order. For more information, see Middleware order. For example, `UseCors` must be called before UseResponseCaching when using `UseResponseCaching`.

Each approach is detailed in the following sections.

CORS with named policy and middleware

CORS Middleware handles cross-origin requests. The following code applies a CORS policy to all the app's endpoints with the specified origins:

C#

```
var  MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddCors(options =>
{
    options.AddPolicy(name: MyAllowSpecificOrigins,
                      policy  =>
                      {
                          policy.WithOrigins("http://example.com",
                                             "http://www.contoso.com");
                      });
});

// services.AddResponseCaching();

builder.Services.AddControllers();

var app = builder.Build();
app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseCors(MyAllowSpecificOrigins);

app.UseAuthorization();

app.MapControllers();

app.Run();
```

The preceding code:

- Sets the policy name to `_myAllowSpecificOrigins`. The policy name is arbitrary.
- Calls the UseCors extension method and specifies the `_myAllowSpecificOrigins` CORS policy. `UseCors` adds the CORS middleware. The call to `UseCors` must be placed after `UseRouting`, but before `UseAuthorization`. For more information, see Middleware order.
- Calls AddCors with a lambda expression. The lambda takes a CorsPolicyBuilder object. Configuration options, such as `WithOrigins`, are described later in this article.
- Enables the `_myAllowSpecificOrigins` CORS policy for all controller endpoints. See endpoint routing to apply a CORS policy to specific endpoints.
- When using Response Caching Middleware, call UseCors before UseResponseCaching.

With endpoint routing, the CORS middleware **must** be configured to execute between the calls to `UseRouting` and `UseEndpoints`.

The AddCors method call adds CORS services to the app's service container:

```
C#
```

```
var  MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: MyAllowSpecificOrigins,
                      policy  =>
                      {
                          policy.WithOrigins("http://example.com",
                                             "http://www.contoso.com");
                      });
});

// services.AddResponseCaching();

builder.Services.AddControllers();

var app = builder.Build();
app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseCors(MyAllowSpecificOrigins);

app.UseAuthorization();

app.MapControllers();

app.Run();
```

For more information, see CORS policy options in this document.

The CorsPolicyBuilder methods can be chained, as shown in the following code:

C#

```
var MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(MyAllowSpecificOrigins,
                          policy =>
                          {
                              policy.WithOrigins("http://example.com",
                                                 "http://www.contoso.com")
                                                 .AllowAnyHeader()
                                                 .AllowAnyMethod();
                          });
});
```

```
builder.Services.AddControllers();

var app = builder.Build();
app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseCors(MyAllowSpecificOrigins);

app.UseAuthorization();

app.MapControllers();

app.Run();
```

Note: The specified URL must **not** contain a trailing slash (`/`). If the URL terminates with `/`, the comparison returns `false` and no header is returned.

UseCors and UseStaticFiles order

Typically, `UseStaticFiles` is called before `UseCors`. Apps that use JavaScript to retrieve static files cross site must call `UseCors` before `UseStaticFiles`.

CORS with default policy and middleware

The following highlighted code enables the default CORS policy:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddDefaultPolicy(
        policy =>
        {
            policy.WithOrigins("http://example.com",
                               "http://www.contoso.com");
        });
});

builder.Services.AddControllers();

var app = builder.Build();

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();
```

```
app.UseCors();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

The preceding code applies the default CORS policy to all controller endpoints.

Enable Cors with endpoint routing

With endpoint routing, CORS can be enabled on a per-endpoint basis using the RequireCors set of extension methods:

C#

```
var MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: MyAllowSpecificOrigins,
                      policy =>
                      {
                          policy.WithOrigins("http://example.com",
                                             "http://www.contoso.com");
                      });
});

builder.Services.AddControllers();
builder.Services.AddRazorPages();

var app = builder.Build();

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseCors();

app.UseAuthorization();

app.UseEndpoints(endpoints =>
{
    endpoints.MapGet("/echo",
        context => context.Response.WriteAsync("echo"))
        .RequireCors(MyAllowSpecificOrigins);
```

```
    endpoints.MapControllers()
             .RequireCors(MyAllowSpecificOrigins);

    endpoints.MapGet("/echo2",
        context => context.Response.WriteAsync("echo2"));

    endpoints.MapRazorPages();
});

app.Run();
```

In the preceding code:

- `app.UseCors` enables the CORS middleware. Because a default policy hasn't been configured, `app.UseCors()` alone doesn't enable CORS.
- The `/echo` and controller endpoints allow cross-origin requests using the specified policy.
- The `/echo2` and Razor Pages endpoints do **not** allow cross-origin requests because no default policy was specified.

The [DisableCors] attribute does **not** disable CORS that has been enabled by endpoint routing with `RequireCors`.

See Test CORS with [EnableCors] attribute and RequireCors method for instructions on testing code similar to the preceding.

Enable CORS with attributes

Enabling CORS with the [EnableCors] attribute and applying a named policy to only those endpoints that require CORS provides the finest control.

The [EnableCors] attribute provides an alternative to applying CORS globally. The `[EnableCors]` attribute enables CORS for selected endpoints, rather than all endpoints:

- `[EnableCors]` specifies the default policy.
- `[EnableCors("{Policy String}")]` specifies a named policy.

The `[EnableCors]` attribute can be applied to:

- Razor Page `PageModel`
- Controller
- Controller action method

Different policies can be applied to controllers, page models, or action methods with the `[EnableCors]` attribute. When the `[EnableCors]` attribute is applied to a controller, page

model, or action method, and CORS is enabled in middleware, **both** policies are applied. **We recommend against combining policies. Use the `[EnableCors]` attribute or middleware, not both in the same app.**

The following code applies a different policy to each method:

C#

```
[Route("api/[controller]")]
[ApiController]
public class WidgetController : ControllerBase
{
    // GET api/values
    [EnableCors("AnotherPolicy")]
    [HttpGet]
    public ActionResult<IEnumerable<string>> Get()
    {
        return new string[] { "green widget", "red widget" };
    }

    // GET api/values/5
    [EnableCors("Policy1")]
    [HttpGet("{id}")]
    public ActionResult<string> Get(int id)
    {
        return id switch
        {
            1 => "green widget",
            2 => "red widget",
            _ => NotFound(),
        };
    }
}
```

The following code creates two CORS policies:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy("Policy1",
        policy =>
        {
            policy.WithOrigins("http://example.com",
                               "http://www.contoso.com");
        });

    options.AddPolicy("AnotherPolicy",
        policy =>
```

```
        {
            policy.WithOrigins("http://www.contoso.com")
                                .AllowAnyHeader()
                                .AllowAnyMethod();
        });
});

builder.Services.AddControllers();

var app = builder.Build();

app.UseHttpsRedirection();

app.UseRouting();

app.UseCors();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

For the finest control of limiting CORS requests:

- Use `[EnableCors("MyPolicy")]` with a named policy.
- Don't define a default policy.
- Don't use endpoint routing.

The code in the next section meets the preceding list.

Disable CORS

The [DisableCors] attribute does **not** disable CORS that has been enabled by endpoint routing.

The following code defines the CORS policy `"MyPolicy"`:

C#

```
var MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: "MyPolicy",
        policy =>
        {
            policy.WithOrigins("http://example.com",
```

```
                                    "http://www.contoso.com")
                        .WithMethods("PUT", "DELETE", "GET");
        });
});

builder.Services.AddControllers();
builder.Services.AddRazorPages();

var app = builder.Build();

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseCors();

app.UseAuthorization();

app.UseEndpoints(endpoints => {
    endpoints.MapControllers();
    endpoints.MapRazorPages();
});

app.Run();
```

The following code disables CORS for the `GetValues2` action:

C#

```
[EnableCors("MyPolicy")]
[Route("api/[controller]")]
[ApiController]
public class ValuesController : ControllerBase
{
    // GET api/values
    [HttpGet]
    public IActionResult Get() =>
        ControllerContext.MyDisplayRouteInfo();

    // GET api/values/5
    [HttpGet("{id}")]
    public IActionResult Get(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // PUT api/values/5
    [HttpPut("{id}")]
    public IActionResult Put(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // GET: api/values/GetValues2
    [DisableCors]
    [HttpGet("{action}")]
```

```
    public IActionResult GetValues2() =>
        ControllerContext.MyDisplayRouteInfo();

}
```

The preceding code:

- Doesn't enable CORS with endpoint routing.
- Doesn't define a default CORS policy.
- Uses [EnableCors("MyPolicy")] to enable the `"MyPolicy"` CORS policy for the controller.
- Disables CORS for the `GetValues2` method.

See Test CORS for instructions on testing the preceding code.

CORS policy options

This section describes the various options that can be set in a CORS policy:

- Set the allowed origins
- Set the allowed HTTP methods
- Set the allowed request headers
- Set the exposed response headers
- Credentials in cross-origin requests
- Set the preflight expiration time

AddPolicy is called in `Program.cs`. For some options, it may be helpful to read the How CORS works section first.

Set the allowed origins

AllowAnyOrigin: Allows CORS requests from all origins with any scheme (`http` or `https`). `AllowAnyOrigin` is insecure because *any website* can make cross-origin requests to the app.

> **Note**
>
> Specifying `AllowAnyOrigin` and `AllowCredentials` is an insecure configuration and can result in cross-site request forgery. The CORS service returns an invalid CORS response when an app is configured with both methods.

`AllowAnyOrigin` affects preflight requests and the `Access-Control-Allow-Origin` header. For more information, see the Preflight requests section.

SetIsOriginAllowedToAllowWildcardSubdomains: Sets the IsOriginAllowed property of the policy to be a function that allows origins to match a configured wildcard domain when evaluating if the origin is allowed.

C#

```
var MyAllowSpecificOrigins = "_MyAllowSubdomainPolicy";

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: MyAllowSpecificOrigins,
        policy =>
        {
            policy.WithOrigins("https://*.example.com")
                .SetIsOriginAllowedToAllowWildcardSubdomains();
        });
});

builder.Services.AddControllers();

var app = builder.Build();
```

Set the allowed HTTP methods

AllowAnyMethod:

- Allows any HTTP method:
- Affects preflight requests and the `Access-Control-Allow-Methods` header. For more information, see the Preflight requests section.

Set the allowed request headers

To allow specific headers to be sent in a CORS request, called *author request headers*, call WithHeaders and specify the allowed headers:

C#

```
using Microsoft.Net.Http.Headers;

var MyAllowSpecificOrigins = "_MyAllowSubdomainPolicy";

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddCors(options =>
{
    options.AddPolicy(name: MyAllowSpecificOrigins,
       policy =>
       {
           policy.WithOrigins("http://example.com")
                  .WithHeaders(HeaderNames.ContentType, "x-custom-header");
       });
});

builder.Services.AddControllers();

var app = builder.Build();
```

To allow all author request headers, call AllowAnyHeader:

C#

```
var MyAllowSpecificOrigins = "_MyAllowSubdomainPolicy";

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: MyAllowSpecificOrigins,
        policy =>
        {
            policy.WithOrigins("https://*.example.com")
                  .AllowAnyHeader();
        });
});

builder.Services.AddControllers();

var app = builder.Build();
```

`AllowAnyHeader` affects preflight requests and the Access-Control-Request-Headers header. For more information, see the Preflight requests section.

A CORS Middleware policy match to specific headers specified by `WithHeaders` is only possible when the headers sent in `Access-Control-Request-Headers` exactly match the headers stated in `WithHeaders`.

For instance, consider an app configured as follows:

C#

```
app.UseCors(policy => policy.WithHeaders(HeaderNames.CacheControl));
```

CORS Middleware declines a preflight request with the following request header because `Content-Language` (HeaderNames.ContentLanguage) isn't listed in `WithHeaders`:

```
Access-Control-Request-Headers: Cache-Control, Content-Language
```

The app returns a *200 OK* response but doesn't send the CORS headers back. Therefore, the browser doesn't attempt the cross-origin request.

Set the exposed response headers

By default, the browser doesn't expose all of the response headers to the app. For more information, see W3C Cross-Origin Resource Sharing (Terminology): Simple Response Header.

The response headers that are available by default are:

- `Cache-Control`
- `Content-Language`
- `Content-Type`
- `Expires`
- `Last-Modified`
- `Pragma`

The CORS specification calls these headers *simple response headers*. To make other headers available to the app, call WithExposedHeaders:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy("MyExposeResponseHeadersPolicy",
        policy =>
        {
            policy.WithOrigins("https://*.example.com")
                  .WithExposedHeaders("x-custom-header");
        });
});

builder.Services.AddControllers();

var app = builder.Build();
```

Credentials in cross-origin requests

Credentials require special handling in a CORS request. By default, the browser doesn't send credentials with a cross-origin request. Credentials include cookies and HTTP authentication schemes. To send credentials with a cross-origin request, the client must set `XMLHttpRequest.withCredentials` to `true`.

Using `XMLHttpRequest` directly:

JavaScript

```
var xhr = new XMLHttpRequest();
xhr.open('get', 'https://www.example.com/api/test');
xhr.withCredentials = true;
```

Using jQuery:

JavaScript

```
$.ajax({
  type: 'get',
  url: 'https://www.example.com/api/test',
  xhrFields: {
    withCredentials: true
  }
});
```

Using the Fetch API:

JavaScript

```
fetch('https://www.example.com/api/test', {
    credentials: 'include'
});
```

The server must allow the credentials. To allow cross-origin credentials, call AllowCredentials:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy("MyMyAllowCredentialsPolicy",
        policy =>
        {
```

```
            policy.WithOrigins("http://example.com")
                  .AllowCredentials();
        });
});

builder.Services.AddControllers();

var app = builder.Build();
```

The HTTP response includes an `Access-Control-Allow-Credentials` header, which tells the browser that the server allows credentials for a cross-origin request.

If the browser sends credentials but the response doesn't include a valid `Access-Control-Allow-Credentials` header, the browser doesn't expose the response to the app, and the cross-origin request fails.

Allowing cross-origin credentials is a security risk. A website at another domain can send a signed-in user's credentials to the app on the user's behalf without the user's knowledge.

The CORS specification also states that setting origins to `"*"` (all origins) is invalid if the `Access-Control-Allow-Credentials` header is present.

Preflight requests

For some CORS requests, the browser sends an additional OPTIONS request before making the actual request. This request is called a preflight request. The browser can skip the preflight request if **all** the following conditions are true:

- The request method is GET, HEAD, or POST.
- The app doesn't set request headers other than `Accept`, `Accept-Language`, `Content-Language`, `Content-Type`, or `Last-Event-ID`.
- The `Content-Type` header, if set, has one of the following values:
  - `application/x-www-form-urlencoded`
  - `multipart/form-data`
  - `text/plain`

The rule on request headers set for the client request applies to headers that the app sets by calling `setRequestHeader` on the `XMLHttpRequest` object. The CORS specification calls these headers *author request headers*. The rule doesn't apply to headers the browser can set, such as `User-Agent`, `Host`, or `Content-Length`.

> **Note**
>
> This article contains URLs created by deploying the sample code to two Azure web sites, `https://cors3.azurewebsites.net` and `https://cors.azurewebsites.net`.

The following is an example response similar to the preflight request made from the **[Put test]** button in the Test CORS section of this document.

```
General:
Request URL: https://cors3.azurewebsites.net/api/values/5
Request Method: OPTIONS
Status Code: 204 No Content

Response Headers:
Access-Control-Allow-Methods: PUT,DELETE,GET
Access-Control-Allow-Origin: https://cors1.azurewebsites.net
Server: Microsoft-IIS/10.0
Set-Cookie:
ARRAffinity=8f8...8;Path=/;HttpOnly;Domain=cors1.azurewebsites.net
Vary: Origin

Request Headers:
Accept: */*
Accept-Encoding: gzip, deflate, br
Accept-Language: en-US,en;q=0.9
Access-Control-Request-Method: PUT
Connection: keep-alive
Host: cors3.azurewebsites.net
Origin: https://cors1.azurewebsites.net
Referer: https://cors1.azurewebsites.net/
Sec-Fetch-Dest: empty
Sec-Fetch-Mode: cors
Sec-Fetch-Site: cross-site
User-Agent: Mozilla/5.0
```

The preflight request uses the HTTP OPTIONS method. It may include the following headers:

- Access-Control-Request-Method: The HTTP method that will be used for the actual request.
- Access-Control-Request-Headers: A list of request headers that the app sets on the actual request. As stated earlier, this doesn't include headers that the browser sets, such as `User-Agent`.

If the preflight request is denied, the app returns a `200 OK` response but doesn't set the CORS headers. Therefore, the browser doesn't attempt the cross-origin request. For an example of a denied preflight request, see the Test CORS section of this document.

Using the F12 tools, the console app shows an error similar to one of the following, depending on the browser:

- Firefox: Cross-Origin Request Blocked: The Same Origin Policy disallows reading the remote resource at `https://cors1.azurewebsites.net/api/TodoItems1/MyDelete2/5`. (Reason: CORS request did not succeed). Learn More
- Chromium based: Access to fetch at 'https://cors1.azurewebsites.net/api/TodoItems1/MyDelete2/5' from origin 'https://cors3.azurewebsites.net' has been blocked by CORS policy: Response to preflight request doesn't pass access control check: No 'Access-Control-Allow-Origin' header is present on the requested resource. If an opaque response serves your needs, set the request's mode to 'no-cors' to fetch the resource with CORS disabled.

To allow specific headers, call WithHeaders:

C#

```
using Microsoft.Net.Http.Headers;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy("MyAllowHeadersPolicy",
        policy =>
        {
        policy.WithOrigins("http://example.com")
                    .WithHeaders(HeaderNames.ContentType, "x-custom-header");
        });
});

builder.Services.AddControllers();

var app = builder.Build();
```

To allow all author request headers, call AllowAnyHeader:

C#

```
using Microsoft.Net.Http.Headers;
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy("MyAllowAllHeadersPolicy",
        policy =>
        {
            policy.WithOrigins("https://*.example.com")
                  .AllowAnyHeader();
        });
});

builder.Services.AddControllers();

var app = builder.Build();
```

Browsers aren't consistent in how they set `Access-Control-Request-Headers`. If either:

- Headers are set to anything other than `"*"`
- AllowAnyHeader is called: Include at least `Accept`, `Content-Type`, and `Origin`, plus any custom headers that you want to support.

Automatic preflight request code

When the CORS policy is applied either:

- Globally by calling `app.UseCors` in `Program.cs`.
- Using the `[EnableCors]` attribute.

ASP.NET Core responds to the preflight OPTIONS request.

The Test CORS section of this document demonstrates this behavior.

[HttpOptions] attribute for preflight requests

When CORS is enabled with the appropriate policy, ASP.NET Core generally responds to CORS preflight requests automatically.

The following code uses the [HttpOptions] attribute to create endpoints for OPTIONS requests:

C#

```
[Route("api/[controller]")]
[ApiController]
public class TodoItems2Controller : ControllerBase
{
```

```
    // OPTIONS: api/TodoItems2/5
    [HttpOptions("{id}")]
    public IActionResult PreflightRoute(int id)
    {
        return NoContent();
    }

    // OPTIONS: api/TodoItems2
    [HttpOptions]
    public IActionResult PreflightRoute()
    {
        return NoContent();
    }

    [HttpPut("{id}")]
    public IActionResult PutTodoItem(int id)
    {
        if (id < 1)
        {
            return BadRequest();
        }

        return ControllerContext.MyDisplayRouteInfo(id);
    }
```

See Test CORS with [EnableCors] attribute and RequireCors method for instructions on testing the preceding code.

Set the preflight expiration time

The `Access-Control-Max-Age` header specifies how long the response to the preflight request can be cached. To set this header, call SetPreflightMaxAge:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy("MySetPreflightExpirationPolicy",
        policy =>
        {
            policy.WithOrigins("http://example.com")
                  .SetPreflightMaxAge(TimeSpan.FromSeconds(2520));
        });
});

builder.Services.AddControllers();

var app = builder.Build();
```

Enable CORS on an endpoint

How CORS works

This section describes what happens in a CORS request at the level of the HTTP messages.

- CORS is **not** a security feature. CORS is a W3C standard that allows a server to relax the same-origin policy.
  - For example, a malicious actor could use Cross-Site Scripting (XSS) against your site and execute a cross-site request to their CORS enabled site to steal information.
- An API isn't safer by allowing CORS.
  - It's up to the client (browser) to enforce CORS. The server executes the request and returns the response, it's the client that returns an error and blocks the response. For example, any of the following tools will display the server response:
    - Fiddler
    - .NET HttpClient
    - A web browser by entering the URL in the address bar.
- It's a way for a server to allow browsers to execute a cross-origin XHR or Fetch API request that otherwise would be forbidden.
  - Browsers without CORS can't do cross-origin requests. Before CORS, JSONP was used to circumvent this restriction. JSONP doesn't use XHR, it uses the `<script>` tag to receive the response. Scripts are allowed to be loaded cross-origin.

The CORS specification introduced several new HTTP headers that enable cross-origin requests. If a browser supports CORS, it sets these headers automatically for cross-origin requests. Custom JavaScript code isn't required to enable CORS.

The following is an example of a cross-origin request from the **Values** test button to `https://cors1.azurewebsites.net/api/values`. The `Origin` header:

- Provides the domain of the site that's making the request.
- Is required and must be different from the host.

General headers

```
```

```
Request URL: https://cors1.azurewebsites.net/api/values
Request Method: GET
Status Code: 200 OK
```

Response headers

```
Content-Encoding: gzip
Content-Type: text/plain; charset=utf-8
Server: Microsoft-IIS/10.0
Set-Cookie: ARRAffinity=8f...;Path=/;HttpOnly;Domain=cors1.azurewebsites.net
Transfer-Encoding: chunked
Vary: Accept-Encoding
X-Powered-By: ASP.NET
```

Request headers

```
Accept: */*
Accept-Encoding: gzip, deflate, br
Accept-Language: en-US,en;q=0.9
Connection: keep-alive
Host: cors1.azurewebsites.net
Origin: https://cors3.azurewebsites.net
Referer: https://cors3.azurewebsites.net/
Sec-Fetch-Dest: empty
Sec-Fetch-Mode: cors
Sec-Fetch-Site: cross-site
User-Agent: Mozilla/5.0 ...
```

In `OPTIONS` requests, the server sets the **Response headers** `Access-Control-Allow-Origin: {allowed origin}` header in the response. For example, in the sample code, the `Delete [EnableCors]` button `OPTIONS` request contains the following headers:

General headers

```
Request URL: https://cors3.azurewebsites.net/api/TodoItems2/MyDelete2/5
Request Method: OPTIONS
Status Code: 204 No Content
```

Response headers

```
Access-Control-Allow-Headers: Content-Type,x-custom-header
Access-Control-Allow-Methods: PUT,DELETE,GET,OPTIONS
Access-Control-Allow-Origin: https://cors1.azurewebsites.net
Server: Microsoft-IIS/10.0
Set-Cookie: ARRAffinity=8f...;Path=/;HttpOnly;Domain=cors3.azurewebsites.net
Vary: Origin
X-Powered-By: ASP.NET
```

Request headers

```
Accept: */*
Accept-Encoding: gzip, deflate, br
Accept-Language: en-US,en;q=0.9
Access-Control-Request-Headers: content-type
Access-Control-Request-Method: DELETE
Connection: keep-alive
Host: cors3.azurewebsites.net
Origin: https://cors1.azurewebsites.net
Referer: https://cors1.azurewebsites.net/test?number=2
Sec-Fetch-Dest: empty
Sec-Fetch-Mode: cors
Sec-Fetch-Site: cross-site
User-Agent: Mozilla/5.0
```

In the preceding **Response headers**, the server sets the Access-Control-Allow-Origin header in the response. The `https://cors1.azurewebsites.net` value of this header matches the `Origin` header from the request.

If AllowAnyOrigin is called, the `Access-Control-Allow-Origin: *`, the wildcard value, is returned. `AllowAnyOrigin` allows any origin.

If the response doesn't include the `Access-Control-Allow-Origin` header, the cross-origin request fails. Specifically, the browser disallows the request. Even if the server returns a successful response, the browser doesn't make the response available to the client app.

HTTP redirection to HTTPS causes ERR_INVALID_REDIRECT on the CORS preflight request

Requests to an endpoint using HTTP that are redirected to HTTPS by UseHttpsRedirection fail with `ERR_INVALID_REDIRECT on the CORS preflight request`.

API projects can reject HTTP requests rather than use `UseHttpsRedirection` to redirect requests to HTTPS.

CORS in IIS

When deploying to IIS, CORS has to run before Windows Authentication if the server isn't configured to allow anonymous access. To support this scenario, the IIS CORS module needs to be installed and configured for the app.

Test CORS

The sample download has code to test CORS. See how to download. The sample is an API project with Razor Pages added:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: "MyPolicy",
        policy =>
        {
            policy.WithOrigins("http://example.com",
                    "http://www.contoso.com",
                    "https://cors1.azurewebsites.net",
                    "https://cors3.azurewebsites.net",
                    "https://localhost:44398",
                    "https://localhost:5001")
                .WithMethods("PUT", "DELETE", "GET");
        });
});

builder.Services.AddControllers();
builder.Services.AddRazorPages();

var app = builder.Build();

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseCors();

app.UseAuthorization();

app.MapControllers();
app.MapRazorPages();
```

```
app.Run();
```

> ⚠ **Warning**
>
> `WithOrigins("https://localhost:<port>");` should only be used for testing a sample app similar to the download sample code.

The following `ValuesController` provides the endpoints for testing:

C#

```
[EnableCors("MyPolicy")]
[Route("api/[controller]")]
[ApiController]
public class ValuesController : ControllerBase
{
    // GET api/values
    [HttpGet]
    public IActionResult Get() =>
        ControllerContext.MyDisplayRouteInfo();

    // GET api/values/5
    [HttpGet("{id}")]
    public IActionResult Get(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // PUT api/values/5
    [HttpPut("{id}")]
    public IActionResult Put(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // GET: api/values/GetValues2
    [DisableCors]
    [HttpGet("{action}")]
    public IActionResult GetValues2() =>
        ControllerContext.MyDisplayRouteInfo();

}
```

MyDisplayRouteInfo is provided by the Rick.Docs.Samples.RouteInfo NuGet package and displays route information.

Test the preceding sample code by using one of the following approaches:

- Run the sample with `dotnet run` using the default URL of `https://localhost:5001`.

- Run the sample from Visual Studio with the port set to 44398 for a URL of `https://localhost:44398`.

Using a browser with the F12 tools:

- Select the **Values** button and review the headers in the **Network** tab.
- Select the **PUT test** button. See Display OPTIONS requests for instructions on displaying the OPTIONS request. The **PUT test** creates two requests, an OPTIONS preflight request and the PUT request.
- Select the **`GetValues2 [DisableCors]`** button to trigger a failed CORS request. As mentioned in the document, the response returns 200 success, but the CORS request is not made. Select the **Console** tab to see the CORS error. Depending on the browser, an error similar to the following is displayed:

  Access to fetch at `'https://cors1.azurewebsites.net/api/values/GetValues2'` from origin `'https://cors3.azurewebsites.net'` has been blocked by CORS policy: No 'Access-Control-Allow-Origin' header is present on the requested resource. If an opaque response serves your needs, set the request's mode to 'no-cors' to fetch the resource with CORS disabled.

CORS-enabled endpoints can be tested with a tool, such as curl or Fiddler. When using a tool, the origin of the request specified by the `Origin` header must differ from the host receiving the request. If the request isn't *cross-origin* based on the value of the `Origin` header:

- There's no need for CORS Middleware to process the request.
- CORS headers aren't returned in the response.

The following command uses `curl` to issue an OPTIONS request with information:

```
Bash

curl -X OPTIONS https://cors3.azurewebsites.net/api/TodoItems2/5 -i
```

Test CORS with [EnableCors] attribute and RequireCors method

Consider the following code which uses endpoint routing to enable CORS on a per-endpoint basis using `RequireCors`:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: "MyPolicy",
        policy =>
        {
            policy.WithOrigins("http://example.com",
                    "http://www.contoso.com",
                    "https://cors1.azurewebsites.net",
                    "https://cors3.azurewebsites.net",
                    "https://localhost:44398",
                    "https://localhost:5001")
                .WithMethods("PUT", "DELETE", "GET");
        });
});

builder.Services.AddControllers();
builder.Services.AddRazorPages();

var app = builder.Build();

app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseRouting();

app.UseCors();

app.UseAuthorization();

app.UseEndpoints(endpoints =>
{
    endpoints.MapGet("/echo",
        context => context.Response.WriteAsync("echo"))
        .RequireCors("MyPolicy");

    endpoints.MapControllers();
    endpoints.MapRazorPages();
});

app.Run();
```

Notice that only the `/echo` endpoint is using the `RequireCors` to allow cross-origin requests using the specified policy. The controllers below enable CORS using [EnableCors] attribute.

The following `TodoItems1Controller` provides endpoints for testing:

```
C#
```

```
[Route("api/[controller]")]
[ApiController]
public class TodoItems1Controller : ControllerBase
{
    // PUT: api/TodoItems1/5
    [HttpPut("{id}")]
    public IActionResult PutTodoItem(int id) {
        if (id < 1) {
            return Content($"ID = {id}");
        }

        return ControllerContext.MyDisplayRouteInfo(id);
    }

    // Delete: api/TodoItems1/5
    [HttpDelete("{id}")]
    public IActionResult MyDelete(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // GET: api/TodoItems1
    [HttpGet]
    public IActionResult GetTodoItems() =>
        ControllerContext.MyDisplayRouteInfo();

    [EnableCors("MyPolicy")]
    [HttpGet("{action}")]
    public IActionResult GetTodoItems2() =>
        ControllerContext.MyDisplayRouteInfo();

    // Delete: api/TodoItems1/MyDelete2/5
    [EnableCors("MyPolicy")]
    [HttpDelete("{action}/{id}")]
    public IActionResult MyDelete2(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);
}
```

The **Delete [EnableCors]** and **GET [EnableCors]** buttons succeed, because the endpoints have `[EnableCors]` and respond to preflight requests. The other endpoints fails. The **GET** button fails, because the JavaScript sends:

JavaScript

```
 headers: {
      "Content-Type": "x-custom-header"
 },
```

The following `TodoItems2Controller` provides similar endpoints, but includes explicit code to respond to OPTIONS requests:

C#

```
[Route("api/[controller]")]
[ApiController]
public class TodoItems2Controller : ControllerBase
{
    // OPTIONS: api/TodoItems2/5
    [HttpOptions("{id}")]
    public IActionResult PreflightRoute(int id)
    {
        return NoContent();
    }

    // OPTIONS: api/TodoItems2
    [HttpOptions]
    public IActionResult PreflightRoute()
    {
        return NoContent();
    }

    [HttpPut("{id}")]
    public IActionResult PutTodoItem(int id)
    {
        if (id < 1)
        {
            return BadRequest();
        }

        return ControllerContext.MyDisplayRouteInfo(id);
    }

    // [EnableCors] // Not needed as OPTIONS path provided.
    [HttpDelete("{id}")]
    public IActionResult MyDelete(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);

    // [EnableCors] //  Warning ASP0023 Route '{id}' conflicts with another
action route.
    //                  An HTTP request that matches multiple routes results
in an ambiguous
    //                  match error.
    [EnableCors("MyPolicy")] // Required for this path.
    [HttpGet]
    public IActionResult GetTodoItems() =>
        ControllerContext.MyDisplayRouteInfo();

    [HttpGet("{action}")]
    public IActionResult GetTodoItems2() =>
        ControllerContext.MyDisplayRouteInfo();

    [EnableCors("MyPolicy")]  // Required for this path.
    [HttpDelete("{action}/{id}")]
    public IActionResult MyDelete2(int id) =>
        ControllerContext.MyDisplayRouteInfo(id);
}
```

The preceding code can be tested by deploying the sample to Azure. In the **Controller** drop down list, select **Preflight** and then **Set Controller**. All the CORS calls to the `TodoItems2Controller` endpoints succeed.

Share authentication cookies among ASP.NET apps

Article • 06/17/2024

By Rick Anderson

Websites often consist of individual web apps working together. To provide a single sign-on (SSO) experience, web apps within a site must share authentication cookies. To support this scenario, the data protection stack allows sharing Katana cookie authentication and ASP.NET Core cookie authentication tickets.

In the examples that follow:

- The authentication cookie name is set to a common value of `.AspNet.SharedCookie`.
- The `AuthenticationType` is set to `Identity.Application` either explicitly or by default.
- A common app name, `SharedCookieApp`, is used to enable the data protection system to share data protection keys.
- `Identity.Application` is used as the authentication scheme. Whatever scheme is used, it must be used consistently *within and across* the shared cookie apps either as the default scheme or by explicitly setting it. The scheme is used when encrypting and decrypting cookies, so a consistent scheme must be used across apps.
- A common data protection key storage location is used.
  - In ASP.NET Core apps, PersistKeysToFileSystem is used to set the key storage location.
  - In .NET Framework apps, Cookie Authentication Middleware uses an implementation of DataProtectionProvider. `DataProtectionProvider` provides data protection services for the encryption and decryption of authentication cookie payload data. The `DataProtectionProvider` instance is isolated from the data protection system used by other parts of the app. DataProtectionProvider.Create(System.IO.DirectoryInfo, Action<IDataProtectionBuilder>) accepts a DirectoryInfo to specify the location for data protection key storage.
- `DataProtectionProvider` requires the Microsoft.AspNetCore.DataProtection.Extensions NuGet package:
  - In .NET Framework apps, add a package reference to Microsoft.AspNetCore.DataProtection.Extensions.

- SetApplicationName sets the common app name.

Share authentication cookies with ASP.NET Core Identity

When using ASP.NET Core Identity:

- Data protection keys and the app name must be shared among apps. A common key storage location is provided to the PersistKeysToFileSystem method in the following examples. Use SetApplicationName to configure a common shared app name (`SharedCookieApp` in the following examples). For more information, see Configure ASP.NET Core Data Protection.
- Use the ConfigureApplicationCookie extension method to set up the data protection service for cookies.
- The default authentication type is `Identity.Application`.

In `Program.cs`:

C#

```
using Microsoft.AspNetCore.DataProtection;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDataProtection()
    .PersistKeysToFileSystem(new DirectoryInfo(@"c:\PATH TO COMMON KEY RING
FOLDER"))
    .SetApplicationName("SharedCookieApp");

builder.Services.ConfigureApplicationCookie(options => {
    options.Cookie.Name = ".AspNet.SharedCookie";
});

var app = builder.Build();
```

Note: The preceding instructions don't work with `ITicketStore` (`CookieAuthenticationOptions.SessionStore`). For more information, see this GitHub issue.

For security reasons, authentication cookies are not compressed in ASP.NET Core. When using authentication cookies, developers should minimize the number of claim information included to just that necessary for their needs.

Share authentication cookies without ASP.NET Core Identity

When using cookies directly without ASP.NET Core Identity, configure data protection and authentication. In the following example, the authentication type is set to `Identity.Application`:

C#

```
using Microsoft.AspNetCore.DataProtection;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDataProtection()
    .PersistKeysToFileSystem(new DirectoryInfo(@"c:\PATH TO COMMON KEY RING
FOLDER"))
    .SetApplicationName("SharedCookieApp");

builder.Services.AddAuthentication("Identity.Application")
    .AddCookie("Identity.Application", options =>
    {
        options.Cookie.Name = ".AspNet.SharedCookie";
    });

var app = builder.Build();
```

For security reasons, authentication cookies are not compressed in ASP.NET Core. When using authentication cookies, developers should minimize the number of claim information included to just that necessary for their needs.

Share cookies across different base paths

An authentication cookie uses the HttpRequest.PathBase as its default Cookie.Path. If the app's cookie must be shared across different base paths, `Path` must be overridden:

C#

```
using Microsoft.AspNetCore.DataProtection;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
```

```
builder.Services.AddDataProtection()
    .PersistKeysToFileSystem(new DirectoryInfo(@"c:\PATH TO COMMON KEY RING
FOLDER"))
    .SetApplicationName("SharedCookieApp");

builder.Services.ConfigureApplicationCookie(options => {
    options.Cookie.Name = ".AspNet.SharedCookie";
    options.Cookie.Path = "/";
});
var app = builder.Build();
```

Share cookies across subdomains

When hosting apps that share cookies across subdomains, specify a common domain in the Cookie.Domain property. To share cookies across apps at `contoso.com`, such as `first_subdomain.contoso.com` and `second_subdomain.contoso.com`, specify the `Cookie.Domain` as `.contoso.com`:

C#

```
options.Cookie.Domain = ".contoso.com";
```

Encrypt data protection keys at rest

For production deployments, configure the `DataProtectionProvider` to encrypt keys at rest with DPAPI or an X509Certificate. For more information, see Key encryption at rest in Windows and Azure using ASP.NET Core. In the following example, a certificate thumbprint is provided to ProtectKeysWithCertificate:

C#

```
using Microsoft.AspNetCore.DataProtection;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDataProtection()
    .ProtectKeysWithCertificate("{CERTIFICATE THUMBPRINT}");
```

Use a common user database

When apps use the same Identity schema (same version of Identity), confirm that the Identity system for each app is pointed at the same user database. Otherwise, the identity system produces failures at runtime when it attempts to match the information in the authentication cookie against the information in its database.

When the Identity schema is different among apps, usually because apps are using different Identity versions, sharing a common database based on the latest version of Identity isn't possible without remapping and adding columns in other app's Identity schemas. It's often more efficient to upgrade the other apps to use the latest Identity version so that a common database can be shared by the apps.

Application name change

In .NET 6, WebApplicationBuilder normalizes the content root path to end with a DirectorySeparatorChar. Most apps migrating from HostBuilder or WebHostBuilder won't have the same app name because they aren't normalized. For more information, see SetApplicationName

Share authentication cookies between ASP.NET 4.x and ASP.NET Core apps

ASP.NET 4.x apps that use Microsoft.Owin Cookie Authentication Middleware can be configured to generate authentication cookies that are compatible with the ASP.NET Core Cookie Authentication Middleware. This can be useful if a web application consists of both ASP.NET 4.x apps and ASP.NET Core apps that must share a single sign-on experience. A specific example of such a scenario is incrementally migrating a web app from ASP.NET to ASP.NET Core. In such scenarios, it's common for some parts of an app to be served by the original ASP.NET app while others are served by the new ASP.NET Core app. Users should only have to sign in once, though. This can be accomplished by either of the following approaches:

- Using the System.Web adapters' remote authentication feature, which uses the ASP.NET app to sign users in.
- Configuring the ASP.NET app to use Microsoft.Owin Cookie Authentication Middleware so that authentication cookies are shared with the ASP.NET Core app.

To configure ASP.NET Microsoft.Owin Cookie Authentication Middleware to share cookies with an ASP.NET Core app, follow the preceding instructions to configure the ASP.NET Core app to use a specific cookie name, app name, and to persist data protection keys to a well-known location. See Configure ASP.NET Core Data Protection for more information on persisting data protection keys.

In the ASP.NET app, install the Microsoft.Owin.Security.Interop package.

Update the `UseCookieAuthentication` call in Startup.Auth.cs to configure an AspNetTicketDataFormat to match the ASP.NET Core app's settings:

C#

```
app.UseCookieAuthentication(new CookieAuthenticationOptions
{
    LoginPath = new PathString("/Account/Login"),
    Provider = new CookieAuthenticationProvider
    {
        OnValidateIdentity =
SecurityStampValidator.OnValidateIdentity<ApplicationUserManager,
ApplicationUser>(
            validateInterval: TimeSpan.FromMinutes(30),
            regenerateIdentity: (manager, user) =>
user.GenerateUserIdentityAsync(manager))
    },

    // Settings to configure shared cookie with ASP.NET Core app
    CookieName = ".AspNet.ApplicationCookie",
    AuthenticationType = "Identity.Application",
    TicketDataFormat = new AspNetTicketDataFormat(
        new DataProtectorShim(
            DataProtectionProvider.Create(new DirectoryInfo(@"c:\PATH TO
COMMON KEY RING FOLDER"),
            builder => builder.SetApplicationName("SharedCookieApp"))
            .CreateProtector(

"Microsoft.AspNetCore.Authentication.Cookies.CookieAuthenticationMiddleware"
,
                // Must match the Scheme name used in the ASP.NET Core app,
i.e. IdentityConstants.ApplicationScheme
                "Identity.Application",
                "v2"))),
    CookieManager = new ChunkingCookieManager()
});
```

Important items configured here include:

- The cookie name is set to the same name as in the ASP.NET Core app.
- A data protection provider is created using the same key ring path. Note that in these examples, data protection keys are stored on disk but other data protection providers can be used. For example, Redis or Azure Blob Storage can be used for data protection providers as long as the configuration matches between the apps. See Configure ASP.NET Core Data Protection for more information on persisting data protection keys.

- The app name is set to be the same as the app name used in the ASP.NET Core app.
- The authentication type is set to the name of the authentication scheme in the ASP.NET Core app.
- `System.Web.Helpers.AntiForgeryConfig.UniqueClaimTypeIdentifier` is set to a claim from the ASP.NET Core identity that will be unique to a user.

Because the authentication type was changed to match the authentication scheme of the ASP.NET Core app, it's also necessary to update how the ASP.NET app generates new identities to use that same name. This is typically done in `Models/IdentityModels.cs`:

C#

```
public class ApplicationUser : IdentityUser
{
    public async Task<ClaimsIdentity>
GenerateUserIdentityAsync(UserManager<ApplicationUser> manager)
    {
        // Note the authenticationType must match the one defined in
CookieAuthenticationOptions.AuthenticationType
        var userIdentity = await manager.CreateIdentityAsync(this,
"Identity.Application");

        // Add custom user claims here
        return userIdentity;
    }
}
```

With these changes, the ASP.NET and ASP.NET Core apps are able to use the same authentication cookies so that users signing in or out of one app are reflected in the other app.

Note that because there are differences between ASP.NET Identity and ASP.NET Core Identity's database schemas, it is recommended that users only *sign-in* using one of the apps - either the ASP.NET or ASP.NET Core app. Once users are signed in, the steps documented in this section will allow the authentication cookie to be *used* by either app and both apps should be able to log users out.

Work with SameSite cookies in ASP.NET Core

Article • 06/17/2024

By Rick Anderson

SameSite is an IETF draft standard designed to provide some protection against cross-site request forgery (CSRF) attacks. Originally drafted in 2016, the draft standard was updated in 2019. The updated standard is not backward compatible with the previous standard, with the following being the most noticeable differences:

- Cookies without SameSite header are treated as `SameSite=Lax` by default.
- `SameSite=None` must be used to allow cross-site cookie use.
- Cookies that assert `SameSite=None` must also be marked as `Secure`.
- Applications that use <iframe> may experience issues with `sameSite=Lax` or `sameSite=Strict` cookies because `<iframe>` is treated as cross-site scenarios.
- The value `SameSite=None` is not allowed by the 2016 standard and causes some implementations to treat such cookies as `SameSite=Strict`. See Supporting older browsers in this document.

The `SameSite=Lax` setting works for most application cookies. Some forms of authentication like OpenID Connect (OIDC) and WS-Federation default to POST based redirects. The POST based redirects trigger the SameSite browser protections, so SameSite is disabled for these components. Most OAuth logins are not affected due to differences in how the request flows.

Each ASP.NET Core component that emits cookies needs to decide if SameSite is appropriate.

SameSite and Identity

ASP.NET Core Identity is largely unaffected by SameSite cookies except for advanced scenarios like `IFrames` or `OpenIdConnect` integration.

When using `Identity`, do ***not*** add any cookie providers or call `services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)`, `Identity` takes care of that.

SameSite test sample code

The following sample can be downloaded and tested:

Expand table

Sample	Document
.NET Core Razor Pages	ASP.NET Core 3.1 Razor Pages SameSite cookie sample

.NET Core support for the sameSite attribute

.NET Core supports the 2019 draft standard for SameSite. Developers are able to programmatically control the value of the sameSite attribute using the `HttpCookie.SameSite` property. Setting the `SameSite` property to `Strict`, `Lax`, or `None` results in those values being written on the network with the cookie. Setting to `SameSiteMode.Unspecified` indicates no sameSite should be sent with the cookie.

C#

```
    var cookieOptions = new CookieOptions
    {
        // Set the secure flag, which Chrome's changes will require for
SameSite none.
        // Note this will also require you to be running on HTTPS.
        Secure = true,

        // Set the cookie to HTTP only which is good practice unless you
really do need
        // to access it client side in scripts.
        HttpOnly = true,

        // Add the SameSite attribute, this will emit the attribute with a
value of none.
        SameSite = SameSiteMode.None

        // The client should follow its default cookie policy.
        // SameSite = SameSiteMode.Unspecified
    };

    // Add the cookie to the response cookie collection
    Response.Cookies.Append("MyCookie", "cookieValue", cookieOptions);
}
```

API usage with SameSite

HttpContext.Response.Cookies.Append defaults to `Unspecified`, meaning no SameSite attribute added to the cookie and the client will use its default behavior (Lax for new

browsers, None for old ones). The following code shows how to change the cookie SameSite value to `SameSiteMode.Lax`:

```
C#

HttpContext.Response.Cookies.Append(
                    "name", "value",
                    new CookieOptions() { SameSite = SameSiteMode.Lax });
```

All ASP.NET Core components that emit cookies override the preceding defaults with settings appropriate for their scenarios. The overridden preceding default values haven't changed.

Expand table

Component	cookie	Default
CookieBuilder	SameSite	`Unspecified`
Session	SessionOptions.Cookie	`Lax`
CookieTempDataProvider	CookieTempDataProviderOptions.Cookie	`Lax`
IAntiforgery	AntiforgeryOptions.Cookie	`Strict`
Cookie Authentication	CookieAuthenticationOptions.Cookie	`Lax`
AddTwitter	TwitterOptions.StateCookie	`Lax`
RemoteAuthenticationHandler<TOptions>	RemoteAuthenticationOptions.CorrelationCookie	`None`
AddOpenIdConnect	OpenIdConnectOptions.NonceCookie	`None`
HttpContext.Response.Cookies.Append	CookieOptions	`Unspecified`

ASP.NET Core 3.1 and later provides the following SameSite support:

- Redefines the behavior of `SameSiteMode.None` to emit `SameSite=None`
- Adds a new value `SameSiteMode.Unspecified` to omit the SameSite attribute.
- All cookies APIs default to `Unspecified`. Some components that use cookies set values more specific to their scenarios. See the table above for examples.

In ASP.NET Core 3.0 and later the SameSite defaults were changed to avoid conflicting with inconsistent client defaults. The following APIs have changed the default from `SameSiteMode.Lax` to `-1` to avoid emitting a SameSite attribute for these cookies:

- CookieOptions used with HttpContext.Response.Cookies.Append
- CookieBuilder used as a factory for `CookieOptions`

- CookiePolicyOptions.MinimumSameSitePolicy

History and changes

SameSite support was first implemented in ASP.NET Core in 2.0 using the 2016 draft standard. The 2016 standard was opt-in. ASP.NET Core opted-in by setting several cookies to `Lax` by default. After encountering several issues with authentication, most SameSite usage was disabled.

Patches were issued in November 2019 to update from the 2016 standard to the 2019 standard. The 2019 draft of the SameSite specification:

- Is **not** backwards compatible with the 2016 draft. For more information, see Supporting older browsers in this document.
- Specifies cookies are treated as `SameSite=Lax` by default.
- Specifies cookies that explicitly assert `SameSite=None` in order to enable cross-site delivery should be marked as `Secure`. `None` is a new entry to opt out.
- Is supported by patches issued for ASP.NET Core 2.1, 2.2, and 3.0. ASP.NET Core 3.1 and later has additional SameSite support.
- Is scheduled to be enabled by Chrome by default in Feb 2020. Browsers started moving to this standard in 2019.

APIs impacted by the change from the 2016 SameSite draft standard to the 2019 draft standard

- Http.SameSiteMode
- CookieOptions.SameSite
- CookieBuilder.SameSite
- CookiePolicyOptions.MinimumSameSitePolicy
- Microsoft.Net.Http.Headers.SameSiteMode
- Microsoft.Net.Http.Headers.SetCookieHeaderValue.SameSite

Supporting older browsers

The 2016 SameSite standard mandated that unknown values must be treated as `SameSite=Strict` values. Apps accessed from older browsers which support the 2016 SameSite standard may break when they get a SameSite property with a value of `None`. Web apps must implement browser detection if they intend to support older browsers. ASP.NET Core doesn't implement browser detection because User-Agents values are highly

volatile and change frequently. An extension point in Microsoft.AspNetCore.CookiePolicy allows plugging in User-Agent specific logic.

In `Program.cs`, add code that calls UseCookiePolicy before calling UseAuthentication or *any* method that writes cookies:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.Configure<CookiePolicyOptions>(options =>
{
    options.MinimumSameSitePolicy = SameSiteMode.Unspecified;
    options.OnAppendCookie = cookieContext =>
        CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
    options.OnDeleteCookie = cookieContext =>
        CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
});

void CheckSameSite(HttpContext httpContext, CookieOptions options)
{
    if (options.SameSite == SameSiteMode.None)
    {
        var userAgent = httpContext.Request.Headers["User-Agent"].ToString();
        if (MyUserAgentDetectionLib.DisallowsSameSiteNone(userAgent))
        {
            options.SameSite = SameSiteMode.Unspecified;
        }
    }
}

    builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseCookiePolicy();
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

In `Program.cs`, add code similar to the following highlighted code:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.Configure<CookiePolicyOptions>(options =>
{
    options.MinimumSameSitePolicy = SameSiteMode.Unspecified;
    options.OnAppendCookie = cookieContext =>
        CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
    options.OnDeleteCookie = cookieContext =>
        CheckSameSite(cookieContext.Context, cookieContext.CookieOptions);
});

void CheckSameSite(HttpContext httpContext, CookieOptions options)
{
    if (options.SameSite == SameSiteMode.None)
    {
        var userAgent = httpContext.Request.Headers["User-Agent"].ToString();
        if (MyUserAgentDetectionLib.DisallowsSameSiteNone(userAgent))
        {
            options.SameSite = SameSiteMode.Unspecified;
        }
    }
}

    builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseCookiePolicy();
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

In the preceding sample, `MyUserAgentDetectionLib.DisallowsSameSiteNone` is a user supplied library that detects if the user agent doesn't support SameSite `None`:

C#

```
if (MyUserAgentDetectionLib.DisallowsSameSiteNone(userAgent))
{
    options.SameSite = SameSiteMode.Unspecified;
}
```

The following code shows a sample `DisallowsSameSiteNone` method:

> ⚠ **Warning**
>
> The following code is for demonstration only:
>
> - It should not be considered complete.
> - It is not maintained or supported.

C#

```
public static bool DisallowsSameSiteNone(string userAgent)
{
    // Check if a null or empty string has been passed in, since this
    // will cause further interrogation of the useragent to fail.
     if (String.IsNullOrWhiteSpace(userAgent))
        return false;

    // Cover all iOS based browsers here. This includes:
    // - Safari on iOS 12 for iPhone, iPod Touch, iPad
    // - WkWebview on iOS 12 for iPhone, iPod Touch, iPad
    // - Chrome on iOS 12 for iPhone, iPod Touch, iPad
    // All of which are broken by SameSite=None, because they use the iOS
networking
    // stack.
    if (userAgent.Contains("CPU iPhone OS 12") ||
        userAgent.Contains("iPad; CPU OS 12"))
    {
        return true;
    }

    // Cover Mac OS X based browsers that use the Mac OS networking stack.
    // This includes:
    // - Safari on Mac OS X.
    // This does not include:
    // - Chrome on Mac OS X
    // Because they do not use the Mac OS networking stack.
    if (userAgent.Contains("Macintosh; Intel Mac OS X 10_14") &&
        userAgent.Contains("Version/") && userAgent.Contains("Safari"))
    {
        return true;
    }

    // Cover Chrome 50-69, because some versions are broken by SameSite=None,
```

```
    // and none in this range require it.
    // Note: this covers some pre-Chromium Edge versions,
    // but pre-Chromium Edge does not require SameSite=None.
    if (userAgent.Contains("Chrome/5") || userAgent.Contains("Chrome/6"))
    {
        return true;
    }

    return false;
}
```

Test apps for SameSite problems

Apps that interact with remote sites such as through third-party login need to:

- Test the interaction on multiple browsers.
- Apply the CookiePolicy browser detection and mitigation discussed in this document.

Test web apps using a client version that can opt-in to the new SameSite behavior. Chrome, Firefox, and Chromium Edge all have new opt-in feature flags that can be used for testing. After your app applies the SameSite patches, test it with older client versions, especially Safari. For more information, see Supporting older browsers in this document.

Test with Chrome

Chrome 78+ gives misleading results because it has a temporary mitigation in place. The Chrome 78+ temporary mitigation allows cookies less than two minutes old. Chrome 76 or 77 with the appropriate test flags enabled provides more accurate results. To test the new SameSite behavior toggle `chrome://flags/#same-site-by-default-cookies` to **Enabled**. Older versions of Chrome (75 and below) are reported to fail with the new `None` setting. See Supporting older browsers in this document.

Google does not make older chrome versions available. Follow the instructions at Download Chromium to test older versions of Chrome. Do **not** download Chrome from links provided by searching for older versions of chrome.

- Chromium 76 Win64
- Chromium 74 Win64

Starting in Canary version `80.0.3975.0`, the Lax+POST temporary mitigation can be disabled for testing purposes using the new flag `--enable-features=SameSiteDefaultChecksMethodRigorously` to allow testing of sites and services in the eventual end state of the feature where the mitigation has been removed. For more information, see The Chromium Projects SameSite Updates

Test with Safari

Safari 12 strictly implemented the prior draft and fails when the new `None` value is in a cookie. `None` is avoided via the browser detection code Supporting older browsers in this document. Test Safari 12, Safari 13, and WebKit based OS style logins using MSAL, ADAL or whatever library you are using. The problem is dependent on the underlying OS version. OSX Mojave (10.14) and iOS 12 are known to have compatibility problems with the new SameSite behavior. Upgrading the OS to OSX Catalina (10.15) or iOS 13 fixes the problem. Safari does not currently have an opt-in flag for testing the new spec behavior.

Test with Firefox

Firefox support for the new standard can be tested on version 68+ by opting in on the `about:config` page with the feature flag `network.cookie.sameSite.laxByDefault`. There haven't been reports of compatibility issues with older versions of Firefox.

Test with Edge browser

Edge supports the old SameSite standard. Edge version 44 doesn't have any known compatibility problems with the new standard.

Test with Edge (Chromium)

SameSite flags are set on the `edge://flags/#same-site-by-default-cookies` page. No compatibility issues were discovered with Edge Chromium.

Test with Electron

Versions of Electron include older versions of Chromium. For example, the version of Electron used by Teams is Chromium 66, which exhibits the older behavior. You must perform your own compatibility testing with the version of Electron your product uses. See Supporting older browsers in the following section.

Client IP safelist for ASP.NET Core

Article • 10/25/2024

By Damien Bowden and Tom Dykstra

This article shows three ways to implement an IP address safelist (also known as an allow list) in an ASP.NET Core app. An accompanying sample app demonstrates all three approaches. You can use:

- Middleware to check the remote IP address of every request.
- MVC action filters to check the remote IP address of requests for specific controllers or action methods.
- Razor Pages filters to check the remote IP address of requests for Razor pages.

In each case, a string containing approved client IP addresses is stored in an app setting. The middleware or filter:

- Parses the string into an array.
- Checks if the remote IP address exists in the array.

Access is allowed if the array contains the IP address. Otherwise, an HTTP 403 Forbidden status code is returned.

View or download sample code (how to download)

IP address safelist

In the sample app, the IP address safelist is:

- Defined by the `AdminSafeList` property in the `appsettings.json` file.
- A semicolon-delimited string that may contain both Internet Protocol version 4 (IPv4) and Internet Protocol version 6 (IPv6) addresses.

JSON

```
{
  "AdminSafeList": "127.0.0.1;192.168.1.5;::1",
  "Logging": {
```

In the preceding example, the IPv4 addresses of `127.0.0.1` and `192.168.1.5` and the IPv6 loopback address of `::1` (compressed format for `0:0:0:0:0:0:0:1`) are allowed.

Middleware

The `Startup.Configure` method adds the custom `AdminSafeListMiddleware` middleware type to the app's request pipeline. The safelist is retrieved with the .NET Core configuration provider and is passed as a constructor parameter.

C#

```
app.UseMiddleware<AdminSafeListMiddleware>(Configuration["AdminSafeList"]);
```

The middleware parses the string into an array and searches for the remote IP address in the array. If the remote IP address isn't found, the middleware returns HTTP 403 Forbidden. This validation process is bypassed for HTTP GET requests.

C#

```
public class AdminSafeListMiddleware
{
    private readonly RequestDelegate _next;
    private readonly ILogger<AdminSafeListMiddleware> _logger;
    private readonly byte[][] _safelist;

    public AdminSafeListMiddleware(
        RequestDelegate next,
        ILogger<AdminSafeListMiddleware> logger,
        string safelist)
    {
        var ips = safelist.Split(';');
        _safelist = new byte[ips.Length][];
        for (var i = 0; i < ips.Length; i++)
        {
            _safelist[i] = IPAddress.Parse(ips[i]).GetAddressBytes();
        }

        _next = next;
        _logger = logger;
    }

    public async Task Invoke(HttpContext context)
    {
        if (context.Request.Method != HttpMethod.Get.Method)
        {
            var remoteIp = context.Connection.RemoteIpAddress;
            _logger.LogDebug("Request from Remote IP address: {RemoteIp}",
remoteIp);

            var bytes = remoteIp.GetAddressBytes();
            var badIp = true;
            foreach (var address in _safelist)
            {
```

```
                if (address.SequenceEqual(bytes))
                {
                    badIp = false;
                    break;
                }
            }

            if (badIp)
            {
                _logger.LogWarning(
                    "Forbidden Request from Remote IP address: {RemoteIp}",
remoteIp);
                context.Response.StatusCode = (int)
HttpStatusCode.Forbidden;
                return;
            }
        }

        await _next.Invoke(context);
    }
}
```

Action filter

If you want safelist-driven access control for specific MVC controllers or action methods, use an action filter. For example:

C#

```
public class ClientIpCheckActionFilter : ActionFilterAttribute
{
    private readonly ILogger _logger;
    private readonly string _safelist;

    public ClientIpCheckActionFilter(string safelist, ILogger logger)
    {
        _safelist = safelist;
        _logger = logger;
    }

    public override void OnActionExecuting(ActionExecutingContext context)
    {
        var remoteIp = context.HttpContext.Connection.RemoteIpAddress;
        _logger.LogDebug("Remote IpAddress: {RemoteIp}", remoteIp);
        var ip = _safelist.Split(';');
        var badIp = true;

        if (remoteIp.IsIPv4MappedToIPv6)
        {
            remoteIp = remoteIp.MapToIPv4();
        }
```

```
        foreach (var address in ip)
        {
            var testIp = IPAddress.Parse(address);

            if (testIp.Equals(remoteIp))
            {
                badIp = false;
                break;
            }
        }

        if (badIp)
        {
            _logger.LogWarning("Forbidden Request from IP: {RemoteIp}",
remoteIp);
            context.Result = new
StatusCodeResult(StatusCodes.Status403Forbidden);
            return;
        }

        base.OnActionExecuting(context);
    }
}
```

In `Startup.ConfigureServices`, add the action filter to the MVC filters collection. In the following example, a `ClientIpCheckActionFilter` action filter is added. A safelist and a console logger instance are passed as constructor parameters.

C#

```
services.AddScoped<ClientIpCheckActionFilter>(container =>
{
    var loggerFactory = container.GetRequiredService<ILoggerFactory>();
    var logger = loggerFactory.CreateLogger<ClientIpCheckActionFilter>();

    return new ClientIpCheckActionFilter(
        Configuration["AdminSafeList"], logger);
});
```

The action filter can then be applied to a controller or action method with the [ServiceFilter] attribute:

C#

```
[ServiceFilter(typeof(ClientIpCheckActionFilter))]
[HttpGet]
public IEnumerable<string> Get()
```

In the sample app, the action filter is applied to the controller's `Get` action method. When you test the app by sending:

- An HTTP GET request, the `[ServiceFilter]` attribute validates the client IP address. If access is allowed to the `Get` action method, a variation of the following console output is produced by the action filter and action method:

```
dbug: ClientIpSafelistComponents.Filters.ClientIpCheckActionFilter[0]
      Remote IpAddress: ::1
dbug: ClientIpAspNetCore.Controllers.ValuesController[0]
      successful HTTP GET
```

- An HTTP request verb other than GET, the `AdminSafeListMiddleware` middleware validates the client IP address.

Razor Pages filter

If you want safelist-driven access control for a Razor Pages app, use a Razor Pages filter. For example:

C#

```
public class ClientIpCheckPageFilter : IPageFilter
{
    private readonly ILogger _logger;
    private readonly IPAddress[] _safelist;

    public ClientIpCheckPageFilter(
        string safelist,
        ILogger logger)
    {
        var ips = safelist.Split(';');
        _safelist = new IPAddress[ips.Length];
        for (var i = 0; i < ips.Length; i++)
        {
            _safelist[i] = IPAddress.Parse(ips[i]);
        }

        _logger = logger;
    }

    public void OnPageHandlerExecuting(PageHandlerExecutingContext context)
    {
        var remoteIp = context.HttpContext.Connection.RemoteIpAddress;
        if (remoteIp.IsIPv4MappedToIPv6)
        {
```

```
            remoteIp = remoteIp.MapToIPv4();
        }
        _logger.LogDebug(
            "Remote IpAddress: {RemoteIp}", remoteIp);

        var badIp = true;
        foreach (var testIp in _safelist)
        {
            if (testIp.Equals(remoteIp))
            {
                badIp = false;
                break;
            }
        }

        if (badIp)
        {
            _logger.LogWarning(
                "Forbidden Request from Remote IP address: {RemoteIp}",
remoteIp);
            context.Result = new
StatusCodeResult(StatusCodes.Status403Forbidden);
            return;
        }
    }

    public void OnPageHandlerExecuted(PageHandlerExecutedContext context)
    {
    }

    public void OnPageHandlerSelected(PageHandlerSelectedContext context)
    {
    }
}
```

In `Startup.ConfigureServices`, enable the Razor Pages filter by adding it to the MVC filters collection. In the following example, a `ClientIpCheckPageFilter` Razor Pages filter is added. A safelist and a console logger instance are passed as constructor parameters.

C#

```
services.AddRazorPages()
    .AddMvcOptions(options =>
    {
        var logger = LoggerFactory.Create(builder => builder.AddConsole())
                        .CreateLogger<ClientIpCheckPageFilter>();
        var filter = new ClientIpCheckPageFilter(
            Configuration["AdminSafeList"], logger);

        options.Filters.Add(filter);
    });
```

When the sample app's *Index* Razor page is requested, the Razor Pages filter validates the client IP address. The filter produces a variation of the following console output:

```
dbug: ClientIpSafelistComponents.Filters.ClientIpCheckPageFilter[0]
      Remote IpAddress: ::1
```

By Rick Anderson and Tom Dykstra

In-memory caching

In-memory caching uses server memory to store cached data. This type of caching is suitable for a single server or multiple servers using session affinity. Session affinity is also known as *sticky sessions*. Session affinity means that the requests from a client are always routed to the same server for processing.

For more information, see Cache in-memory in ASP.NET Core and Troubleshoot Azure Application Gateway session affinity issues.

Distributed Cache

Use a distributed cache to store data when the app is hosted in a cloud or server farm. The cache is shared across the servers that process requests. A client can submit a request that's handled by any server in the group if cached data for the client is available. ASP.NET Core works with SQL Server, Redis, and NCache distributed caches.

For more information, see Distributed caching in ASP.NET Core.

HybridCache

The HybridCache API bridges some gaps in the IDistributedCache and IMemoryCache APIs. `HybridCache` is an abstract class wth a default implementation that handles most aspects of saving to cache and retrieving from cache.

Features

`HybridCache` has the following features that the other APIs don't have:

- A unified API for both in-process and out-of-process caching.

  `HybridCache` is designed to be a drop-in replacement for existing `IDistributedCache` and `IMemoryCache` usage, and it provides a simple API for adding new caching code. If the app has an `IDistributedCache` implementation, the `HybridCache` service uses it for secondary caching. This two-level caching strategy allows `HybridCache` to provide the speed of an in-memory cache and the durability of a distributed or persistent cache.

- Stampede protection.

  Cache stampede happens when a frequently used cache entry is revoked, and too many requests try to repopulate the same cache entry at the same time. `HybridCache` combines concurrent operations, ensuring that all requests for a given response wait for the first request to populate the cache.

- Configurable serialization.

  Serialization is configured as part of registering the service, with support for type-specific and generalized serializers via the `WithSerializer` and `WithSerializerFactory` methods, chained from the `AddHybridCache` call. By default, the service handles `string` and `byte[]` internally, and uses `System.Text.Json` for everything else. It can be configured for other types of serializers, such as protobuf or XML.

To see the relative simplicity of the `HybridCache` API, compare code that uses it to code that uses `IDistributedCache`. Here's an example of what using `IDistributedCache` looks like:

C#

```
public class SomeService(IDistributedCache cache)
{
    public async Task<SomeInformation> GetSomeInformationAsync
        (string name, int id, CancellationToken token = default)
    {
        var key = $"someinfo:{name}:{id}"; // Unique key for this
combination.
        var bytes = await cache.GetAsync(key, token); // Try to get from
cache.
        SomeInformation info;
        if (bytes is null)
```

```
        {
            // Cache miss; get the data from the real source.
            info = await SomeExpensiveOperationAsync(name, id, token);

            // Serialize and cache it.
            bytes = SomeSerializer.Serialize(info);
            await cache.SetAsync(key, bytes, token);
        }
        else
        {
            // Cache hit; deserialize it.
            info = SomeSerializer.Deserialize<SomeInformation>(bytes);
        }
        return info;
    }

    // This is the work we're trying to cache.
    private async Task<SomeInformation> SomeExpensiveOperationAsync(string
name, int id,
        CancellationToken token = default)
    { /* ... */ }
}
```

That's a lot of work to get right each time, including things like serialization. And in the "cache miss" scenario, you could end up with multiple concurrent threads, all getting a cache miss, all fetching the underlying data, all serializing it, and all sending that data to the cache.

Here's equivalent code using `HybridCache`:

C#

```
public class SomeService(HybridCache cache)
{
    public async Task<SomeInformation> GetSomeInformationAsync
        (string name, int id, CancellationToken token = default)
    {
        return await cache.GetOrCreateAsync(
            $"someinfo:{name}:{id}", // Unique key for this entry.
            async cancel => await SomeExpensiveOperationAsync(name, id,
cancel),
            token: token
        );
    }
}
```

The code is simpler and the library provides stampede protection and other features that `IDistributedCache` doesn't.

Compatibility

The library supports older .NET runtimes, down to .NET Framework 4.7.2 and .NET Standard 2.0.

Additional resources

For more information, see the following resources:

- HybridCache library in ASP.NET Core
- GitHub issue dotnet/aspnetcore #54647
- HybridCache source code

Response caching

The Response caching middleware:

- Enables caching server responses based on HTTP cache headers. Implements the standard HTTP caching semantics. Caches based on HTTP cache headers like proxies do.
- Is typically not beneficial for UI apps such as Razor Pages because browsers generally set request headers that prevent caching. Output caching, which is available in ASP.NET Core 7.0 and later, benefits UI apps. With output caching, configuration decides what should be cached independently of HTTP headers.
- May be beneficial for public GET or HEAD API requests from clients where the Conditions for caching are met.

To test response caching, use Fiddler, or another tool that can explicitly set request headers. Setting headers explicitly is preferred for testing caching. For more information, see Troubleshooting.

For more information, see Response caching in ASP.NET Core.

Output caching

The output caching middleware enables caching of HTTP responses. Output caching differs from response caching in the following ways:

- The caching behavior is configurable on the server.

  Response caching behavior is defined by HTTP headers. For example, when you visit a website with Chrome or Edge, the browser automatically sends a `Cache-`

`control: max-age=0` header. This header effectively disables response caching, since the server follows the directions provided by the client. A new response is returned for every request, even if the server has a fresh cached response. With output caching the client doesn't override the caching behavior that you configure on the server.

- The cache storage medium is extensible.

  Memory is used by default. Response caching is limited to memory.

- You can programmatically invalidate selected cache entries.

  Response caching's dependence on HTTP headers leaves you with few options for invalidating cache entries.

- Resource locking mitigates the risk of cache stampede and thundering herd.

  Cache stampede happens when a frequently used cache entry is revoked, and too many requests try to repopulate the same cache entry at the same time. *Thundering herd* is similar: a burst of requests for the same response that isn't already in a cache entry. Resource locking ensures that all requests for a given response wait for the first request to populate the cache. Response caching doesn't have a resource locking feature.

- Cache revalidation minimizes bandwidth usage.

  Cache revalidation means the server can return a `304 Not Modified` HTTP status code instead of a cached response body. This status code informs the client that the response to the request is unchanged from what was previously received. Response caching doesn't do cache revalidation.

For more information, see Output caching middleware in ASP.NET Core.

Cache Tag Helper

Cache the content from an MVC view or Razor Page with the Cache Tag Helper. The Cache Tag Helper uses in-memory caching to store data.

For more information, see Cache Tag Helper in ASP.NET Core MVC.

Distributed Cache Tag Helper

Cache the content from an MVC view or Razor Page in distributed cloud or web farm scenarios with the Distributed Cache Tag Helper. The Distributed Cache Tag Helper uses SQL Server, Redis, or NCache to store data.

For more information, see Distributed Cache Tag Helper in ASP.NET Core.

Cache in-memory in ASP.NET Core

Article • 04/23/2024

By Rick Anderson, John Luo, and Steve Smith

Caching can significantly improve the performance and scalability of an app by reducing the work required to generate content. Caching works best with data that changes infrequently **and** is expensive to generate. Caching makes a copy of data that can be returned much faster than from the source. Apps should be written and tested to **never** depend on cached data.

ASP.NET Core supports several different caches. The simplest cache is based on the IMemoryCache. `IMemoryCache` represents a cache stored in the memory of the web server. Apps running on a server farm (multiple servers) should ensure sessions are sticky when using the in-memory cache. Sticky sessions ensure that requests from a client all go to the same server. For example, Azure Web apps use Application Request Routing (ARR) to route all requests to the same server.

Non-sticky sessions in a web farm require a distributed cache to avoid cache consistency problems. For some apps, a distributed cache can support higher scale-out than an in-memory cache. Using a distributed cache offloads the cache memory to an external process.

The in-memory cache can store any object. The distributed cache interface is limited to `byte[]`. The in-memory and distributed cache store cache items as key-value pairs.

System.Runtime.Caching/MemoryCache

System.Runtime.Caching/MemoryCache (NuGet package) can be used with:

- .NET Standard 2.0 or later.
- Any .NET implementation that targets .NET Standard 2.0 or later. For example, ASP.NET Core 3.1 or later.
- .NET Framework 4.5 or later.

Microsoft.Extensions.Caching.Memory / `IMemoryCache` (described in this article) is recommended over `System.Runtime.Caching`/`MemoryCache` because it's better integrated into ASP.NET Core. For example, `IMemoryCache` works natively with ASP.NET Core dependency injection.

Use `System.Runtime.Caching`/`MemoryCache` as a compatibility bridge when porting code from ASP.NET 4.x to ASP.NET Core.

Cache guidelines

- Code should always have a fallback option to fetch data and **not** depend on a cached value being available.
- The cache uses a scarce resource, memory. Limit cache growth:
  - Do **not** insert external input into the cache. As an example, using arbitrary user-provided input as a cache key is not recommended since the input might consume an unpredictable amount of memory.
  - Use expirations to limit cache growth.
  - Use SetSize, Size, and SizeLimit to limit cache size. The ASP.NET Core runtime does **not** limit cache size based on memory pressure. It's up to the developer to limit cache size.

Use IMemoryCache

> ⚠ **Warning**
>
> Using a *shared* memory cache from Dependency Injection and calling `SetSize`, `Size`, or `SizeLimit` to limit cache size can cause the app to fail. When a size limit is set on a cache, all entries must specify a size when being added. This can lead to issues since developers may not have full control on what uses the shared cache. When using `SetSize`, `Size`, or `SizeLimit` to limit cache, create a cache singleton for caching. For more information and an example, see Use SetSize, Size, and SizeLimit to limit cache size. A shared cache is one shared by other frameworks or libraries.

In-memory caching is a *service* that's referenced from an app using Dependency Injection. Request the `IMemoryCache` instance in the constructor:

C#

```
public class IndexModel : PageModel
{
    private readonly IMemoryCache _memoryCache;

    public IndexModel(IMemoryCache memoryCache) =>
        _memoryCache = memoryCache;
```

```
    // ...
```

The following code uses TryGetValue to check if a time is in the cache. If a time isn't cached, a new entry is created and added to the cache with Set:

C#

```
public void OnGet()
{
    CurrentDateTime = DateTime.Now;

    if (!_memoryCache.TryGetValue(CacheKeys.Entry, out DateTime cacheValue))
    {
        cacheValue = CurrentDateTime;

        var cacheEntryOptions = new MemoryCacheEntryOptions()
            .SetSlidingExpiration(TimeSpan.FromSeconds(3));

        _memoryCache.Set(CacheKeys.Entry, cacheValue, cacheEntryOptions);
    }

    CacheCurrentDateTime = cacheValue;
}
```

In the preceding code, the cache entry is configured with a sliding expiration of three seconds. If the cache entry isn't accessed for more than three seconds, it gets evicted from the cache. Each time the cache entry is accessed, it remains in the cache for a further 3 seconds. The `CacheKeys` class is part of the download sample.

The current time and the cached time are displayed:

CSHTML

```
<ul>
    <li>Current Time: @Model.CurrentDateTime</li>
    <li>Cached Time: @Model.CacheCurrentDateTime</li>
</ul>
```

The following code uses the `Set` extension method to cache data for a relative time without `MemoryCacheEntryOptions`:

C#

```
_memoryCache.Set(CacheKeys.Entry, DateTime.Now, TimeSpan.FromDays(1));
```

In the preceding code, the cache entry is configured with a relative expiration of one day. The cache entry gets evicted from the cache after one day, even if it's accessed within this timeout period.

The following code uses GetOrCreate and GetOrCreateAsync to cache data.

C#

```
public void OnGetCacheGetOrCreate()
{
    var cachedValue = _memoryCache.GetOrCreate(
        CacheKeys.Entry,
        cacheEntry =>
        {
            cacheEntry.SlidingExpiration = TimeSpan.FromSeconds(3);
            return DateTime.Now;
        });

    // ...
}

public async Task OnGetCacheGetOrCreateAsync()
{
    var cachedValue = await _memoryCache.GetOrCreateAsync(
        CacheKeys.Entry,
        cacheEntry =>
        {
            cacheEntry.SlidingExpiration = TimeSpan.FromSeconds(3);
            return Task.FromResult(DateTime.Now);
        });

    // ...
}
```

The following code calls Get to fetch the cached time:

C#

```
var cacheEntry = _memoryCache.Get<DateTime?>(CacheKeys.Entry);
```

The following code gets or creates a cached item with absolute expiration:

C#

```
var cachedValue = _memoryCache.GetOrCreate(
    CacheKeys.Entry,
    cacheEntry =>
    {
        cacheEntry.AbsoluteExpirationRelativeToNow =
TimeSpan.FromSeconds(20);
```

```
        return DateTime.Now;
    });
```

A cached item set with only a sliding expiration is at risk of never expiring. If the cached item is repeatedly accessed within the sliding expiration interval, the item never expires. Combine a sliding expiration with an absolute expiration to guarantee the item expires. The absolute expiration sets an upper bound on how long the item can be cached while still allowing the item to expire earlier if it isn't requested within the sliding expiration interval. If either the sliding expiration interval *or* the absolute expiration time pass, the item is evicted from the cache.

The following code gets or creates a cached item with both sliding *and* absolute expiration:

C#

```
var cachedValue = _memoryCache.GetOrCreate(
    CacheKeys.CallbackEntry,
    cacheEntry =>
    {
        cacheEntry.SlidingExpiration = TimeSpan.FromSeconds(3);
        cacheEntry.AbsoluteExpirationRelativeToNow =
TimeSpan.FromSeconds(20);
        return DateTime.Now;
    });
```

The preceding code guarantees the data won't be cached longer than the absolute time.

GetOrCreate, GetOrCreateAsync, and Get are extension methods in the CacheExtensions class. These methods extend the capability of IMemoryCache.

`MemoryCacheEntryOptions`

The following example:

- Sets the cache priority to CacheItemPriority.NeverRemove.
- Sets a PostEvictionDelegate that gets called after the entry is evicted from the cache. The callback is run on a different thread from the code that removes the item from the cache.

C#

```
public void OnGetCacheRegisterPostEvictionCallback()
{
    var memoryCacheEntryOptions = new MemoryCacheEntryOptions()
```

```
            .SetPriority(CacheItemPriority.NeverRemove)
            .RegisterPostEvictionCallback(PostEvictionCallback, _memoryCache);

        _memoryCache.Set(CacheKeys.CallbackEntry, DateTime.Now,
    memoryCacheEntryOptions);
    }

    private static void PostEvictionCallback(
        object cacheKey, object cacheValue, EvictionReason evictionReason,
    object state)
    {
        var memoryCache = (IMemoryCache)state;

        memoryCache.Set(
            CacheKeys.CallbackMessage,
            $"Entry {cacheKey} was evicted: {evictionReason}.");
    }
```

Use SetSize, Size, and SizeLimit to limit cache size

A `MemoryCache` instance may optionally specify and enforce a size limit. The cache size limit doesn't have a defined unit of measure because the cache has no mechanism to measure the size of entries. If the cache size limit is set, all entries must specify size. The ASP.NET Core runtime doesn't limit cache size based on memory pressure. It's up to the developer to limit cache size. The size specified is in units the developer chooses.

For example:

- If the web app was primarily caching strings, each cache entry size could be the string length.
- The app could specify the size of all entries as 1, and the size limit is the count of entries.

If SizeLimit isn't set, the cache grows without bound. The ASP.NET Core runtime doesn't trim the cache when system memory is low. Apps must be architected to:

- Limit cache growth.
- Call Compact or Remove when available memory is limited.

The following code creates a unitless fixed size MemoryCache accessible by dependency injection:

```
C#
```

```
public class MyMemoryCache
{
    public MemoryCache Cache { get; } = new MemoryCache(
        new MemoryCacheOptions
        {
            SizeLimit = 1024
        });
}
```

`SizeLimit` doesn't have units. Cached entries must specify size in whatever units they consider most appropriate if the cache size limit has been set. All users of a cache instance should use the same unit system. An entry won't be cached if the sum of the cached entry sizes exceeds the value specified by `SizeLimit`. If no cache size limit is set, the cache size set on the entry is ignored.

The following code registers `MyMemoryCache` with the dependency injection container:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddSingleton<MyMemoryCache>();
```

`MyMemoryCache` is created as an independent memory cache for components that are aware of this size limited cache and know how to set cache entry size appropriately.

The size of the cache entry can be set using the SetSize extension method or the Size property:

C#

```
if (!_myMemoryCache.Cache.TryGetValue(CacheKeys.Entry, out DateTime
cacheValue))
{
    var cacheEntryOptions = new MemoryCacheEntryOptions()
        .SetSize(1);

    // cacheEntryOptions.Size = 1;

    _myMemoryCache.Cache.Set(CacheKeys.Entry, cacheValue,
cacheEntryOptions);
}
```

In the preceding code, the two highlighted lines achieve the same result of setting the size of the cache entry. `SetSize` is provided for convenience when chaining calls onto

`new MemoryCacheOptions()`.

MemoryCache.Compact

`MemoryCache.Compact` attempts to remove the specified percentage of the cache in the following order:

- All expired items.
- Items by priority. Lowest priority items are removed first.
- Least recently used objects.
- Items with the earliest absolute expiration.
- Items with the earliest sliding expiration.

Pinned items with priority NeverRemove are never removed. The following code removes a cache item and calls `Compact` to remove 25% of cached entries:

C#

```
_myMemoryCache.Cache.Remove(CacheKeys.Entry);
_myMemoryCache.Cache.Compact(.25);
```

For more information, see the Compact source on GitHub.

Cache dependencies

The following sample shows how to expire a cache entry if a dependent entry expires. A CancellationChangeToken is added to the cached item. When `Cancel` is called on the `CancellationTokenSource`, both cache entries are evicted:

C#

```
public void OnGetCacheCreateDependent()
{
    var cancellationTokenSource = new CancellationTokenSource();

    _memoryCache.Set(
        CacheKeys.DependentCancellationTokenSource,
        cancellationTokenSource);

    using var parentCacheEntry = _memoryCache.CreateEntry(CacheKeys.Parent);

    parentCacheEntry.Value = DateTime.Now;

    _memoryCache.Set(
        CacheKeys.Child,
```

```
            DateTime.Now,
            new CancellationChangeToken(cancellationTokenSource.Token));
    }

    public void OnGetCacheRemoveDependent()
    {
        var cancellationTokenSource = _memoryCache.Get<CancellationTokenSource>(
            CacheKeys.DependentCancellationTokenSource);

        cancellationTokenSource.Cancel();
    }
```

Using a CancellationTokenSource allows multiple cache entries to be evicted as a group. With the `using` pattern in the code above, cache entries created inside the `using` scope inherit triggers and expiration settings.

Additional notes

- Expiration doesn't happen in the background. There's no timer that actively scans the cache for expired items. Any activity on the cache (`Get`, `Set`, `Remove`) can trigger a background scan for expired items. A timer on the `CancellationTokenSource` (CancelAfter) also removes the entry and triggers a scan for expired items. The following example uses CancellationTokenSource(TimeSpan) for the registered token. When this token fires, it removes the entry immediately and fires the eviction callbacks:

  C#

  ```
  if (!_memoryCache.TryGetValue(CacheKeys.Entry, out DateTime
  cacheValue))
  {
      cacheValue = DateTime.Now;

      var cancellationTokenSource = new CancellationTokenSource(
          TimeSpan.FromSeconds(10));

      var cacheEntryOptions = new MemoryCacheEntryOptions()
          .AddExpirationToken(
              new CancellationChangeToken(cancellationTokenSource.Token))
          .RegisterPostEvictionCallback((key, value, reason, state) =>
          {
              ((CancellationTokenSource)state).Dispose();
          }, cancellationTokenSource);

      _memoryCache.Set(CacheKeys.Entry, cacheValue, cacheEntryOptions);
  }
  ```

- When using a callback to repopulate a cache item:
  - Multiple requests can find the cached key value empty because the callback hasn't completed.
  - This can result in several threads repopulating the cached item.
- When one cache entry is used to create another, the child copies the parent entry's expiration tokens and time-based expiration settings. The child isn't expired by manual removal or updating of the parent entry.
- Use PostEvictionCallbacks to set the callbacks that will be fired after the cache entry is evicted from the cache.
- For most apps, `IMemoryCache` is enabled. For example, calling `AddMvc`, `AddControllersWithViews`, `AddRazorPages`, `AddMvcCore().AddRazorViewEngine`, and many other `Add{Service}` methods in `Program.cs`, enables `IMemoryCache`. For apps that don't call one of the preceding `Add{Service}` methods, it may be necessary to call AddMemoryCache in `Program.cs`.

Background cache update

Use a background service such as IHostedService to update the cache. The background service can recompute the entries and then assign them to the cache only when they're ready.

Distributed caching in ASP.NET Core

Article • 10/04/2024

By Mohsin Nasir and smandia

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

A distributed cache is a cache shared by multiple app servers, typically maintained as an external service to the app servers that access it. A distributed cache can improve the performance and scalability of an ASP.NET Core app, especially when the app is hosted by a cloud service or a server farm.

A distributed cache has several advantages over other caching scenarios where cached data is stored on individual app servers.

When cached data is distributed, the data:

- Is *coherent* (consistent) across requests to multiple servers.
- Survives server restarts and app deployments.
- Doesn't use local memory.

Distributed cache configuration is implementation specific. This article describes how to configure SQL Server and Redis distributed caches. Third party implementations are also available, such as NCache (NCache on GitHub). Regardless of which implementation is selected, the app interacts with the cache using the IDistributedCache interface.

View or download sample code (how to download)

> **⚠ Warning**
>
> This article uses a local database that doesn't require the user to be authenticated. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production apps, see Secure authentication flows.

Prerequisites

Add a package reference for the distributed cache provider used:

- For a Redis distributed cache, Microsoft.Extensions.Caching.StackExchangeRedis.
- For SQL Server, Microsoft.Extensions.Caching.SqlServer.
- For the NCache distributed cache, NCache.Microsoft.Extensions.Caching.OpenSource.

IDistributedCache interface

The IDistributedCache interface provides the following methods to manipulate items in the distributed cache implementation:

- Get, GetAsync: Accepts a string key and retrieves a cached item as a `byte[]` array if found in the cache.
- Set, SetAsync: Adds an item (as `byte[]` array) to the cache using a string key.
- Refresh, RefreshAsync: Refreshes an item in the cache based on its key, resetting its sliding expiration timeout (if any).
- Remove, RemoveAsync: Removes a cache item based on its string key.

Establish distributed caching services

Register an implementation of IDistributedCache in `Program.cs`. Framework-provided implementations described in this topic include:

- Distributed Redis cache
- Distributed Memory Cache
- Distributed SQL Server cache
- Distributed NCache cache
- Distributed Azure CosmosDB cache

Distributed Redis Cache

We recommend production apps use the Distributed Redis Cache because it's the most performant. For more information see Recommendations.

Redis is an open source in-memory data store, which is often used as a distributed cache. You can configure an Azure Cache for Redis for an Azure-hosted ASP.NET Core app, and use an Azure Cache for Redis for local development.

An app configures the cache implementation using a RedisCache instance, by calling AddStackExchangeRedisCache. For output caching, use `AddStackExchangeRedisOutputCache`.

1. Create an Azure Cache for Redis.
2. Copy the Primary connection string (StackExchange.Redis) to Configuration.

    - Local development: Save the connection string with Secret Manager.
    - Azure: Save the connection string in a secure store such as Azure Key Vault

The following code enables the Azure Cache for Redis:

```
C#

builder.Services.AddStackExchangeRedisCache(options =>
 {
     options.Configuration =
builder.Configuration.GetConnectionString("MyRedisConStr");
     options.InstanceName = "SampleInstance";
 });
```

The preceding code assumes the Primary connection string (StackExchange.Redis) was saved in configuration with the key name `MyRedisConStr`.

For more information, see Azure Cache for Redis.

See this GitHub issue for a discussion on alternative approaches to a local Redis cache.

Distributed Memory Cache

The Distributed Memory Cache (AddDistributedMemoryCache) is a framework-provided implementation of IDistributedCache that stores items in memory. The Distributed Memory Cache isn't an actual distributed cache. Cached items are stored by the app instance on the server where the app is running.

The Distributed Memory Cache is a useful implementation:

- In development and testing scenarios.
- When a single server is used in production and memory consumption isn't an issue. Implementing the Distributed Memory Cache abstracts cached data storage. It allows for implementing a true distributed caching solution in the future if multiple nodes or fault tolerance become necessary.

The sample app makes use of the Distributed Memory Cache when the app is run in the Development environment in `Program.cs`:

C#

```
builder.Services.AddDistributedMemoryCache();
```

Distributed SQL Server Cache

The Distributed SQL Server Cache implementation (AddDistributedSqlServerCache) allows the distributed cache to use a SQL Server database as its backing store. To create a SQL Server cached item table in a SQL Server instance, you can use the `sql-cache` tool. The tool creates a table with the name and schema that you specify.

Create a table in SQL Server by running the `sql-cache create` command. Provide the SQL Server instance (`Data Source`), database (`Initial Catalog`), schema (for example, `dbo`), and table name (for example, `TestCache`):

.NET CLI

```
dotnet sql-cache create "Data Source=(localdb)/MSSQLLocalDB;Initial
Catalog=DistCache;Integrated Security=True;" dbo TestCache
```

A message is logged to indicate that the tool was successful:

Console

```
Table and index were created successfully.
```

The table created by the `sql-cache` tool has the following schema:

	Name	Data Type	Allow Nulls
🔑	Id	nvarchar(449)	☐
	Value	varbinary(MAX)	☐
	ExpiresAtTime	datetimeoffset(7)	☐
	SlidingExpirationInSeconds	bigint	☑
	AbsoluteExpiration	datetimeoffset(7)	☑

ⓘ Note

An app should manipulate cache values using an instance of IDistributedCache, not a SqlServerCache.

The sample app implements SqlServerCache in a non-Development environment in `Program.cs`:

C#

```
builder.Services.AddDistributedSqlServerCache(options =>
{
    options.ConnectionString = builder.Configuration.GetConnectionString(
        "DistCache_ConnectionString");
    options.SchemaName = "dbo";
    options.TableName = "TestCache";
});
```

Note

A ConnectionString (and optionally, SchemaName and TableName) are typically stored outside of source control (for example, stored by the Secret Manager or in `appsettings.json` / `appsettings.{Environment}.json` files). The connection string may contain credentials that should be kept out of source control systems.

Distributed NCache Cache

NCache is an open source in-memory distributed cache developed natively in .NET and .NET Core. NCache works both locally and configured as a distributed cache cluster for an ASP.NET Core app running in Azure or on other hosting platforms.

To install and configure NCache on your local machine, see Getting Started Guide for Windows (.NET and .NET Core).

To configure NCache:

1. Install NCache open source NuGet.
2. Configure the cache cluster in client.ncconf.
3. Add the following code to `Program.cs`:

C#

```
builder.Services.AddNCacheDistributedCache(configuration =>
{
    configuration.CacheName = "democache";
    configuration.EnableLogs = true;
```

```
    configuration.ExceptionsEnabled = true;
});
```

Distributed Azure CosmosDB Cache

Azure Cosmos DB can be used in ASP.NET Core as a session state provider by using the `IDistributedCache` interface. Azure Cosmos DB is a fully managed NoSQL and relational database for modern app development that offers high availability, scalability, and low-latency access to data for mission-critical applications.

After installing the Microsoft.Extensions.Caching.Cosmos NuGet package, configure an Azure Cosmos DB distributed cache as follows:

Reuse an existing client

The easiest way to configure distributed cache is by reusing an existing Azure Cosmos DB client. In this case, the `CosmosClient` instance won't be disposed when the provider is disposed.

C#

```
services.AddCosmosCache((CosmosCacheOptions cacheOptions) =>
{
    cacheOptions.ContainerName = Configuration["CosmosCacheContainer"];
    cacheOptions.DatabaseName = Configuration["CosmosCacheDatabase"];
    cacheOptions.CosmosClient = existingCosmosClient;
    cacheOptions.CreateIfNotExists = true;
});
```

Create a new client

Alternatively, instantiate a new client. In this case, the `CosmosClient` instance will get disposed when the provider is disposed.

C#

```
services.AddCosmosCache((CosmosCacheOptions cacheOptions) =>
{
    cacheOptions.ContainerName = Configuration["CosmosCacheContainer"];
    cacheOptions.DatabaseName = Configuration["CosmosCacheDatabase"];
    cacheOptions.ClientBuilder = new
CosmosClientBuilder(Configuration["CosmosConnectionString"]);
    cacheOptions.CreateIfNotExists = true;
});
```

Use the distributed cache

To use the IDistributedCache interface, request an instance of IDistributedCache in the app. The instance is provided by dependency injection (DI).

When the sample app starts, IDistributedCache is injected into `Program.cs`. The current time is cached using IHostApplicationLifetime (for more information, see Generic Host: IHostApplicationLifetime):

C#

```
app.Lifetime.ApplicationStarted.Register(() =>
{
    var currentTimeUTC = DateTime.UtcNow.ToString();
    byte[] encodedCurrentTimeUTC =
System.Text.Encoding.UTF8.GetBytes(currentTimeUTC);
    var options = new DistributedCacheEntryOptions()
        .SetSlidingExpiration(TimeSpan.FromSeconds(20));
    app.Services.GetService<IDistributedCache>()
                                .Set("cachedTimeUTC", encodedCurrentTimeUTC,
options);
});
```

The sample app injects IDistributedCache into the `IndexModel` for use by the Index page.

Each time the Index page is loaded, the cache is checked for the cached time in `OnGetAsync`. If the cached time hasn't expired, the time is displayed. If 20 seconds have elapsed since the last time the cached time was accessed (the last time this page was loaded), the page displays *Cached Time Expired*.

Immediately update the cached time to the current time by selecting the **Reset Cached Time** button. The button triggers the `OnPostResetCachedTime` handler method.

C#

```
public class IndexModel : PageModel
{
    private readonly IDistributedCache _cache;

    public IndexModel(IDistributedCache cache)
    {
        _cache = cache;
    }

    public string? CachedTimeUTC { get; set; }
    public string? ASP_Environment { get; set; }

    public async Task OnGetAsync()
```

```
    {
        CachedTimeUTC = "Cached Time Expired";
        var encodedCachedTimeUTC = await _cache.GetAsync("cachedTimeUTC");

        if (encodedCachedTimeUTC != null)
        {
            CachedTimeUTC = Encoding.UTF8.GetString(encodedCachedTimeUTC);
        }

        ASP_Environment =
Environment.GetEnvironmentVariable("ASPNETCORE_ENVIRONMENT");
        if (String.IsNullOrEmpty(ASP_Environment))
        {
            ASP_Environment = "Null, so Production";
        }
    }
    public async Task<IActionResult> OnPostResetCachedTime()
    {
        var currentTimeUTC = DateTime.UtcNow.ToString();
        byte[] encodedCurrentTimeUTC =
Encoding.UTF8.GetBytes(currentTimeUTC);
        var options = new DistributedCacheEntryOptions()
            .SetSlidingExpiration(TimeSpan.FromSeconds(20));
        await _cache.SetAsync("cachedTimeUTC", encodedCurrentTimeUTC,
options);

        return RedirectToPage();
    }
}
```

> There's ***no*** need to use a Singleton or Scoped lifetime for IDistributedCache instances with the built-in implementations.
>
> You can also create an IDistributedCache instance wherever you might need one instead of using DI, but creating an instance in code can make your code harder to test and violates the Explicit Dependencies Principle.

Recommendations

When deciding which implementation of IDistributedCache is best for your app, consider the following:

- Existing infrastructure
- Performance requirements
- Cost
- Team experience

Caching solutions usually rely on in-memory storage to provide fast retrieval of cached data, but memory is a limited resource and costly to expand. Only store commonly used data in a cache.

For most apps, a Redis cache provides higher throughput and lower latency than a SQL Server cache. However, benchmarking is recommended to determine the performance characteristics of caching strategies.

When SQL Server is used as a distributed cache backing store, use of the same database for the cache and the app's ordinary data storage and retrieval can negatively impact the performance of both. We recommend using a dedicated SQL Server instance for the distributed cache backing store.

HybridCache library in ASP.NET Core

Article • 11/06/2024

> **Important**
>
> `HybridCache` is currently still in preview but will be fully released *after* .NET 9.0 in a future minor release of .NET Extensions.

This article explains how to configure and use the `HybridCache` library in an ASP.NET Core app. For an introduction to the library, see the HybridCache section of the Caching overview.

Get the library

Install the `Microsoft.Extensions.Caching.Hybrid` package.

.NET CLI

```
dotnet add package Microsoft.Extensions.Caching.Hybrid --version "9.0.0-preview.7.24406.2"
```

Register the service

Add the `HybridCache` service to the dependency injection (DI) container by calling AddHybridCache:

C#

```
// Add services to the container.
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddAuthorization();

builder.Services.AddHybridCache();
```

The preceding code registers the `HybridCache` service with default options. The registration API can also configure options and serialization.

Get and store cache entries

The `HybridCache` service provides a GetOrCreateAsync method with two overloads, taking a key and:

- A factory method.
- State, and a factory method.

The method uses the key to try to retrieve the object from the primary cache. If the item isn't found in the primary cache (a cache miss), it then checks the secondary cache if one is configured. If it doesn't find the data there (another cache miss), it calls the factory method to get the object from the data source. It then stores the object in both primary and secondary caches. The factory method is never called if the object is found in the primary or secondary cache (a cache hit).

The `HybridCache` service ensures that only one concurrent caller for a given key calls the factory method, and all other callers wait for the result of that call. The `CancellationToken` passed to `GetOrCreateAsync` represents the combined cancellation of all concurrent callers.

The main `GetOrCreateAsync` overload

The stateless overload of `GetOrCreateAsync` is recommended for most scenarios. The code to call it is relatively simple. Here's an example:

C#

```
public class SomeService(HybridCache cache)
{
    private HybridCache _cache = cache;

    public async Task<string> GetSomeInfoAsync(string name, int id,
CancellationToken token = default)
    {
        return await _cache.GetOrCreateAsync(
            $"{name}-{id}", // Unique key to the cache entry
            async cancel => await GetDataFromTheSourceAsync(name, id,
cancel),
            cancellationToken: token
        );
    }

    public async Task<string> GetDataFromTheSourceAsync(string name, int id,
CancellationToken token)
    {
        string someInfo = $"someinfo-{name}-{id}";
        return someInfo;
```

```
    }
}
```

The alternative `GetOrCreateAsync` overload

The alternative overload might reduce some overhead from captured variables and per-instance callbacks, but at the expense of more complex code. For most scenarios the performance increase doesn't outweigh the code complexity. Here's an example that uses the alternative overload:

C#

```
public class SomeService(HybridCache cache)
{
    private HybridCache _cache = cache;

    public async Task<string> GetSomeInfoAsync(string name, int id,
CancellationToken token = default)
    {
        return await _cache.GetOrCreateAsync(
            $"{name}-{id}", // Unique key to the cache entry
            (name, id, obj: this),
            static async (state, token) =>
            await state.obj.GetDataFromTheSourceAsync(state.name, state.id,
token),
            cancellationToken: token
        );
    }

    public async Task<string> GetDataFromTheSourceAsync(string name, int id,
CancellationToken token)
    {
        string someInfo = $"someinfo-{name}-{id}";
        return someInfo;
    }
}
```

The `SetAsync` method

In many scenarios, `GetOrCreateAsync` is the only API needed. But `HybridCache` also has SetAsync to store an object in cache without trying to retrieve it first.

Remove cache entries by key

When the underlying data for a cache entry changes before it expires, remove the entry explicitly by calling RemoveAsync with the key to the entry. An overload lets you

specify a collection of key values.

When an entry is removed, it is removed from both the primary and secondary caches.

Remove cache entries by tag

Tags can be used to group cache entries and invalidate them together.

Set tags when calling `GetOrCreateAsync`, as shown in the following example:

C#

```
public class SomeService(HybridCache cache)
{
    private HybridCache _cache = cache;

    public async Task<string> GetSomeInfoAsync(string name, int id,
CancellationToken token = default)
    {
        var tags = new List<string> { "tag1", "tag2", "tag3" };
        var entryOptions = new HybridCacheEntryOptions
        {
            Expiration = TimeSpan.FromMinutes(1),
            LocalCacheExpiration = TimeSpan.FromMinutes(1)
        };
        return await _cache.GetOrCreateAsync(
            $"{name}-{id}", // Unique key to the cache entry
            async cancel => await GetDataFromTheSourceAsync(name, id,
cancel),
            entryOptions,
            tags,
            cancellationToken: token
        );
    }

    public async Task<string> GetDataFromTheSourceAsync(string name, int id,
CancellationToken token)
    {
        string someInfo = $"someinfo-{name}-{id}";
        return someInfo;
    }
}
```

Remove all entries for a specified tag by calling RemoveByTagAsync with the tag value. An overload lets you specify a collection of tag values.

When an entry is removed, it is removed from both the primary and secondary caches.

Options

The `AddHybridCache` method can be used to configure global defaults. The following example shows how to configure some of the available options:

C#

```
// Add services to the container.
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization();

builder.Services.AddHybridCache(options =>
    {
        options.MaximumPayloadBytes = 1024 * 1024;
        options.MaximumKeyLength = 1024;
        options.DefaultEntryOptions = new HybridCacheEntryOptions
        {
            Expiration = TimeSpan.FromMinutes(5),
            LocalCacheExpiration = TimeSpan.FromMinutes(5)
        };
    });
```

The `GetOrCreateAsync` method can also take a `HybridCacheEntryOptions` object to override the global defaults for a specific cache entry. Here's an example:

C#

```
public class SomeService(HybridCache cache)
{
    private HybridCache _cache = cache;

    public async Task<string> GetSomeInfoAsync(string name, int id,
CancellationToken token = default)
    {
        var tags = new List<string> { "tag1", "tag2", "tag3" };
        var entryOptions = new HybridCacheEntryOptions
        {
            Expiration = TimeSpan.FromMinutes(1),
            LocalCacheExpiration = TimeSpan.FromMinutes(1)
        };
        return await _cache.GetOrCreateAsync(
            $"{name}-{id}", // Unique key to the cache entry
            async cancel => await GetDataFromTheSourceAsync(name, id,
cancel),
            entryOptions,
            tags,
            cancellationToken: token
        );
    }
```

```
    public async Task<string> GetDataFromTheSourceAsync(string name, int id,
CancellationToken token)
    {
        string someInfo = $"someinfo-{name}-{id}";
        return someInfo;
    }
}
```

For more information about the options, see the source code:

- HybridCacheOptions class.
- HybridCacheEntryOptions class.

Limits

The following properties of `HybridCacheOptions` let you configure limits that apply to all cache entries:

- MaximumPayloadBytes - Maximum size of a cache entry. Default value is 1 MB. Attempts to store values over this size are logged, and the value isn't stored in cache.
- MaximumKeyLength - Maximum length of a cache key. Default value is 1024 characters. Attempts to store values over this size are logged, and the value isn't stored in cache.

Serialization

Use of a secondary, out-of-process cache requires serialization. Serialization is configured as part of registering the `HybridCache` service. Type-specific and general-purpose serializers can be configured via the AddSerializer and AddSerializerFactory methods, chained from the `AddHybridCache` call. By default, the library handles `string` and `byte[]` internally, and uses `System.Text.Json` for everything else. `HybridCache` can also use other serializers, such as protobuf or XML.

The following example configures the service to use a type-specific protobuf serializer:

C#

```
// Add services to the container.

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization();
```

```
builder.Services.AddHybridCache(options =>
    {
        options.DefaultEntryOptions = new HybridCacheEntryOptions
        {
            Expiration = TimeSpan.FromSeconds(10),
            LocalCacheExpiration = TimeSpan.FromSeconds(5)
        };
    }).AddSerializer<SomeProtobufMessage,
        GoogleProtobufSerializer<SomeProtobufMessage>>();
```

The following example configures the service to use a general-purpose protobuf serializer that can handle many protobuf types:

C#

```
// Add services to the container.

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization();

builder.Services.AddHybridCache(options =>
{
    options.DefaultEntryOptions = new HybridCacheEntryOptions
    {
        Expiration = TimeSpan.FromSeconds(10),
        LocalCacheExpiration = TimeSpan.FromSeconds(5)
    };
}).AddSerializerFactory<GoogleProtobufSerializerFactory>();
```

The secondary cache requires a data store, such as Redis or SqlServer. To use Azure Cache for Redis, for example:

- Install the `Microsoft.Extensions.Caching.StackExchangeRedis` package.
- Create an instance of Azure Cache for Redis.
- Get a connection string that connects to the Redis instance. Find the connection string by selecting **Show access keys** on the **Overview** page in the Azure portal.
- Store the connection string in the app's configuration. For example, use a user secrets file that looks like the following JSON, with the connection string in the `ConnectionStrings` section. Replace `<the connection string>` with the actual connection string:

  JSON

  ```
  {
    "ConnectionStrings": {
  ```

```
    "RedisConnectionString": "<the connection string>"
  }
}
```

- Register in DI the `IDistributedCache` implementation that the Redis package provides. To do that, call `AddStackExchangeRedisCache`, and pass in the connection string. For example:

```
C#

builder.Services.AddStackExchangeRedisCache(options =>
{
    options.Configuration =

builder.Configuration.GetConnectionString("RedisConnectionString");
});
```

- The Redis `IDistributedCache` implementation is now available from the app's DI container. `HybridCache` uses it as the secondary cache and uses the serializer configured for it.

For more information, see the HybridCache serialization sample app.

Cache storage

By default `HybridCache` uses MemoryCache for its primary cache storage. Cache entries are stored in-process, so each server has a separate cache that is lost whenever the server process is restarted. For secondary out-of-process storage, such as Redis or SQL Server, `HybridCache` uses the configured IDistributedCache implementation, if any. But even without an `IDistributedCache` implementation, the `HybridCache` service still provides in-process caching and stampede protection.

Optimize performance

To optimize performance, configure `HybridCache` to reuse objects and avoid `byte[]` allocations.

Reuse objects

By reusing instances, `HybridCache` can reduce the overhead of CPU and object allocations associated with per-call deserialization. This can lead to performance improvements in scenarios where the cached objects are large or accessed frequently.

In typical existing code that uses `IDistributedCache`, every retrieval of an object from the cache results in deserialization. This behavior means that each concurrent caller gets a separate instance of the object, which can't interact with other instances. The result is thread safety, as there's no risk of concurrent modifications to the same object instance.

Because much `HybridCache` usage will be adapted from existing `IDistributedCache` code, `HybridCache` preserves this behavior by default to avoid introducing concurrency bugs. However, objects are inherently thread-safe if:

- They are immutable types.
- The code doesn't modify them.

In such cases, inform `HybridCache` that it's safe to reuse instances by:

- Marking the type as `sealed`. The `sealed` keyword in C# means that the class can't be inherited.
- Applying the `[ImmutableObject(true)]` attribute to the type. The `[ImmutableObject(true)]` attribute indicates that the object's state can't be changed after it's created.

Avoid `byte[]` allocations

`HybridCache` also provides optional APIs for `IDistributedCache` implementations, to avoid `byte[]` allocations. This feature is implemented by the preview versions of the `Microsoft.Extensions.Caching.StackExchangeRedis` and `Microsoft.Extensions.Caching.SqlServer` packages. For more information, see IBufferDistributedCache Here are the .NET CLI commands to install the packages:

.NET CLI

```
dotnet add package Microsoft.Extensions.Caching.StackExchangeRedis --
prerelease
```

.NET CLI

```
dotnet add package Microsoft.Extensions.Caching.SqlServer --prerelease
```

Custom HybridCache implementations

A concrete implementation of the `HybridCache` abstract class is included in the shared framework and is provided via dependency injection. But developers are welcome to

provide custom implementations of the API.

Compatibility

The `HybridCache` library supports older .NET runtimes, down to .NET Framework 4.7.2 and .NET Standard 2.0.

- HybridCache source code

Output caching middleware in ASP.NET Core

Article • 07/11/2024

By Tom Dykstra

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to configure output caching middleware in an ASP.NET Core app. For an introduction to output caching, see Output caching.

The output caching middleware can be used in all types of ASP.NET Core apps: Minimal API, Web API with controllers, MVC, and Razor Pages. Code examples are provided for minimal APIs and controller-based APIs. The controller-based API examples show how to use attributes to configure caching. These attributes can also be used in MVC and Razor Pages apps.

The code examples refer to a Gravatar class that generates an image and provides a "generated at" date and time. The class is defined and used only in the sample app. Its purpose is to make it easy to see when cached output is being used. For more information, see How to download a sample and Preprocessor directives in sample code.

Add the middleware to the app

Add the output caching middleware to the service collection by calling AddOutputCache.

Add the middleware to the request processing pipeline by calling UseOutputCache.

For example:

C#

```
builder.Services.AddOutputCache();
```

C#

```
var app = builder.Build();

// Configure the HTTP request pipeline.
app.UseHttpsRedirection();
app.UseOutputCache();
app.UseAuthorization();
```

Calling `AddOutputCache` and `UseOutputCache` doesn't start caching behavior, it makes caching available. To make the app cache responses, caching must be configured as shown in the following sections.

> ⓘ Note
>
> - In apps that use CORS middleware, `UseOutputCache` must be called after UseCors.
> - In Razor Pages apps and apps with controllers, `UseOutputCache` must be called after `UseRouting`.

Configure one endpoint or page

For minimal API apps, configure an endpoint to do caching by calling CacheOutput, or by applying the [OutputCache] attribute, as shown in the following examples:

C#

```
app.MapGet("/cached", Gravatar.WriteGravatar).CacheOutput();
app.MapGet("/attribute", [OutputCache] (context) =>
    Gravatar.WriteGravatar(context));
```

For apps with controllers, apply the `[OutputCache]` attribute to the action method as shown here:

C#

```
[ApiController]
[Route("/[controller]")]
[OutputCache]
public class CachedController : ControllerBase
{
    public async Task GetAsync()
```

```
    {
        await Gravatar.WriteGravatar(HttpContext);
    }
}
```

For Razor Pages apps, apply the attribute to the Razor page class.

Configure multiple endpoints or pages

Create *policies* when calling `AddOutputCache` to specify caching configuration that applies to multiple endpoints. A policy can be selected for specific endpoints, while a base policy provides default caching configuration for a collection of endpoints.

The following highlighted code configures caching for all of the app's endpoints, with expiration time of 10 seconds. If an expiration time isn't specified, it defaults to one minute.

C#

```
builder.Services.AddOutputCache(options =>
{
    options.AddBasePolicy(builder =>
        builder.Expire(TimeSpan.FromSeconds(10)));
    options.AddPolicy("Expire20", builder =>
        builder.Expire(TimeSpan.FromSeconds(20)));
    options.AddPolicy("Expire30", builder =>
        builder.Expire(TimeSpan.FromSeconds(30)));
});
```

The following highlighted code creates two policies, each specifying a different expiration time. Selected endpoints can use the 20-second expiration, and others can use the 30-second expiration.

C#

```
builder.Services.AddOutputCache(options =>
{
    options.AddBasePolicy(builder =>
        builder.Expire(TimeSpan.FromSeconds(10)));
    options.AddPolicy("Expire20", builder =>
        builder.Expire(TimeSpan.FromSeconds(20)));
    options.AddPolicy("Expire30", builder =>
        builder.Expire(TimeSpan.FromSeconds(30)));
});
```

You can select a policy for an endpoint when calling the `CacheOutput` method or using the `[OutputCache]` attribute.

In a minimal API app, the following code configures one endpoint with a 20-second expiration and one with a 30-second expiration:

C#

```
app.MapGet("/20", Gravatar.WriteGravatar).CacheOutput("Expire20");
app.MapGet("/30", [OutputCache(PolicyName = "Expire30")] (context) =>
    Gravatar.WriteGravatar(context));
```

For apps with controllers, apply the `[OutputCache]` attribute to the action method to select a policy:

C#

```
[ApiController]
[Route("/[controller]")]
[OutputCache(PolicyName = "Expire20")]
public class Expire20Controller : ControllerBase
{
    public async Task GetAsync()
    {
        await Gravatar.WriteGravatar(HttpContext);
    }
}
```

For Razor Pages apps, apply the attribute to the Razor page class.

Default output caching policy

By default, output caching follows these rules:

- Only HTTP 200 responses are cached.
- Only HTTP GET or HEAD requests are cached.
- Responses that set cookies aren't cached.
- Responses to authenticated requests aren't cached.

The following code applies all of the default caching rules to all of an app's endpoints:

C#

```
builder.Services.AddOutputCache(options =>
{
```

```
    options.AddBasePolicy(builder => builder.Cache());
});
```

Override the default policy

The following code shows how to override the default rules. The highlighted lines in the following custom policy code enable caching for HTTP POST methods and HTTP 301 responses:

C#

```
using Microsoft.AspNetCore.OutputCaching;
using Microsoft.Extensions.Primitives;

namespace OCMinimal;

public sealed class MyCustomPolicy : IOutputCachePolicy
{
    public static readonly MyCustomPolicy Instance = new();

    private MyCustomPolicy()
    {
    }

    ValueTask IOutputCachePolicy.CacheRequestAsync(
        OutputCacheContext context,
        CancellationToken cancellationToken)
    {
        var attemptOutputCaching = AttemptOutputCaching(context);
        context.EnableOutputCaching = true;
        context.AllowCacheLookup = attemptOutputCaching;
        context.AllowCacheStorage = attemptOutputCaching;
        context.AllowLocking = true;

        // Vary by any query by default
        context.CacheVaryByRules.QueryKeys = "*";

        return ValueTask.CompletedTask;
    }

    ValueTask IOutputCachePolicy.ServeFromCacheAsync
        (OutputCacheContext context, CancellationToken cancellationToken)
    {
        return ValueTask.CompletedTask;
    }

    ValueTask IOutputCachePolicy.ServeResponseAsync
        (OutputCacheContext context, CancellationToken cancellationToken)
    {
        var response = context.HttpContext.Response;
```

```
        // Verify existence of cookie headers
        if (!StringValues.IsNullOrEmpty(response.Headers.SetCookie))
        {
            context.AllowCacheStorage = false;
            return ValueTask.CompletedTask;
        }

        // Check response code
        if (response.StatusCode != StatusCodes.Status200OK &&
            response.StatusCode != StatusCodes.Status301MovedPermanently)
        {
            context.AllowCacheStorage = false;
            return ValueTask.CompletedTask;
        }

        return ValueTask.CompletedTask;
    }

    private static bool AttemptOutputCaching(OutputCacheContext context)
    {
        // Check if the current request fulfills the requirements
        // to be cached
        var request = context.HttpContext.Request;

        // Verify the method
        if (!HttpMethods.IsGet(request.Method) &&
            !HttpMethods.IsHead(request.Method) &&
            !HttpMethods.IsPost(request.Method))
        {
            return false;
        }

        // Verify existence of authorization headers
        if (!StringValues.IsNullOrEmpty(request.Headers.Authorization) ||
            request.HttpContext.User?.Identity?.IsAuthenticated == true)
        {
            return false;
        }

        return true;
    }
}
```

To use this custom policy, create a named policy:

C#

```
builder.Services.AddOutputCache(options =>
{
    options.AddPolicy("CachePost", MyCustomPolicy.Instance);
});
```

And select the named policy for an endpoint. The following code selects the custom policy for an endpoint in a minimal API app:

C#

```
app.MapPost("/cachedpost", Gravatar.WriteGravatar)
    .CacheOutput("CachePost");
```

The following code does the same for a controller action:

C#

```
[ApiController]
[Route("/[controller]")]
[OutputCache(PolicyName = "CachePost")]
public class PostController : ControllerBase
{
    public async Task GetAsync()
    {
        await Gravatar.WriteGravatar(HttpContext);
    }
}
```

Alternative default policy override

Alternatively, use Dependency Injection (DI) to initialize an instance, with the following changes to the custom policy class:

- A public constructor instead of a private constructor.
- Eliminate the `Instance` property in the custom policy class.

For example:

C#

```
public sealed class MyCustomPolicy2 : IOutputCachePolicy
{

    public MyCustomPolicy2()
    {
    }
```

The remainder of the class is the same as shown previously. Add the custom policy as shown in the following example:

C#

```
builder.Services.AddOutputCache(options =>
{
    options.AddBasePolicy(builder =>
        builder.AddPolicy<MyCustomPolicy2>(), true);
});
```

The preceding code uses DI to create the instance of the custom policy class. Any public arguments in the constructor are resolved.

When using a custom policy as a base policy, don't call `OutputCache()` (with no arguments) or use the `[OutputCache]` attribute on any endpoint that the base policy should apply to. Calling `OutputCache()` or using the attribute adds the default policy to the endpoint.

Specify the cache key

By default, every part of the URL is included as the key to a cache entry, that is, the scheme, host, port, path, and query string. However, you might want to explicitly control the cache key. For example, suppose you have an endpoint that returns a unique response only for each unique value of the `culture` query string. Variation in other parts of the URL, such as other query strings, shouldn't result in different cache entries. You can specify such rules in a policy, as shown in the following highlighted code:

C#

```
builder.Services.AddOutputCache(options =>
{
    options.AddBasePolicy(builder => builder
        .With(c => c.HttpContext.Request.Path.StartsWithSegments("/blog"))
        .Tag("tag-blog"));
    options.AddBasePolicy(builder => builder.Tag("tag-all"));
    options.AddPolicy("Query", builder =>
builder.SetVaryByQuery("culture"));
    options.AddPolicy("NoCache", builder => builder.NoCache());
    options.AddPolicy("NoLock", builder => builder.SetLocking(false));
});
```

You can then select the `VaryByQuery` policy for an endpoint. In a minimal API app, the following code selects the `VaryByQuery` policy for an endpoint that returns a unique response only for each unique value of the `culture` query string:

C#

```
app.MapGet("/query", Gravatar.WriteGravatar).CacheOutput("Query");
```

The following code does the same for a controller action:

C#

```
[ApiController]
[Route("/[controller]")]
[OutputCache(PolicyName = "Query")]
public class QueryController : ControllerBase
{
    public async Task GetAsync()
    {
        await Gravatar.WriteGravatar(HttpContext);
    }
}
```

Here are some of the options for controlling the cache key:

- SetVaryByQuery - Specify one or more query string names to add to the cache key.
- SetVaryByHeader - Specify one or more HTTP headers to add to the cache key.
- VaryByValue- Specify a value to add to the cache key. The following example uses a value that indicates whether the current server time in seconds is odd or even. A new response is generated only when the number of seconds goes from odd to even or even to odd.

  C#

  ```
  builder.Services.AddOutputCache(options =>
  {
      options.AddBasePolicy(builder => builder
          .With(c =>
  c.HttpContext.Request.Path.StartsWithSegments("/blog"))
          .Tag("tag-blog"));
      options.AddBasePolicy(builder => builder.Tag("tag-all"));
      options.AddPolicy("Query", builder =>
  builder.SetVaryByQuery("culture"));
      options.AddPolicy("NoCache", builder => builder.NoCache());
      options.AddPolicy("NoLock", builder => builder.SetLocking(false));
      options.AddPolicy("VaryByValue", builder =>
          builder.VaryByValue((context) =>
              new KeyValuePair<string, string>(
              "time", (DateTime.Now.Second % 2)
                  .ToString(CultureInfo.InvariantCulture))));
  });
  ```

Use OutputCacheOptions.UseCaseSensitivePaths to specify that the path part of the key is case sensitive. The default is case insensitive.

For more options, see the OutputCachePolicyBuilder class.

Cache revalidation

Cache revalidation means the server can return a `304 Not Modified` HTTP status code instead of the full response body. This status code informs the client that the response to the request is unchanged from what the client previously received.

The following code illustrates the use of an Etag header to enable cache revalidation. If the client sends an If-None-Match header with the etag value of an earlier response, and the cache entry is fresh, the server returns 304 Not Modified instead of the full response. Here's how to set the etag value in a policy, in a Minimal API app:

C#

```
app.MapGet("/etag", async (context) =>
{
    var etag = $"\"{Guid.NewGuid():n}\"";
    context.Response.Headers.ETag = etag;
    await Gravatar.WriteGravatar(context);

}).CacheOutput();
```

And here's how to set the etag value in a controller-based API:

C#

```
[ApiController]
[Route("/[controller]")]
[OutputCache]
public class EtagController : ControllerBase
{
    public async Task GetAsync()
    {
        var etag = $"\"{Guid.NewGuid():n}\"";
        HttpContext.Response.Headers.ETag = etag;
        await Gravatar.WriteGravatar(HttpContext);
    }
}
```

Another way to do cache revalidation is to check the date of the cache entry creation compared to the date requested by the client. When the request header `If-Modified-`

`Since` is provided, output caching returns 304 if the cached entry is older and isn't expired.

Cache revalidation is automatic in response to these headers sent from the client. No special configuration is required on the server to enable this behavior, aside from enabling output caching.

Use tags to evict cache entries

You can use tags to identify a group of endpoints and evict all cache entries for the group. For example, the following minimal API code creates a pair of endpoints whose URLs begin with "blog", and tags them "tag-blog":

C#

```
app.MapGet("/blog", Gravatar.WriteGravatar)
    .CacheOutput(builder => builder.Tag("tag-blog"));
app.MapGet("/blog/post/{id}", Gravatar.WriteGravatar)
    .CacheOutput(builder => builder.Tag("tag-blog"));
```

The following code shows how to assign tags to an endpoint in a controller-based API:

C#

```
[ApiController]
[Route("/[controller]")]
[OutputCache(Tags = new[] { "tag-blog", "tag-all" })]
public class TagEndpointController : ControllerBase
{
    public async Task GetAsync()
    {
        await Gravatar.WriteGravatar(HttpContext);
    }
}
```

An alternative way to assign tags for endpoints with routes that begin with `blog` is to define a base policy that applies to all endpoints with that route. The following code shows how to do that:

C#

```
builder.Services.AddOutputCache(options =>
{
    options.AddBasePolicy(builder => builder
        .With(c => c.HttpContext.Request.Path.StartsWithSegments("/blog"))
        .Tag("tag-blog"));
```

```
    options.AddBasePolicy(builder => builder.Tag("tag-all"));
    options.AddPolicy("Query", builder =>
builder.SetVaryByQuery("culture"));
    options.AddPolicy("NoCache", builder => builder.NoCache());
    options.AddPolicy("NoLock", builder => builder.SetLocking(false));
});
```

Another alternative for minimal API apps is to call `MapGroup`:

C#

```
var blog = app.MapGroup("blog")
    .CacheOutput(builder => builder.Tag("tag-blog"));
blog.MapGet("/", Gravatar.WriteGravatar);
blog.MapGet("/post/{id}", Gravatar.WriteGravatar);
```

In the preceding tag assignment examples, both endpoints are identified by the `tag-blog` tag. You can then evict the cache entries for those endpoints with a single statement that references that tag:

C#

```
app.MapPost("/purge/{tag}", async (IOutputCacheStore cache, string tag) =>
{
    await cache.EvictByTagAsync(tag, default);
});
```

With this code, an HTTP POST request sent to `https://localhost:<port>/purge/tag-blog` evicts cache entries for these endpoints.

You might want a way to evict all cache entries for all endpoints. To do that, create a base policy for all endpoints as the following code does:

C#

```
builder.Services.AddOutputCache(options =>
{
    options.AddBasePolicy(builder => builder
        .With(c => c.HttpContext.Request.Path.StartsWithSegments("/blog"))
        .Tag("tag-blog"));
    options.AddBasePolicy(builder => builder.Tag("tag-all"));
    options.AddPolicy("Query", builder =>
builder.SetVaryByQuery("culture"));
    options.AddPolicy("NoCache", builder => builder.NoCache());
    options.AddPolicy("NoLock", builder => builder.SetLocking(false));
});
```

This base policy enables you to use the "tag-all" tag to evict everything in cache.

Disable resource locking

By default, resource locking is enabled to mitigate the risk of cache stampede and thundering herd. For more information, see Output Caching.

To disable resource locking, call SetLocking(false) while creating a policy, as shown in the following example:

C#

```
builder.Services.AddOutputCache(options =>
{
    options.AddBasePolicy(builder => builder
        .With(c => c.HttpContext.Request.Path.StartsWithSegments("/blog"))
        .Tag("tag-blog"));
    options.AddBasePolicy(builder => builder.Tag("tag-all"));
    options.AddPolicy("Query", builder =>
builder.SetVaryByQuery("culture"));
    options.AddPolicy("NoCache", builder => builder.NoCache());
    options.AddPolicy("NoLock", builder => builder.SetLocking(false));
});
```

The following example selects the no-locking policy for an endpoint in a minimal API app:

C#

```
app.MapGet("/nolock", Gravatar.WriteGravatar)
    .CacheOutput("NoLock");
```

In a controller-based API, use the attribute to select the policy:

C#

```
[ApiController]
[Route("/[controller]")]
[OutputCache(PolicyName = "NoLock")]
public class NoLockController : ControllerBase
{
    public async Task GetAsync()
    {
        await Gravatar.WriteGravatar(HttpContext);
    }
}
```

Limits

The following properties of OutputCacheOptions let you configure limits that apply to all endpoints:

- SizeLimit - Maximum size of cache storage. When this limit is reached, no new responses are cached until older entries are evicted. Default value is 100 MB.
- MaximumBodySize - If the response body exceeds this limit, it isn't cached. Default value is 64 MB.
- DefaultExpirationTimeSpan - The expiration time duration that applies when not specified by a policy. Default value is 60 seconds.

Cache storage

IOutputCacheStore is used for storage. By default it's used with MemoryCache. Cached responses are stored in-process, so each server has a separate cache that is lost whenever the server process is restarted.

Redis cache

An alternative is to use Redis cache. Redis cache provides consistency between server nodes via a shared cache that outlives individual server processes. To use Redis for output caching:

- Install the Microsoft.AspNetCore.OutputCaching.StackExchangeRedis NuGet package.
- Call `builder.Services.AddStackExchangeRedisOutputCache` (not `AddStackExchangeRedisCache`), and provide a connection string that points to a Redis server.

  For example:

  C#

```
builder.Services.AddStackExchangeRedisOutputCache(options =>
{
    options.Configuration =
        builder.Configuration.GetConnectionString("MyRedisConStr");
    options.InstanceName = "SampleInstance";
});

builder.Services.AddOutputCache(options =>
{
```

```
    options.AddBasePolicy(builder =>
        builder.Expire(TimeSpan.FromSeconds(10)));
});
```

- options.Configuration - A connection string to an on-premises Redis server or to a hosted offering such as Azure Cache for Redis. For example, `<instance_name>.redis.cache.windows.net:6380,password=<password>,ssl=True,abortConnect=False` for Azure cache for Redis.
- options.InstanceName - Optional, specifies a logical partition for the cache.

The configuration options are identical to the Redis-based distributed caching options.

`IDistributedCache` not recommended

We don't recommend IDistributedCache for use with output caching. `IDistributedCache` doesn't have atomic features, which are required for tagging. We recommend that you use the built-in support for Redis or create custom IOutputCacheStore implementations by using direct dependencies on the underlying storage mechanism.

Response caching in ASP.NET Core

Article • 04/10/2024

By Rick Anderson and Kirk Larkin

View or download sample code (how to download)

Response caching reduces the number of requests a client or proxy makes to a web server. Response caching also reduces the amount of work the web server performs to generate a response. Response caching is set in headers.

The ResponseCache attribute sets response caching headers. Clients and intermediate proxies should honor the headers for caching responses under RFC 9111: HTTP Caching.

For server-side caching that follows the HTTP 1.1 Caching specification, use Response Caching Middleware. The middleware can use the ResponseCacheAttribute properties to influence server-side caching behavior.

The Response caching middleware:

- Enables caching server responses based on HTTP cache headers. Implements the standard HTTP caching semantics. Caches based on HTTP cache headers like proxies do.
- Is typically not beneficial for UI apps such as Razor Pages because browsers generally set request headers that prevent caching. Output caching, which is available in ASP.NET Core 7.0 and later, benefits UI apps. With output caching, configuration decides what should be cached independently of HTTP headers.
- May be beneficial for public GET or HEAD API requests from clients where the Conditions for caching are met.

To test response caching, use Fiddler, or another tool that can explicitly set request headers. Setting headers explicitly is preferred for testing caching. For more information, see Troubleshooting.

HTTP-based response caching

RFC 9111: HTTP Caching describes how Internet caches should behave. The primary HTTP header used for caching is Cache-Control, which is used to specify cache directives. The directives control caching behavior as requests make their way from clients to servers and as responses make their way from servers back to clients. Requests

and responses move through proxy servers, and proxy servers must also conform to the HTTP 1.1 Caching specification.

Common `Cache-Control` directives are shown in the following table.

Expand table

Directive	Action
public	A cache may store the response.
private	The response must not be stored by a shared cache. A private cache may store and reuse the response.
max-age	The client doesn't accept a response whose age is greater than the specified number of seconds. Examples: `max-age=60` (60 seconds), `max-age=2592000` (1 month)
no-cache	**On requests**: A cache must not use a stored response to satisfy the request. The origin server regenerates the response for the client, and the middleware updates the stored response in its cache. **On responses**: The response must not be used for a subsequent request without validation on the origin server.
no-store	**On requests**: A cache must not store the request. **On responses**: A cache must not store any part of the response.

Other cache headers that play a role in caching are shown in the following table.

Expand table

Header	Function
Age	An estimate of the amount of time in seconds since the response was generated or successfully validated at the origin server.
Expires	The time after which the response is considered stale.
Pragma	Exists for backwards compatibility with HTTP/1.0 caches for setting `no-cache` behavior. If the `Cache-Control` header is present, the `Pragma` header is ignored.
Vary	Specifies that a cached response must not be sent unless all of the `Vary` header fields match in both the cached response's original request and the new request.

HTTP-based caching respects request Cache-Control directives

RFC 9111: HTTP Caching (Section 5.2. Cache-Control) requires a cache to honor a valid `Cache-Control` header sent by the client. A client can make requests with a `no-cache` header value and force the server to generate a new response for every request.

Always honoring client `Cache-Control` request headers makes sense if you consider the goal of HTTP caching. Under the official specification, caching is meant to reduce the latency and network overhead of satisfying requests across a network of clients, proxies, and servers. It isn't necessarily a way to control the load on an origin server.

There's no developer control over this caching behavior when using the Response Caching Middleware because the middleware adheres to the official caching specification. Support for *output caching* to better control server load was added in .NET 7. For more information, see Output caching.

ResponseCache attribute

The ResponseCacheAttribute specifies the parameters necessary for setting appropriate headers in response caching.

> ⚠ **Warning**
>
> Disable caching for content that contains information for authenticated clients. Caching should only be enabled for content that doesn't change based on a user's identity or whether a user is signed in.

VaryByQueryKeys varies the stored response by the values of the given list of query keys. When a single value of `*` is provided, the middleware varies responses by all request query string parameters.

Response Caching Middleware must be enabled to set the VaryByQueryKeys property. Otherwise, a runtime exception is thrown. There isn't a corresponding HTTP header for the VaryByQueryKeys property. The property is an HTTP feature handled by Response Caching Middleware. For the middleware to serve a cached response, the query string and query string value must match a previous request. For example, consider the sequence of requests and results shown in the following table:

Expand table

Request	Returned from
`http://example.com?key1=value1`	Server

Request	Returned from
`http://example.com?key1=value1`	Middleware
`http://example.com?key1=NewValue`	Server

The first request is returned by the server and cached in middleware. The second request is returned by middleware because the query string matches the previous request. The third request isn't in the middleware cache because the query string value doesn't match a previous request.

The ResponseCacheAttribute is used to configure and create (via IFilterFactory) a `Microsoft.AspNetCore.Mvc.Internal.ResponseCacheFilter`. The `ResponseCacheFilter` performs the work of updating the appropriate HTTP headers and features of the response. The filter:

- Removes any existing headers for `Vary`, `Cache-Control`, and `Pragma`.
- Writes out the appropriate headers based on the properties set in the ResponseCacheAttribute.
- Updates the response caching HTTP feature if VaryByQueryKeys is set.

Vary

This header is only written when the VaryByHeader property is set. The property set to the `Vary` property's value. The following sample uses the VaryByHeader property:

C#

```
[ApiController]
public class TimeController : ControllerBase
{
    [Route("api/[controller]")]
    [HttpGet]
    [ResponseCache(VaryByHeader = "User-Agent", Duration = 30)]
    public ContentResult GetTime() => Content(
                      DateTime.Now.Millisecond.ToString());
```

View the response headers with Fiddler or another tool. The response headers include:

text

```
Cache-Control: public,max-age=30
Vary: User-Agent
```

The preceding code requires adding the Response Caching Middleware services AddResponseCaching to the service collection and configures the app to use the middleware with the UseResponseCaching extension method.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddResponseCaching();

var app = builder.Build();

app.UseHttpsRedirection();

// UseCors must be called before UseResponseCaching
//app.UseCors();

app.UseResponseCaching();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

`NoStore` and `Location.None`

NoStore overrides most of the other properties. When this property is set to `true`, the `Cache-Control` header is set to `no-store`. If Location is set to `None`:

- `Cache-Control` is set to `no-store,no-cache`.
- `Pragma` is set to `no-cache`.

If NoStore is `false` and Location is `None`, `Cache-Control`, and `Pragma` are set to `no-cache`.

NoStore is typically set to `true` for error pages. The following produces response headers that instruct the client not to store the response.

C#

```
[Route("api/[controller]/ticks")]
[HttpGet]
[ResponseCache(Location = ResponseCacheLocation.None, NoStore = true)]
public ContentResult GetTimeTicks() => Content(
                  DateTime.Now.Ticks.ToString());
```

The preceding code includes the following headers in the response:

```
Cache-Control: no-store,no-cache
Pragma: no-cache
```

To apply the ResponseCacheAttribute to all of the app's MVC controller or Razor Pages page responses, add it with an MVC filter or Razor Pages filter.

In an MVC app:

C#

```
builder.Services.AddControllersWithViews().AddMvcOptions(options =>
    options.Filters.Add(
        new ResponseCacheAttribute
        {
            NoStore = true,
            Location = ResponseCacheLocation.None
        }));
```

For an approach that applies to Razor Pages apps, see Adding ResponseCacheAttribute to MVC global filter list does not apply to Razor Pages (dotnet/aspnetcore #18890). The example provided in the issue comment was written for apps targeting ASP.NET Core prior to the release of Minimal APIs at 6.0. For 6.0 or later apps, change the service registration in the example to `builder.Services.AddSingleton...` for `Program.cs`.

Location and Duration

To enable caching, Duration must be set to a positive value and Location must be either `Any` (the default) or `Client`. The framework sets the `Cache-Control` header to the location value followed by the `max-age` of the response.

Location's options of `Any` and `Client` translate into `Cache-Control` header values of `public` and `private`, respectively. As noted in the NoStore and Location.None section, setting Location to `None` sets both `Cache-Control` and `Pragma` headers to `no-cache`.

`Location.Any` (`Cache-Control` set to `public`) indicates that the *client or any intermediate proxy* may cache the value, including Response Caching Middleware.

`Location.Client` (`Cache-Control` set to `private`) indicates that *only the client* may cache the value. No intermediate cache should cache the value, including Response Caching Middleware.

Cache control headers provide guidance to clients and intermediary proxies when and how to cache responses. There's no guarantee that clients and proxies will honor RFC 9111: HTTP Caching. Response Caching Middleware always follows the caching rules laid out by the specification.

The following example shows the headers produced by setting Duration and leaving the default Location value:

C#

```
[Route("api/[controller]/ms")]
[HttpGet]
[ResponseCache(Duration = 10, Location = ResponseCacheLocation.Any, NoStore
= false)]
public ContentResult GetTimeMS() => Content(
                  DateTime.Now.Millisecond.ToString());
```

The preceding code includes the following headers in the response:

```
Cache-Control: public,max-age=10
```

Cache profiles

Instead of duplicating response cache settings on many controller action attributes, cache profiles can be configured as options when setting up MVC/Razor Pages. Values found in a referenced cache profile are used as the defaults by the ResponseCacheAttribute and are overridden by any properties specified on the attribute.

The following example shows a 30 second cache profile:

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddResponseCaching();
builder.Services.AddControllers(options =>
{
    options.CacheProfiles.Add("Default30",
        new CacheProfile()
        {
            Duration = 30
        });
});

var app = builder.Build();

app.UseHttpsRedirection();

// UseCors must be called before UseResponseCaching
//app.UseCors();

app.UseResponseCaching();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

The following code references the `Default30` cache profile:

C#

```
[ApiController]
[ResponseCache(CacheProfileName = "Default30")]
public class Time2Controller : ControllerBase
{
    [Route("api/[controller]")]
    [HttpGet]
    public ContentResult GetTime() => Content(
                    DateTime.Now.Millisecond.ToString());

    [Route("api/[controller]/ticks")]
    [HttpGet]
    public ContentResult GetTimeTicks() => Content(
                    DateTime.Now.Ticks.ToString());
}
```

The resulting header response by the `Default30` cache profile includes:

```
Cache-Control: public,max-age=30
```

The [ResponseCache] attribute can be applied to:

- Razor Pages: Attributes can't be applied to handler methods. Browsers used with UI apps prevent response caching.
- MVC controllers.
- MVC action methods: Method-level attributes override the settings specified in class-level attributes.

The following code applies the `[ResponseCache]` attribute at the controller level and method level:

C#

```
[ApiController]
[ResponseCache(VaryByHeader = "User-Agent", Duration = 30)]
public class Time4Controller : ControllerBase
{
    [Route("api/[controller]")]
    [HttpGet]
    public ContentResult GetTime() => Content(
                      DateTime.Now.Millisecond.ToString());

    [Route("api/[controller]/ticks")]
    [HttpGet]
    public ContentResult GetTimeTicks() => Content(
                  DateTime.Now.Ticks.ToString());

    [Route("api/[controller]/ms")]
    [HttpGet]
    [ResponseCache(Duration = 10, Location = ResponseCacheLocation.Any,
NoStore = false)]
    public ContentResult GetTimeMS() => Content(
                      DateTime.Now.Millisecond.ToString());
}
```

Response Caching Middleware in ASP.NET Core

Article • 07/16/2024

By John Luo and Rick Anderson

This article explains how to configure Response Caching Middleware in an ASP.NET Core app. The middleware determines when responses are cacheable, stores responses, and serves responses from cache. For an introduction to HTTP caching and the [ResponseCache] attribute, see Response Caching.

The Response caching middleware:

- Enables caching server responses based on HTTP cache headers. Implements the standard HTTP caching semantics. Caches based on HTTP cache headers like proxies do.
- Is typically not beneficial for UI apps such as Razor Pages because browsers generally set request headers that prevent caching. Output caching, which is available in ASP.NET Core 7.0 and later, benefits UI apps. With output caching, configuration decides what should be cached independently of HTTP headers.
- May be beneficial for public GET or HEAD API requests from clients where the Conditions for caching are met.

To test response caching, use Fiddler, or another tool that can explicitly set request headers. Setting headers explicitly is preferred for testing caching. For more information, see Troubleshooting.

Configuration

In `Program.cs`, add the Response Caching Middleware services AddResponseCaching to the service collection and configure the app to use the middleware with the UseResponseCaching extension method. `UseResponseCaching` adds the middleware to the request processing pipeline:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCaching();

var app = builder.Build();
```

```
app.UseHttpsRedirection();

// UseCors must be called before UseResponseCaching
//app.UseCors();

app.UseResponseCaching();
```

> ⚠ **Warning**
>
> UseCors must be called before UseResponseCaching when using CORS middleware.

The sample app adds headers to control caching on subsequent requests:

- Cache-Control: Caches cacheable responses for up to 10 seconds.
- Vary: Configures the middleware to serve a cached response only if the Accept-Encoding header of subsequent requests matches that of the original request.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCaching();

var app = builder.Build();

app.UseHttpsRedirection();

// UseCors must be called before UseResponseCaching
//app.UseCors();

app.UseResponseCaching();

app.Use(async (context, next) =>
{
    context.Response.GetTypedHeaders().CacheControl =
        new Microsoft.Net.Http.Headers.CacheControlHeaderValue()
        {
            Public = true,
            MaxAge = TimeSpan.FromSeconds(10)
        };
    context.Response.Headers[Microsoft.Net.Http.Headers.HeaderNames.Vary] =
        new string[] { "Accept-Encoding" };

    await next();
});

app.MapGet("/", () => DateTime.Now.Millisecond);
```

```
app.Run();
```

The preceding headers are not written to the response and are overridden when a controller, action, or Razor Page:

- Has a [ResponseCache] attribute. This applies even if a property isn't set. For example, omitting the VaryByHeader property will cause the corresponding header to be removed from the response.

Response Caching Middleware only caches server responses that result in a 200 (OK) status code. Any other responses, including error pages, are ignored by the middleware.

> ⚠ **Warning**
>
> Responses containing content for authenticated clients must be marked as not cacheable to prevent the middleware from storing and serving those responses. See **Conditions for caching** for details on how the middleware determines if a response is cacheable.

The preceding code typically doesn't return a cached value to a browser. Use Fiddler or another tool that can explicitly set request headers and is preferred for testing caching. For more information, see Troubleshooting in this article.

Options

Response caching options are shown in the following table.

Expand table

Option	Description
MaximumBodySize	The largest cacheable size for the response body in bytes. The default value is `64 * 1024 * 1024` (64 MB).
SizeLimit	The size limit for the response cache middleware in bytes. The default value is `100 * 1024 * 1024` (100 MB).
UseCaseSensitivePaths	Determines if responses are cached on case-sensitive paths. The default value is `false`.

The following example configures the middleware to:

- Cache responses with a body size smaller than or equal to 1,024 bytes.

- Store the responses by case-sensitive paths. For example, `/page1` and `/Page1` are stored separately.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCaching(options =>
{
    options.MaximumBodySize = 1024;
    options.UseCaseSensitivePaths = true;
});

var app = builder.Build();

app.UseHttpsRedirection();

// UseCors must be called before UseResponseCaching
//app.UseCors();

app.UseResponseCaching();

app.Use(async (context, next) =>
{
    context.Response.GetTypedHeaders().CacheControl =
        new Microsoft.Net.Http.Headers.CacheControlHeaderValue()
        {
            Public = true,
            MaxAge = TimeSpan.FromSeconds(10)
        };
    context.Response.Headers[Microsoft.Net.Http.Headers.HeaderNames.Vary] =
        new string[] { "Accept-Encoding" };

    await next(context);
});

app.MapGet("/", () => DateTime.Now.Millisecond);

app.Run();
```

VaryByQueryKeys

When using MVC, web API controllers, or Razor Pages page models, the [ResponseCache] attribute specifies the parameters necessary for setting the appropriate headers for response caching. The only parameter of the `[ResponseCache]` attribute that strictly requires the middleware is VaryByQueryKeys, which doesn't correspond to an actual HTTP header. For more information, see Response caching in ASP.NET Core.

When not using the `[ResponseCache]` attribute, response caching can be varied with `VaryByQueryKeys`. Use the ResponseCachingFeature directly from the HttpContext.Features:

```
C#

var responseCachingFeature =
context.HttpContext.Features.Get<IResponseCachingFeature>();

if (responseCachingFeature != null)
{
    responseCachingFeature.VaryByQueryKeys = new[] { "MyKey" };
}
```

Using a single value equal to `*` in `VaryByQueryKeys` varies the cache by all request query parameters.

HTTP headers used by Response Caching Middleware

The following table provides information on HTTP headers that affect response caching.

Expand table

Header	Details
`Authorization`	The response isn't cached if the header exists.
`Cache-Control`	The middleware only considers caching responses marked with the `public` cache directive. Control caching with the following parameters: • max-age • max-stale† • min-fresh • must-revalidate • no-cache • no-store • only-if-cached • private • public • s-maxage • proxy-revalidate‡ †If no limit is specified to `max-stale`, the middleware takes no action. ‡`proxy-revalidate` has the same effect as `must-revalidate`.

Header	Details
	For more information, see RFC 9111: Request Directives.
`Pragma`	A `Pragma: no-cache` header in the request produces the same effect as `Cache-Control: no-cache`. This header is overridden by the relevant directives in the `Cache-Control` header, if present. Considered for backward compatibility with HTTP/1.0.
`Set-Cookie`	The response isn't cached if the header exists. Any middleware in the request processing pipeline that sets one or more cookies prevents the Response Caching Middleware from caching the response (for example, the cookie-based TempData provider).
`Vary`	The `Vary` header is used to vary the cached response by another header. For example, cache responses by encoding by including the `Vary: Accept-Encoding` header, which caches responses for requests with headers `Accept-Encoding: gzip` and `Accept-Encoding: text/plain` separately. A response with a header value of `*` is never stored.
`Expires`	A response deemed stale by this header isn't stored or retrieved unless overridden by other `Cache-Control` headers.
`If-None-Match`	The full response is served from cache if the value isn't `*` and the `ETag` of the response doesn't match any of the values provided. Otherwise, a 304 (Not Modified) response is served.
`If-Modified-Since`	If the `If-None-Match` header isn't present, a full response is served from cache if the cached response date is newer than the value provided. Otherwise, a *304 - Not Modified* response is served.
`Date`	When serving from cache, the `Date` header is set by the middleware if it wasn't provided on the original response.
`Content-Length`	When serving from cache, the `Content-Length` header is set by the middleware if it wasn't provided on the original response.
`Age`	The `Age` header sent in the original response is ignored. The middleware computes a new value when serving a cached response.

Caching respects request Cache-Control directives

The middleware respects the rules of RFC 9111: HTTP Caching (Section 5.2. Cache-Control). The rules require a cache to honor a valid `Cache-Control` header sent by the client. Under the specification, a client can make requests with a `no-cache` header value

and force the server to generate a new response for every request. Currently, there's no developer control over this caching behavior when using the middleware because the middleware adheres to the official caching specification.

For more control over caching behavior, explore other caching features of ASP.NET Core. See the following topics:

- Cache in-memory in ASP.NET Core
- Distributed caching in ASP.NET Core
- Cache Tag Helper in ASP.NET Core MVC
- Distributed Cache Tag Helper in ASP.NET Core

Troubleshooting

The Response Caching Middleware uses IMemoryCache, which has a limited capacity. When the capacity is exceeded, the memory cache is compacted.

If caching behavior isn't as expected, confirm that responses are cacheable and capable of being served from the cache. Examine the request's incoming headers and the response's outgoing headers. Enable logging to help with debugging.

When testing and troubleshooting caching behavior, a browser typically sets request headers that prevent caching. For example, a browser may set the `Cache-Control` header to `no-cache` or `max-age=0` when refreshing a page. Fiddler and other tools can explicitly set request headers and are preferred for testing caching.

Conditions for caching

- The request must result in a server response with a 200 (OK) status code.
- The request method must be GET or HEAD.
- Response Caching Middleware must be placed before middleware that require caching. For more information, see ASP.NET Core Middleware.
- The `Authorization` header must not be present.
- `Cache-Control` header parameters must be valid, and the response must be marked `public` and not marked `private`.
- The `Pragma: no-cache` header must not be present if the `Cache-Control` header isn't present, as the `Cache-Control` header overrides the `Pragma` header when present.
- The `Set-Cookie` header must not be present.
- `Vary` header parameters must be valid and not equal to `*`.

- The `Content-Length` header value (if set) must match the size of the response body.
- The IHttpSendFileFeature isn't used.
- The response must not be stale as specified by the `Expires` header and the `max-age` and `s-maxage` cache directives.
- Response buffering must be successful. The size of the response must be smaller than the configured or default SizeLimit. The body size of the response must be smaller than the configured or default MaximumBodySize.
- The response must be cacheable according to RFC 9111: HTTP Caching. For example, the `no-store` directive must not exist in request or response header fields. See RFC 9111: HTTP Caching (Section 3: *Storing Responses in Caches*) for details.

> **Note**
>
> The Antiforgery system for generating secure tokens to prevent Cross-Site Request Forgery (CSRF) attacks sets the `Cache-Control` and `Pragma` headers to `no-cache` so that responses aren't cached. For information on how to disable antiforgery tokens for HTML form elements, see **Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core**.

Rate limiting middleware in ASP.NET Core

Article • 06/17/2024

By Arvin Kahbazi, Maarten Balliauw, and Rick Anderson

The `Microsoft.AspNetCore.RateLimiting` middleware provides rate limiting middleware. Apps configure rate limiting policies and then attach the policies to endpoints. Apps using rate limiting should be carefully load tested and reviewed before deploying. See Testing endpoints with rate limiting in this article for more information.

For an introduction to rate limiting, see Rate limiting middleware.

Rate limiter algorithms

The RateLimiterOptionsExtensions class provides the following extension methods for rate limiting:

- Fixed window
- Sliding window
- Token bucket
- Concurrency

Fixed window limiter

The AddFixedWindowLimiter method uses a fixed time window to limit requests. When the time window expires, a new time window starts and the request limit is reset.

Consider the following code:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRateLimiter(_ => _
    .AddFixedWindowLimiter(policyName: "fixed", options =>
    {
        options.PermitLimit = 4;
        options.Window = TimeSpan.FromSeconds(12);
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
```

```
        options.QueueLimit = 2;
    }));

var app = builder.Build();

app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Hello {GetTicks()}"))
                          .RequireRateLimiting("fixed");

app.Run();
```

The preceding code:

- Calls AddRateLimiter to add a rate limiting service to the service collection.
- Calls `AddFixedWindowLimiter` to create a fixed window limiter with a policy name of `"fixed"` and sets:
- PermitLimit to 4 and the time Window to 12. A maximum of 4 requests per each 12-second window are allowed.
- QueueProcessingOrder to OldestFirst.
- QueueLimit to 2.
- Calls UseRateLimiter to enable rate limiting.

Apps should use Configuration to set limiter options. The following code updates the preceding code using MyRateLimitOptions for configuration:

C#

```
using System.Threading.RateLimiting;
using Microsoft.AspNetCore.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);
builder.Services.Configure<MyRateLimitOptions>(
    builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit));

var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);
var fixedPolicy = "fixed";

builder.Services.AddRateLimiter(_ => _
    .AddFixedWindowLimiter(policyName: fixedPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
```

```
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();

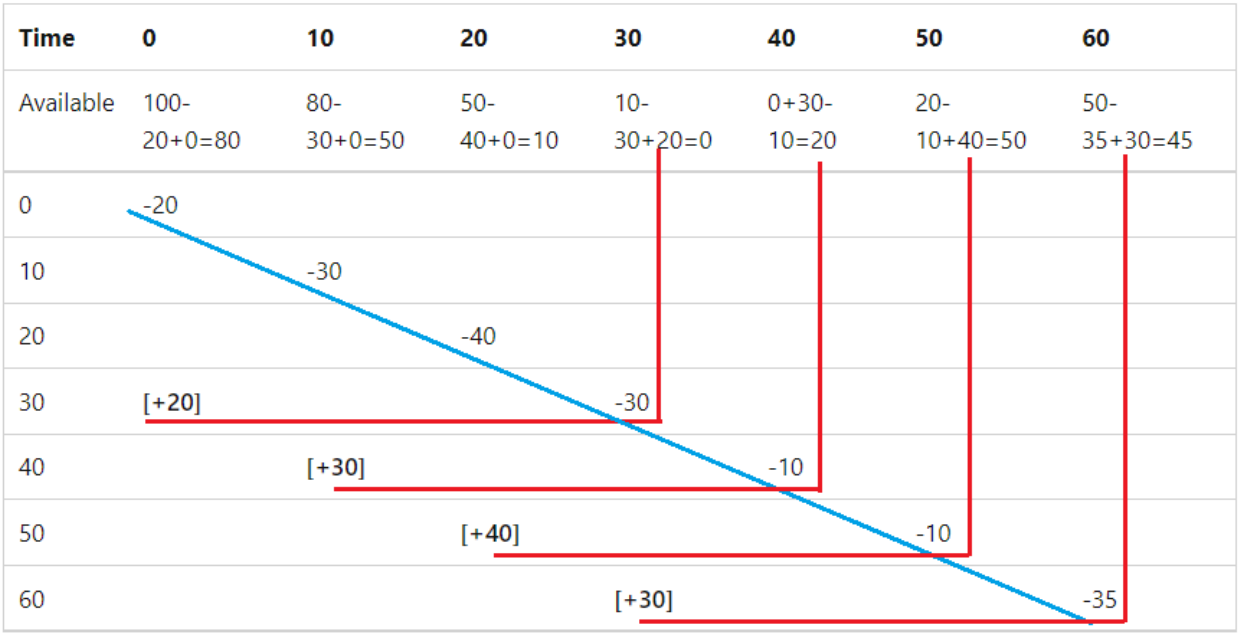
app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Fixed Window Limiter {GetTicks()}"))
                            .RequireRateLimiting(fixedPolicy);

app.Run();
```

UseRateLimiter must be called after `UseRouting` when rate limiting endpoint specific APIs are used. For example, if the [EnableRateLimiting] attribute is used, `UseRateLimiter` must be called after `UseRouting`. When calling only global limiters, `UseRateLimiter` can be called before `UseRouting`.



Sliding window limiter

A sliding window algorithm:

- Is similar to the fixed window limiter but adds segments per window. The window slides one segment each segment interval. The segment interval is (window time)/(segments per window).
- Limits the requests for a window to `permitLimit` requests.
- Each time window is divided in `n` segments per window.
- Requests taken from the expired time segment one window back (`n` segments prior to the current segment) are added to the current segment. We refer to the most expired time segment one window back as the expired segment.

Consider the following table that shows a sliding window limiter with a 30-second window, three segments per window, and a limit of 100 requests:

- The top row and first column shows the time segment.
- The second row shows the remaining requests available. The remaining requests are calculated as the available requests minus the processed requests plus the recycled requests.
- Requests at each time moves along the diagonal blue line.
- From time 30 on, the request taken from the expired time segment are added back to the request limit, as shown in the red lines.

The following table shows the data in the previous graph in a different format. The **Available** column shows the requests available from the previous segment (The **Carry over** from the previous row). The first row shows 100 available requests because there's no previous segment.

Expand table

Time	Available	Taken	Recycled from expired	Carry over
0	100	20	0	80
10	80	30	0	50
20	50	40	0	10
30	10	30	20	0
40	0	10	30	20
50	20	10	40	50
60	50	35	30	45

The following code uses the sliding window rate limiter:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);
```

```
var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);
var slidingPolicy = "sliding";

builder.Services.AddRateLimiter(_ => _
    .AddSlidingWindowLimiter(policyName: slidingPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.SegmentsPerWindow = myOptions.SegmentsPerWindow;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();

app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Sliding Window Limiter {GetTicks()}"))
                          .RequireRateLimiting(slidingPolicy);

app.Run();
```

Token bucket limiter

The token bucket limiter is similar to the sliding window limiter, but rather than adding back the requests taken from the expired segment, a fixed number of tokens are added each replenishment period. The tokens added each segment can't increase the available tokens to a number higher than the token bucket limit. The following table shows a token bucket limiter with a limit of 100 tokens and a 10-second replenishment period.

Expand table

Time	Available	Taken	Added	Carry over
0	100	20	0	80
10	80	10	20	90
20	90	5	15	100
30	100	30	20	90
40	90	6	16	100
50	100	40	20	80

Time	Available	Taken	Added	Carry over
60	80	50	20	50

The following code uses the token bucket limiter:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

var tokenPolicy = "token";
var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);

builder.Services.AddRateLimiter(_ => _
    .AddTokenBucketLimiter(policyName: tokenPolicy, options =>
    {
        options.TokenLimit = myOptions.TokenLimit;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
        options.ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod);
        options.TokensPerPeriod = myOptions.TokensPerPeriod;
        options.AutoReplenishment = myOptions.AutoReplenishment;
    }));

var app = builder.Build();

app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Token Limiter {GetTicks()}"))
                            .RequireRateLimiting(tokenPolicy);

app.Run();
```

When AutoReplenishment is set to `true`, an internal timer replenishes the tokens every ReplenishmentPeriod; when set to `false`, the app must call TryReplenish on the limiter.

Concurrency limiter

The concurrency limiter limits the number of concurrent requests. Each request reduces the concurrency limit by one. When a request completes, the limit is increased by one.

Unlike the other requests limiters that limit the total number of requests for a specified period, the concurrency limiter limits only the number of concurrent requests and doesn't cap the number of requests in a time period.

The following code uses the concurrency limiter:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

var concurrencyPolicy = "Concurrency";
var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);

builder.Services.AddRateLimiter(_ => _
    .AddConcurrencyLimiter(policyName: concurrencyPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();

app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", async () =>
{
    await Task.Delay(500);
    return Results.Ok($"Concurrency Limiter {GetTicks()}");

}).RequireRateLimiting(concurrencyPolicy);

app.Run();
```

Create chained limiters

The CreateChained API allows passing in multiple PartitionedRateLimiter which are combined into one `PartitionedRateLimiter`. The combined limiter runs all the input limiters in sequence.

The following code uses `CreateChained`:

C#

```
using System.Globalization;
using System.Threading.RateLimiting;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRateLimiter(_ =>
{
    _.OnRejected = (context, _) =>
    {
        if (context.Lease.TryGetMetadata(MetadataName.RetryAfter, out var
retryAfter))
        {
            context.HttpContext.Response.Headers.RetryAfter =
                ((int)
retryAfter.TotalSeconds).ToString(NumberFormatInfo.InvariantInfo);
        }

        context.HttpContext.Response.StatusCode =
StatusCodes.Status429TooManyRequests;
        context.HttpContext.Response.WriteAsync("Too many requests. Please
try again later.");

        return new ValueTask();
    };
    _.GlobalLimiter = PartitionedRateLimiter.CreateChained(
        PartitionedRateLimiter.Create<HttpContext, string>(httpContext =>
        {
            var userAgent =
httpContext.Request.Headers.UserAgent.ToString();

            return RateLimitPartition.GetFixedWindowLimiter
            (userAgent, _ =>
                new FixedWindowRateLimiterOptions
                {
                    AutoReplenishment = true,
                    PermitLimit = 4,
                    Window = TimeSpan.FromSeconds(2)
                });
        }),
        PartitionedRateLimiter.Create<HttpContext, string>(httpContext =>
        {
            var userAgent =
httpContext.Request.Headers.UserAgent.ToString();

            return RateLimitPartition.GetFixedWindowLimiter
            (userAgent, _ =>
                new FixedWindowRateLimiterOptions
                {
                    AutoReplenishment = true,
                    PermitLimit = 20,
                    Window = TimeSpan.FromSeconds(30)
                });
```

```
        }));
});

var app = builder.Build();
app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Hello {GetTicks()}"));

app.Run();
```

For more information, see the CreateChained source code

`EnableRateLimiting` and `DisableRateLimiting` attributes

The [EnableRateLimiting] and [DisableRateLimiting] attributes can be applied to a Controller, action method, or Razor Page. For Razor Pages, the attribute must be applied to the Razor Page and not the page handlers. For example, `[EnableRateLimiting]` can't be applied to `OnGet`, `OnPost`, or any other page handler.

The `[DisableRateLimiting]` attribute ***disables*** rate limiting to the Controller, action method, or Razor Page regardless of named rate limiters or global limiters applied. For example, consider the following code which calls RequireRateLimiting to apply the `fixedPolicy` rate limiting to all controller endpoints:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.Configure<MyRateLimitOptions>(
    builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit));

var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);
var fixedPolicy = "fixed";

builder.Services.AddRateLimiter(_ => _
```

```
    .AddFixedWindowLimiter(policyName: fixedPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var slidingPolicy = "sliding";

builder.Services.AddRateLimiter(_ => _
    .AddSlidingWindowLimiter(policyName: slidingPolicy, options =>
    {
        options.PermitLimit = myOptions.SlidingPermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.SegmentsPerWindow = myOptions.SegmentsPerWindow;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();
app.UseRateLimiter();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.MapRazorPages().RequireRateLimiting(slidingPolicy);
app.MapDefaultControllerRoute().RequireRateLimiting(fixedPolicy);

app.Run();
```

In the following code, `[DisableRateLimiting]` disables rate limiting and overrides `[EnableRateLimiting("fixed")]` applied to the `Home2Controller` and `app.MapDefaultControllerRoute().RequireRateLimiting(fixedPolicy)` called in `Program.cs`:

C#

```
[EnableRateLimiting("fixed")]
public class Home2Controller : Controller
{
    private readonly ILogger<Home2Controller> _logger;

    public Home2Controller(ILogger<Home2Controller> logger)
    {
        _logger = logger;
```

```
    }

    public ActionResult Index()
    {
        return View();
    }

    [EnableRateLimiting("sliding")]
    public ActionResult Privacy()
    {
        return View();
    }

    [DisableRateLimiting]
    public ActionResult NoLimit()
    {
        return View();
    }

    [ResponseCache(Duration = 0, Location = ResponseCacheLocation.None,
NoStore = true)]
    public IActionResult Error()
    {
        return View(new ErrorViewModel { RequestId = Activity.Current?.Id ??
HttpContext.TraceIdentifier });
    }
}
```

In the preceding code, the `[EnableRateLimiting("sliding")]` is ***not*** applied to the `Privacy` action method because `Program.cs` called `app.MapDefaultControllerRoute().RequireRateLimiting(fixedPolicy)`.

Consider the following code which doesn't call `RequireRateLimiting` on `MapRazorPages` or `MapDefaultControllerRoute`:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.Configure<MyRateLimitOptions>(
    builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit));

var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
```

```
ons);
var fixedPolicy = "fixed";

builder.Services.AddRateLimiter(_ => _
    .AddFixedWindowLimiter(policyName: fixedPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var slidingPolicy = "sliding";

builder.Services.AddRateLimiter(_ => _
    .AddSlidingWindowLimiter(policyName: slidingPolicy, options =>
    {
        options.PermitLimit = myOptions.SlidingPermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.SegmentsPerWindow = myOptions.SegmentsPerWindow;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();

app.UseRateLimiter();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.MapRazorPages();
app.MapDefaultControllerRoute();  // RequireRateLimiting not called

app.Run();
```

Consider the following controller:

C#

```
[EnableRateLimiting("fixed")]
public class Home2Controller : Controller
{
    private readonly ILogger<Home2Controller> _logger;

    public Home2Controller(ILogger<Home2Controller> logger)
    {
```

```
        _logger = logger;
    }

    public ActionResult Index()
    {
        return View();
    }

    [EnableRateLimiting("sliding")]
    public ActionResult Privacy()
    {
        return View();
    }

    [DisableRateLimiting]
    public ActionResult NoLimit()
    {
        return View();
    }

    [ResponseCache(Duration = 0, Location = ResponseCacheLocation.None,
NoStore = true)]
    public IActionResult Error()
    {
        return View(new ErrorViewModel { RequestId = Activity.Current?.Id ??
HttpContext.TraceIdentifier });
    }
}
```

In the preceding controller:

- The `"fixed"` policy rate limiter is applied to all action methods that don't have `EnableRateLimiting` and `DisableRateLimiting` attributes.
- The `"sliding"` policy rate limiter is applied to the `Privacy` action.
- Rate limiting is disabled on the `NoLimit` action method.

Applying attributes to Razor Pages

For Razor Pages, the attribute must be applied to the Razor Page and not the page handlers. For example, `[EnableRateLimiting]` can't be applied to `OnGet`, `OnPost`, or any other page handler.

The `DisableRateLimiting` attribute disables rate limiting on a Razor Page. `EnableRateLimiting` is only applied to a Razor Page if `MapRazorPages().RequireRateLimiting(Policy)` has ***not*** been called.

Limiter algorithm comparison

The fixed, sliding, and token limiters all limit the maximum number of requests in a time period. The concurrency limiter limits only the number of concurrent requests and doesn't cap the number of requests in a time period. The cost of an endpoint should be considered when selecting a limiter. The cost of an endpoint includes the resources used, for example, time, data access, CPU, and I/O.

Rate limiter samples

The following samples aren't meant for production code but are examples on how to use the limiters.

Limiter with `OnRejected`, `RetryAfter`, and `GlobalLimiter`

The following sample:

- Creates a RateLimiterOptions.OnRejected callback that is called when a request exceeds the specified limit. `retryAfter` can be used with the TokenBucketRateLimiter, FixedWindowLimiter, and SlidingWindowLimiter because these algorithms are able to estimate when more permits will be added. The `ConcurrencyLimiter` has no way of calculating when permits will be available.
- Adds the following limiters:
  - A `SampleRateLimiterPolicy` which implements the `IRateLimiterPolicy<TPartitionKey>` interface. The `SampleRateLimiterPolicy` class is shown later in this article.
  - A `SlidingWindowLimiter`:
    - With a partition for each authenticated user.
    - One shared partition for all anonymous users.
  - A GlobalLimiter that is applied to all requests. The global limiter will be executed first, followed by the endpoint-specific limiter, if one exists. The `GlobalLimiter` creates a partition for each IPAddress.

C#

```
// Preceding code removed for brevity.
using System.Globalization;
using System.Net;
using System.Threading.RateLimiting;
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using WebRateLimitAuth;
using WebRateLimitAuth.Data;
using WebRateLimitAuth.Models;
```

```
var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection") ??
    throw new InvalidOperationException("Connection string
'DefaultConnection' not found.");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();

builder.Services.Configure<MyRateLimitOptions>(
    builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit));

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var userPolicyName = "user";
var helloPolicy = "hello";
var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);

builder.Services.AddRateLimiter(limiterOptions =>
{
    limiterOptions.OnRejected = (context, cancellationToken) =>
    {
        if (context.Lease.TryGetMetadata(MetadataName.RetryAfter, out var
retryAfter))
        {
            context.HttpContext.Response.Headers.RetryAfter =
                ((int)
retryAfter.TotalSeconds).ToString(NumberFormatInfo.InvariantInfo);
        }

        context.HttpContext.Response.StatusCode =
StatusCodes.Status429TooManyRequests;
        context.HttpContext.RequestServices.GetService<ILoggerFactory>()?
            .CreateLogger("Microsoft.AspNetCore.RateLimitingMiddleware")
            .LogWarning("OnRejected: {GetUserEndPoint}",
GetUserEndPoint(context.HttpContext));

        return new ValueTask();
    };

    limiterOptions.AddPolicy<string, SampleRateLimiterPolicy>(helloPolicy);
    limiterOptions.AddPolicy(userPolicyName, context =>
    {
        var username = "anonymous user";
        if (context.User.Identity?.IsAuthenticated is true)
        {
```

```
            username = context.User.ToString()!;
        }

        return RateLimitPartition.GetSlidingWindowLimiter(username,
            _ => new SlidingWindowRateLimiterOptions
            {
                PermitLimit = myOptions.PermitLimit,
                QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                QueueLimit = myOptions.QueueLimit,
                Window = TimeSpan.FromSeconds(myOptions.Window),
                SegmentsPerWindow = myOptions.SegmentsPerWindow
            });

    });

    limiterOptions.GlobalLimiter =
PartitionedRateLimiter.Create<HttpContext, IPAddress>(context =>
    {
        IPAddress? remoteIpAddress = context.Connection.RemoteIpAddress;

        if (!IPAddress.IsLoopback(remoteIpAddress!))
        {
            return RateLimitPartition.GetTokenBucketLimiter
            (remoteIpAddress!, _ =>
                new TokenBucketRateLimiterOptions
                {
                    TokenLimit = myOptions.TokenLimit2,
                    QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                    QueueLimit = myOptions.QueueLimit,
                    ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod),
                    TokensPerPeriod = myOptions.TokensPerPeriod,
                    AutoReplenishment = myOptions.AutoReplenishment
                });
        }

        return RateLimitPartition.GetNoLimiter(IPAddress.Loopback);
    });
});

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
```

```
app.UseRouting();
app.UseRateLimiter();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages().RequireRateLimiting(userPolicyName);
app.MapDefaultControllerRoute();

static string GetUserEndPoint(HttpContext context) =>
   $"User {context.User.Identity?.Name ?? "Anonymous"} endpoint:
{context.Request.Path}"
   + $" {context.Connection.RemoteIpAddress}";
static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/a", (HttpContext context) => $"{GetUserEndPoint(context)}
{GetTicks()}")
    .RequireRateLimiting(userPolicyName);

app.MapGet("/b", (HttpContext context) => $"{GetUserEndPoint(context)}
{GetTicks()}")
    .RequireRateLimiting(helloPolicy);

app.MapGet("/c", (HttpContext context) => $"{GetUserEndPoint(context)}
{GetTicks()}");

app.Run();
```

>
> Creating partitions on client IP addresses makes the app vulnerable to Denial of Service Attacks which employ IP Source Address Spoofing. For more information, see BCP 38 RFC 2827 Network Ingress Filtering: Defeating Denial of Service Attacks which employ IP Source Address Spoofing.

See the samples repository for the complete Program.cs file.

The `SampleRateLimiterPolicy` class

C#

```
using System.Threading.RateLimiting;
using Microsoft.AspNetCore.RateLimiting;
using Microsoft.Extensions.Options;
using WebRateLimitAuth.Models;

namespace WebRateLimitAuth;

public class SampleRateLimiterPolicy : IRateLimiterPolicy<string>
```

```
{
    private Func<OnRejectedContext, CancellationToken, ValueTask>?
_onRejected;
    private readonly MyRateLimitOptions _options;

    public SampleRateLimiterPolicy(ILogger<SampleRateLimiterPolicy> logger,
                                   IOptions<MyRateLimitOptions> options)
    {
        _onRejected = (ctx, token) =>
        {
            ctx.HttpContext.Response.StatusCode =
StatusCodes.Status429TooManyRequests;
            logger.LogWarning($"Request rejected by
{nameof(SampleRateLimiterPolicy)}");
            return ValueTask.CompletedTask;
        };
        _options = options.Value;
    }

    public Func<OnRejectedContext, CancellationToken, ValueTask>? OnRejected
=> _onRejected;

    public RateLimitPartition<string> GetPartition(HttpContext httpContext)
    {
        return RateLimitPartition.GetSlidingWindowLimiter(string.Empty,
            _ => new SlidingWindowRateLimiterOptions
            {
                PermitLimit = _options.PermitLimit,
                QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                QueueLimit = _options.QueueLimit,
                Window = TimeSpan.FromSeconds(_options.Window),
                SegmentsPerWindow = _options.SegmentsPerWindow
            });
    }
}
```

In the preceding code, OnRejected uses OnRejectedContext to set the response status to 429 Too Many Requests. The default rejected status is 503 Service Unavailable.

Limiter with authorization

The following sample uses JSON Web Tokens (JWT) and creates a partition with the JWT access token. In a production app, the JWT would typically be provided by a server acting as a Security token service (STS). For local development, the dotnet user-jwts command line tool can be used to create and manage app-specific local JWTs.

C#

```
using System.Threading.RateLimiting;
using Microsoft.AspNetCore.Authentication;
```

```
using Microsoft.Extensions.Primitives;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization();
builder.Services.AddAuthentication("Bearer").AddJwtBearer();

var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);
var jwtPolicyName = "jwt";

builder.Services.AddRateLimiter(limiterOptions =>
{
    limiterOptions.RejectionStatusCode =
StatusCodes.Status429TooManyRequests;
    limiterOptions.AddPolicy(policyName: jwtPolicyName, partitioner:
httpContext =>
    {
        var accessToken =
httpContext.Features.Get<IAuthenticateResultFeature>()?

.AuthenticateResult?.Properties?.GetTokenValue("access_token")?.ToString()
                           ?? string.Empty;

        if (!StringValues.IsNullOrEmpty(accessToken))
        {
            return RateLimitPartition.GetTokenBucketLimiter(accessToken, _
=>
                new TokenBucketRateLimiterOptions
                {
                    TokenLimit = myOptions.TokenLimit2,
                    QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                    QueueLimit = myOptions.QueueLimit,
                    ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod),
                    TokensPerPeriod = myOptions.TokensPerPeriod,
                    AutoReplenishment = myOptions.AutoReplenishment
                });
        }

        return RateLimitPartition.GetTokenBucketLimiter("Anon", _ =>
            new TokenBucketRateLimiterOptions
            {
                TokenLimit = myOptions.TokenLimit,
                QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                QueueLimit = myOptions.QueueLimit,
                ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod),
                TokensPerPeriod = myOptions.TokensPerPeriod,
                AutoReplenishment = true
            });
    });
});
```

```
var app = builder.Build();

app.UseAuthorization();
app.UseRateLimiter();

app.MapGet("/", () => "Hello, World!");

app.MapGet("/jwt", (HttpContext context) => $"Hello
{GetUserEndPointMethod(context)}")
    .RequireRateLimiting(jwtPolicyName)
    .RequireAuthorization();

app.MapPost("/post", (HttpContext context) => $"Hello
{GetUserEndPointMethod(context)}")
    .RequireRateLimiting(jwtPolicyName)
    .RequireAuthorization();

app.Run();

static string GetUserEndPointMethod(HttpContext context) =>
    $"Hello {context.User.Identity?.Name ?? "Anonymous"} " +
    $"Endpoint:{context.Request.Path} Method: {context.Request.Method}";
```

Limiter with `ConcurrencyLimiter`, `TokenBucketRateLimiter`, and authorization

The following sample:

- Adds a `ConcurrencyLimiter` with a policy name of `"get"` that is used on the Razor Pages.
- Adds a `TokenBucketRateLimiter` with a partition for each authorized user and a partition for all anonymous users.
- Sets RateLimiterOptions.RejectionStatusCode to 429 Too Many Requests.

C#

```
var getPolicyName = "get";
var postPolicyName = "post";
var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);

builder.Services.AddRateLimiter(_ => _
    .AddConcurrencyLimiter(policyName: getPolicyName, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
```

```
    })
    .AddPolicy(policyName: postPolicyName, partitioner: httpContext =>
    {
        string userName = httpContext.User.Identity?.Name ?? string.Empty;

        if (!StringValues.IsNullOrEmpty(userName))
        {
            return RateLimitPartition.GetTokenBucketLimiter(userName, _ =>
                new TokenBucketRateLimiterOptions
                {
                    TokenLimit = myOptions.TokenLimit2,
                    QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                    QueueLimit = myOptions.QueueLimit,
                    ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod),
                    TokensPerPeriod = myOptions.TokensPerPeriod,
                    AutoReplenishment = myOptions.AutoReplenishment
                });
        }

        return RateLimitPartition.GetTokenBucketLimiter("Anon", _ =>
            new TokenBucketRateLimiterOptions
            {
                TokenLimit = myOptions.TokenLimit,
                QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                QueueLimit = myOptions.QueueLimit,
                ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod),
                TokensPerPeriod = myOptions.TokensPerPeriod,
                AutoReplenishment = true
            });
    }));
```

See the samples repository for the complete Program.cs file.

Testing endpoints with rate limiting

Before deploying an app using rate limiting to production, stress test the app to validate the rate limiters and options used. For example, create a JMeter script with a tool like BlazeMeter or Apache JMeter HTTP(S) Test Script Recorder and load the script to Azure Load Testing.

Creating partitions with user input makes the app vulnerable to Denial of Service (DoS) Attacks. For example, creating partitions on client IP addresses makes the app vulnerable to Denial of Service Attacks that employ IP Source Address Spoofing. For more information, see BCP 38 RFC 2827 Network Ingress Filtering: Defeating Denial of Service Attacks that employ IP Source Address Spoofing.

Request timeouts middleware in ASP.NET Core

Article • 04/10/2024

By Tom Dykstra

Apps can apply timeout limits selectively to requests. ASP.NET Core servers don't do this by default since request processing times vary widely by scenario. For example, WebSockets, static files, and calling expensive APIs would each require a different timeout limit. So ASP.NET Core provides middleware that configures timeouts per endpoint as well as a global timeout.

When a timeout limit is hit, a CancellationToken in HttpContext.RequestAborted has IsCancellationRequested set to `true`. Abort() isn't automatically called on the request, so the application may still produce a success or failure response. The default behavior if the app doesn't handle the exception and produce a response is to return status code 504.

This article explains how to configure the timeout middleware. The timeout middleware can be used in all types of ASP.NET Core apps: Minimal API, Web API with controllers, MVC, and Razor Pages. The sample app is a Minimal API, but every timeout feature it illustrates is also supported in the other app types.

Request timeouts are in the Microsoft.AspNetCore.Http.Timeouts namespace.

Note: When an app is running in debug mode, the timeout middleware doesn't trigger. This behavior is the same as for Kestrel timeouts. To test timeouts, run the app without the debugger attached.

Add the middleware to the app

Add the request timeouts middleware to the service collection by calling AddRequestTimeouts.

Add the middleware to the request processing pipeline by calling UseRequestTimeouts.

> **Note**
>
> - In apps that explicitly call UseRouting, `UseRequestTimeouts` must be called after `UseRouting`.

Adding the middleware to the app doesn't automatically start triggering timeouts. Timeout limits have to be explicitly configured.

Configure one endpoint or page

For minimal API apps, configure an endpoint to timeout by calling WithRequestTimeout, or by applying the [RequestTimeout] attribute, as shown in the following example:

C#

```
using Microsoft.AspNetCore.Http.Timeouts;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddRequestTimeouts();

var app = builder.Build();
app.UseRequestTimeouts();

app.MapGet("/", async (HttpContext context) => {
    try
    {
        await Task.Delay(TimeSpan.FromSeconds(10), context.RequestAborted);
    }
    catch (TaskCanceledException)
    {
        return Results.Content("Timeout!", "text/plain");
    }

    return Results.Content("No timeout!", "text/plain");
}).WithRequestTimeout(TimeSpan.FromSeconds(2));
// Returns "Timeout!"

app.MapGet("/attribute",
    [RequestTimeout(milliseconds: 2000)] async (HttpContext context) => {
        try
        {
            await Task.Delay(TimeSpan.FromSeconds(10),
context.RequestAborted);
        }
        catch (TaskCanceledException)
        {
            return Results.Content("Timeout!", "text/plain");
        }

        return Results.Content("No timeout!", "text/plain");
    });
// Returns "Timeout!"

app.Run();
```

For apps with controllers, apply the `[RequestTimeout]` attribute to the action method or the controller class. For Razor Pages apps, apply the attribute to the Razor page class.

Configure multiple endpoints or pages

Create named *policies* to specify timeout configuration that applies to multiple endpoints. Add a policy by calling AddPolicy:

```
C#

builder.Services.AddRequestTimeouts(options => {
    options.DefaultPolicy =
        new RequestTimeoutPolicy { Timeout = TimeSpan.FromMilliseconds(1500)
};
    options.AddPolicy("MyPolicy", TimeSpan.FromSeconds(2));
});
```

A timeout can be specified for an endpoint by policy name:

```
C#

app.MapGet("/namedpolicy", async (HttpContext context) => {
    try
    {
        await Task.Delay(TimeSpan.FromSeconds(10), context.RequestAborted);
    }
    catch (TaskCanceledException)
    {
        return Results.Content("Timeout!", "text/plain");
    }

    return Results.Content("No timeout!", "text/plain");
}).WithRequestTimeout("MyPolicy");
// Returns "Timeout!"
```

The `[RequestTimeout]` attribute can also be used to specify a named policy.

Set global default timeout policy

Specify a policy for the global default timeout configuration:

```
C#

builder.Services.AddRequestTimeouts(options => {
    options.DefaultPolicy =
        new RequestTimeoutPolicy { Timeout = TimeSpan.FromMilliseconds(1500)
};
```

```
    options.AddPolicy("MyPolicy", TimeSpan.FromSeconds(2));
});
```

The default timeout applies to endpoints that don't have a timeout specified. The following endpoint code checks for a timeout although it doesn't call the extension method or apply the attribute. The global timeout configuration applies, so the code checks for a timeout:

C#

```
app.MapGet("/", async (HttpContext context) => {
    try
    {
        await Task.Delay(TimeSpan.FromSeconds(10), context.RequestAborted);
    }
    catch
    {
        return Results.Content("Timeout!", "text/plain");
    }

    return Results.Content("No timeout!", "text/plain");
});
// Returns "Timeout!" due to default policy.
```

Specify the status code in a policy

The RequestTimeoutPolicy class has a property that can automatically set the status code when a timeout is triggered.

C#

```
builder.Services.AddRequestTimeouts(options => {
    options.DefaultPolicy = new RequestTimeoutPolicy {
        Timeout = TimeSpan.FromMilliseconds(1000),
        TimeoutStatusCode = 503
    };
    options.AddPolicy("MyPolicy2", new RequestTimeoutPolicy {
        Timeout = TimeSpan.FromMilliseconds(1000),
        WriteTimeoutResponse = async (HttpContext context) => {
            context.Response.ContentType = "text/plain";
            await context.Response.WriteAsync("Timeout from MyPolicy2!");
        }
    });
});
```

C#

```
app.MapGet("/", async (HttpContext context) => {
    try
    {
        await Task.Delay(TimeSpan.FromSeconds(10), context.RequestAborted);
    }
    catch (TaskCanceledException)
    {
        throw;
    }

    return Results.Content("No timeout!", "text/plain");
});
// Returns status code 503 due to default policy.
```

Use a delegate in a policy

The `RequestTimeoutPolicy` class has a WriteTimeoutResponse property that can be used to customize the response when a timeout is triggered.

C#

```
builder.Services.AddRequestTimeouts(options => {
    options.DefaultPolicy = new RequestTimeoutPolicy {
        Timeout = TimeSpan.FromMilliseconds(1000),
        TimeoutStatusCode = 503
    };
    options.AddPolicy("MyPolicy2", new RequestTimeoutPolicy {
        Timeout = TimeSpan.FromMilliseconds(1000),
        WriteTimeoutResponse = async (HttpContext context) => {
            context.Response.ContentType = "text/plain";
            await context.Response.WriteAsync("Timeout from MyPolicy2!");
        }
    });
});
```

C#

```
app.MapGet("/usepolicy2", async (HttpContext context) => {
    try
    {
        await Task.Delay(TimeSpan.FromSeconds(10), context.RequestAborted);
    }
    catch (TaskCanceledException)
    {
        throw;
    }

    return Results.Content("No timeout!", "text/plain");
}).WithRequestTimeout("MyPolicy2");
```

```
// Returns "Timeout from MyPolicy2!" due to WriteTimeoutResponse in
MyPolicy2.
```

Disable timeouts

To disable all timeouts including the default global timeout, use the [DisableRequestTimeout] attribute or the DisableRequestTimeout extension method:

C#

```
app.MapGet("/disablebyattr", [DisableRequestTimeout] async (HttpContext
context) => {
    try
    {
        await Task.Delay(TimeSpan.FromSeconds(10), context.RequestAborted);
    }
    catch
    {
        return Results.Content("Timeout!", "text/plain");
    }

    return Results.Content("No timeout!", "text/plain");
});
// Returns "No timeout!", ignores default timeout.
```

C#

```
app.MapGet("/disablebyext", async (HttpContext context) => {
    try
    {
        await Task.Delay(TimeSpan.FromSeconds(10), context.RequestAborted);
    }
    catch
    {
        return Results.Content("Timeout!", "text/plain");
    }

    return Results.Content("No timeout!", "text/plain");
}).DisableRequestTimeout();
// Returns "No timeout!", ignores default timeout.
```

Cancel a timeout

To cancel a timeout that has already been started, use the DisableTimeout() method on IHttpRequestTimeoutFeature. Timeouts cannot be canceled after they've expired.

C#

```
app.MapGet("/canceltimeout", async (HttpContext context) => {
    var timeoutFeature = context.Features.Get<IHttpRequestTimeoutFeature>();
    timeoutFeature?.DisableTimeout();

    try
    {
        await Task.Delay(TimeSpan.FromSeconds(10), context.RequestAborted);
    }
    catch (TaskCanceledException)
    {
        return Results.Content("Timeout!", "text/plain");
    }

    return Results.Content("No timeout!", "text/plain");
}).WithRequestTimeout(TimeSpan.FromSeconds(1));
// Returns "No timeout!" since the default timeout is not triggered.
```

Memory management and garbage collection (GC) in ASP.NET Core

Article • 06/17/2024

By Sébastien Ros and Rick Anderson

Memory management is complex, even in a managed framework like .NET. Analyzing and understanding memory issues can be challenging. This article:

- Was motivated by many *memory leak* and *GC not working* issues. Most of these issues were caused by not understanding how memory consumption works in .NET Core, or not understanding how it's measured.
- Demonstrates problematic memory use, and suggests alternative approaches.

How garbage collection (GC) works in .NET Core

The GC allocates heap segments where each segment is a contiguous range of memory. Objects placed in the heap are categorized into one of 3 generations: 0, 1, or 2. The generation determines the frequency the GC attempts to release memory on managed objects that are no longer referenced by the app. Lower numbered generations are GC'd more frequently.

Objects are moved from one generation to another based on their lifetime. As objects live longer, they are moved into a higher generation. As mentioned previously, higher generations are GC'd less often. Short term lived objects always remain in generation 0. For example, objects that are referenced during the life of a web request are short lived. Application level singletons generally migrate to generation 2.

When an ASP.NET Core app starts, the GC:

- Reserves some memory for the initial heap segments.
- Commits a small portion of memory when the runtime is loaded.

The preceding memory allocations are done for performance reasons. The performance benefit comes from heap segments in contiguous memory.

GC.Collect caveats

In general, ASP.NET Core apps in production should **not** use GC.Collect explicitly. Inducing garbage collections at sub-optimal times can decrease performance significantly.

GC.Collect is useful when investigating memory leaks. Calling `GC.Collect()` triggers a blocking garbage collection cycle that tries to reclaim all objects inaccessible from managed code. It's a useful way to understand the size of the reachable live objects in the heap, and track growth of memory size over time.

Analyzing the memory usage of an app

Dedicated tools can help analyzing memory usage:

- Counting object references
- Measuring how much impact the GC has on CPU usage
- Measuring memory space used for each generation

Use the following tools to analyze memory usage:

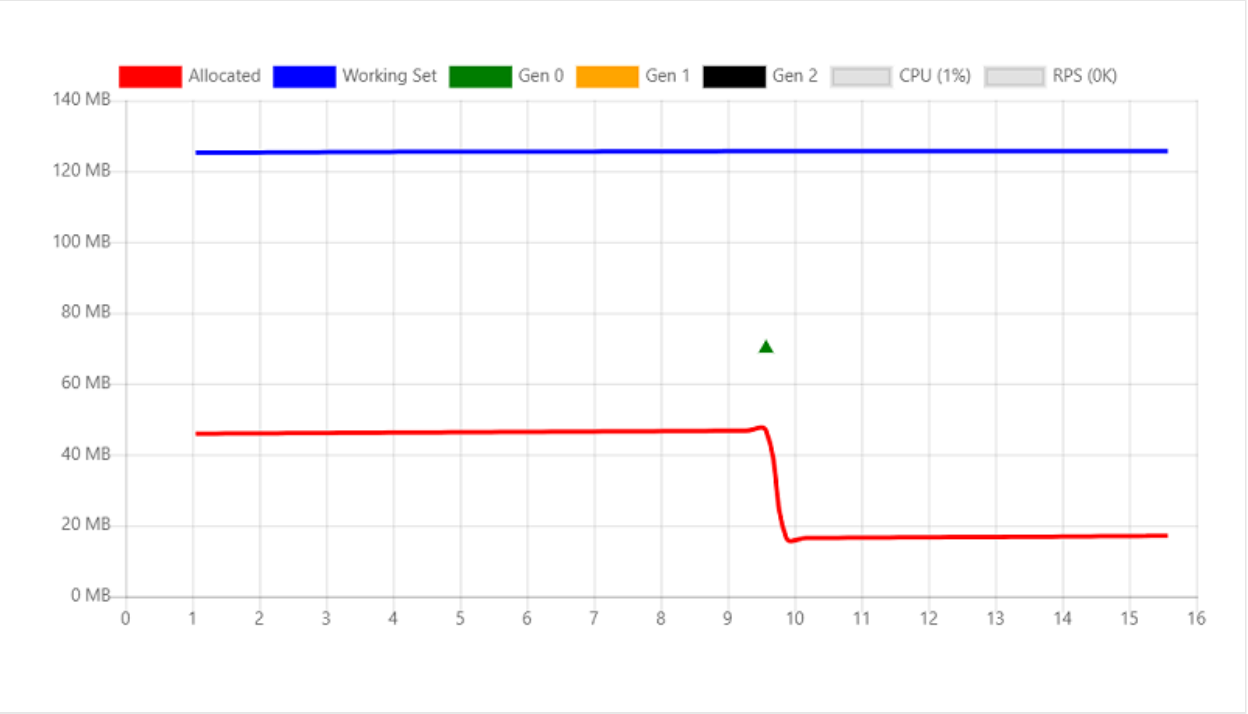
- dotnet-trace: Can be used on production machines.
- Analyze memory usage without the Visual Studio debugger
- Profile memory usage in Visual Studio

Detecting memory issues

Task Manager can be used to get an idea of how much memory an ASP.NET app is using. The Task Manager memory value:

- Represents the amount of memory that is used by the ASP.NET process.
- Includes the app's living objects and other memory consumers such as native memory usage.

If the Task Manager memory value increases indefinitely and never flattens out, the app has a memory leak. The following sections demonstrate and explain several memory usage patterns.



Sample display memory usage app

The MemoryLeak sample app is available on GitHub. The MemoryLeak app:

- Includes a diagnostic controller that gathers real-time memory and GC data for the app.

- Has an Index page that displays the memory and GC data. The Index page is refreshed every second.
- Contains an API controller that provides various memory load patterns.
- Is not a supported tool, however, it can be used to display memory usage patterns of ASP.NET Core apps.

Run MemoryLeak. Allocated memory slowly increases until a GC occurs. Memory increases because the tool allocates custom object to capture data. The following image shows the MemoryLeak Index page when a Gen 0 GC occurs. The chart shows 0 RPS (Requests per second) because no API endpoints from the API controller have been called.

The chart displays two values for the memory usage:

- Allocated: the amount of memory occupied by managed objects
- Working set: The set of pages in the virtual address space of the process that are currently resident in physical memory. The working set shown is the same value Task Manager displays.

Transient objects

The following API creates a 20-KB String instance and returns it to the client. On each request, a new object is allocated in memory and written to the response. Strings are stored as UTF-16 characters in .NET so each character takes 2 bytes in memory.

```
C#
```

```
[HttpGet("bigstring")]
public ActionResult<string> GetBigString()
{
    return new String('x', 10 * 1024);
}
```

The following graph is generated with a relatively small load in to show how memory allocations are impacted by the GC.

The preceding chart shows:

- 4K RPS (Requests per second).
- Generation 0 GC collections occur about every two seconds.
- The working set is constant at approximately 500 MB.
- CPU is 12%.
- The memory consumption and release (through GC) is stable.

The following chart is taken at the max throughput that can be handled by the machine.

The preceding chart shows:

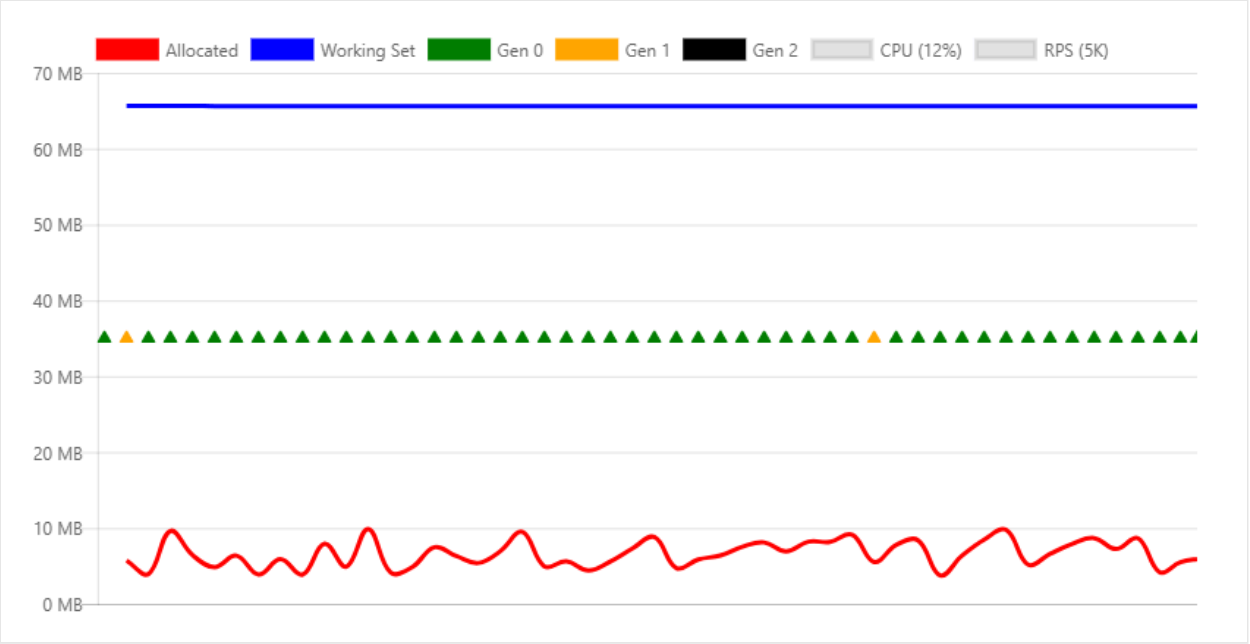
- 22K RPS
- Generation 0 GC collections occur several times per second.
- Generation 1 collections are triggered because the app allocated significantly more memory per second.
- The working set is constant at approximately 500 MB.
- CPU is 33%.
- The memory consumption and release (through GC) is stable.
- The CPU (33%) is not over-utilized, therefore the garbage collection can keep up with a high number of allocations.

Workstation GC vs. Server GC

The .NET Garbage Collector has two different modes:

- **Workstation GC**: Optimized for the desktop.
- **Server GC**. The default GC for ASP.NET Core apps. Optimized for the server.

The GC mode can be set explicitly in the project file or in the `runtimeconfig.json` file of the published app. The following markup shows setting `ServerGarbageCollection` in the project file:



XML

```xml
<PropertyGroup>
  <ServerGarbageCollection>true</ServerGarbageCollection>
</PropertyGroup>
```

Changing `ServerGarbageCollection` in the project file requires the app to be rebuilt.

Note: Server garbage collection is **not** available on machines with a single core. For more information, see IsServerGC.

The following image shows the memory profile under a 5K RPS using the Workstation GC.

The differences between this chart and the server version are significant:

- The working set drops from 500 MB to 70 MB.
- The GC does generation 0 collections multiple times per second instead of every two seconds.
- GC drops from 300 MB to 10 MB.

On a typical web server environment, CPU usage is more important than memory, therefore the Server GC is better. If memory utilization is high and CPU usage is relatively low, the Workstation GC might be more performant. For example, high density hosting several web apps where memory is scarce.

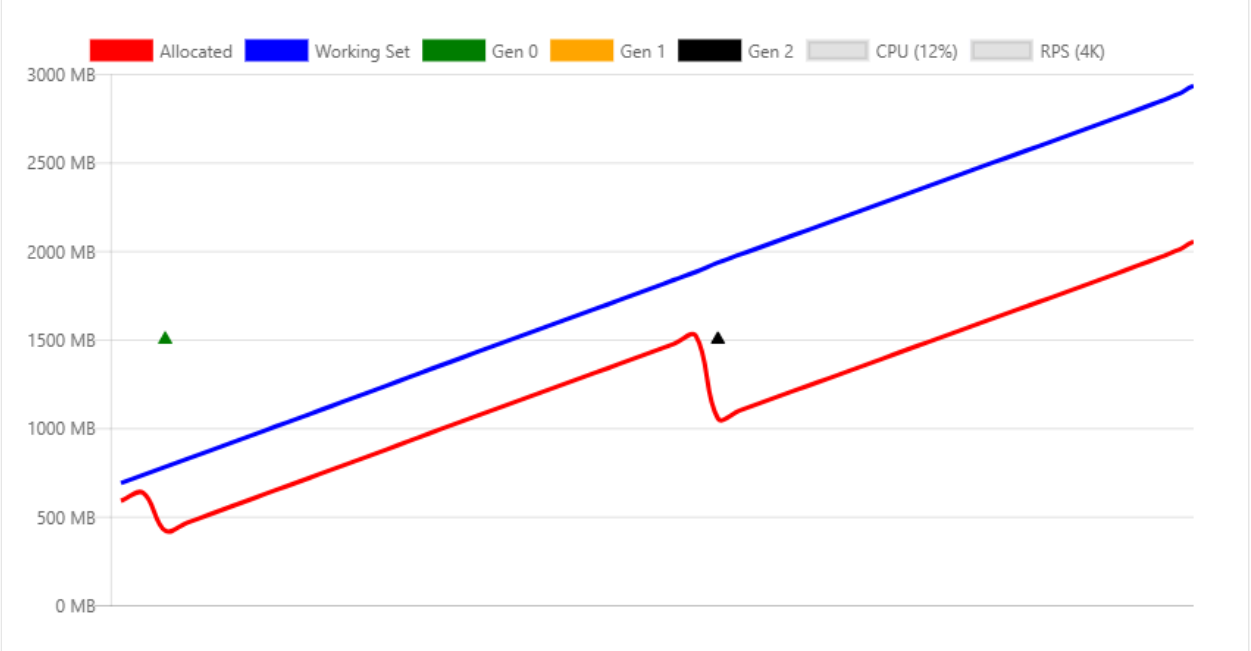
GC using Docker and small containers

When multiple containerized apps are running on one machine, Workstation GC might be more performant than Server GC. For more information, see Running with Server GC in a Small Container and Running with Server GC in a Small Container Scenario Part 1 – Hard Limit for the GC Heap.

Persistent object references

The GC cannot free objects that are referenced. Objects that are referenced but no longer needed result in a memory leak. If the app frequently allocates objects and fails to free them after they are no longer needed, memory usage will increase over time.

The following API creates a 20-KB String instance and returns it to the client. The difference with the previous example is that this instance is referenced by a static member, which means it's never available for collection.



C#

```
private static ConcurrentBag<string> _staticStrings = new
ConcurrentBag<string>();

[HttpGet("staticstring")]
public ActionResult<string> GetStaticString()
{
    var bigString = new String('x', 10 * 1024);
    _staticStrings.Add(bigString);
    return bigString;
}
```

The preceding code:

- Is an example of a typical memory leak.
- With frequent calls, causes app memory to increase until the process crashes with an `OutOfMemory` exception.

In the preceding image:

- Load testing the `/api/staticstring` endpoint causes a linear increase in memory.

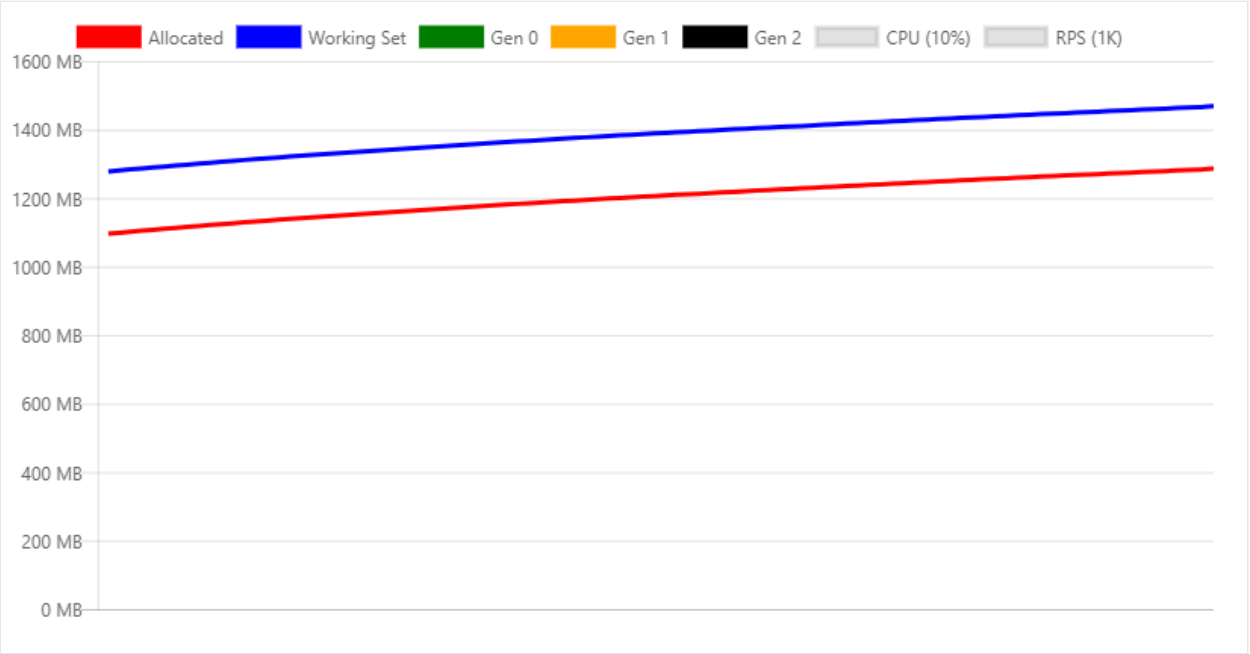
- The GC tries to free memory as the memory pressure grows, by calling a generation 2 collection.
- The GC cannot free the leaked memory. Allocated and working set increase with time.

Some scenarios, such as caching, require object references to be held until memory pressure forces them to be released. The WeakReference class can be used for this type of caching code. A `WeakReference` object is collected under memory pressures. The default implementation of IMemoryCache uses `WeakReference`.

Native memory

Some .NET Core objects rely on native memory. Native memory can **not** be collected by the GC. The .NET object using native memory must free it using native code.

.NET provides the IDisposable interface to let developers release native memory. Even if Dispose is not called, correctly implemented classes call `Dispose` when the finalizer runs.



Consider the following code:

C#

```
[HttpGet("fileprovider")]
public void GetFileProvider()
{
    var fp = new PhysicalFileProvider(TempPath);
    fp.Watch("*.*");
}
```

PhysicalFileProvider is a managed class, so any instance will be collected at the end of the request.

The following image shows the memory profile while invoking the `fileprovider` API continuously.

The preceding chart shows an obvious issue with the implementation of this class, as it keeps increasing memory usage. This is a known problem that is being tracked in this issue.

The same leak could happen in user code, by one of the following:

- Not releasing the class correctly.
- Forgetting to invoke the `Dispose` method of the dependent objects that should be disposed.

Large object heap

Frequent memory allocation/free cycles can fragment memory, especially when allocating large chunks of memory. Objects are allocated in contiguous blocks of memory. To mitigate fragmentation, when the GC frees memory, it tries to defragment it. This process is called **compaction**. Compaction involves moving objects. Moving large objects imposes a performance penalty. For this reason the GC creates a special memory zone for *large* objects, called the large object heap (LOH). Objects that are greater than 85,000 bytes (approximately 83 KB) are:

- Placed on the LOH.
- Not compacted.
- Collected during generation 2 GCs.

When the LOH is full, the GC will trigger a generation 2 collection. Generation 2 collections:

- Are inherently slow.
- Additionally incur the cost of triggering a collection on all other generations.

The following code compacts the LOH immediately:

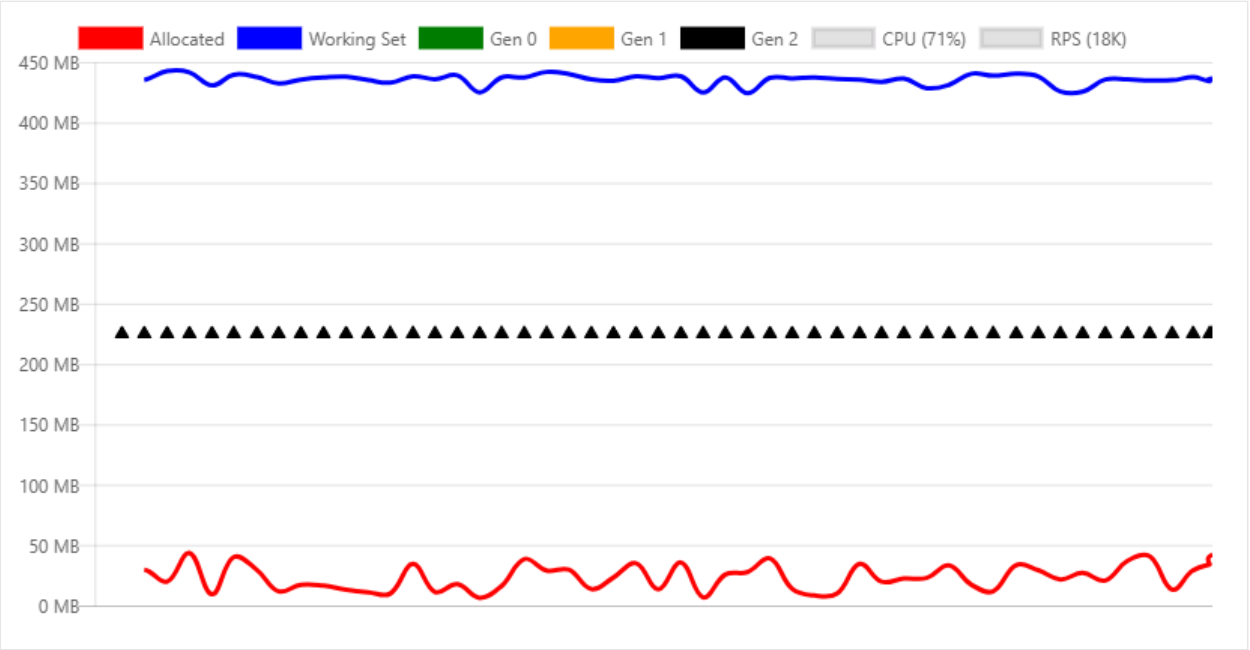
```
C#

GCSettings.LargeObjectHeapCompactionMode =
GCLargeObjectHeapCompactionMode.CompactOnce;
GC.Collect();
```

See LargeObjectHeapCompactionMode for information on compacting the LOH.

In containers using .NET Core 3.0 and later, the LOH is automatically compacted.

The following API that illustrates this behavior:



```
C#

[HttpGet("loh/{size=85000}")]
public int GetLOH1(int size)
{
   return new byte[size].Length;
}
```

The following chart shows the memory profile of calling the `/api/loh/84975` endpoint, under maximum load:

The following chart shows the memory profile of calling the `/api/loh/84976` endpoint, allocating *just one more byte*:

Note: The `byte[]` structure has overhead bytes. That's why 84,976 bytes triggers the 85,000 limit.

Comparing the two preceding charts:

- The working set is similar for both scenarios, about 450 MB.
- The under LOH requests (84,975 bytes) shows mostly generation 0 collections.
- The over LOH requests generate constant generation 2 collections. Generation 2 collections are expensive. More CPU is required and throughput drops almost 50%.

Temporary large objects are particularly problematic because they cause gen2 GCs.

For maximum performance, large object use should be minimized. If possible, split up large objects. For example, Response Caching middleware in ASP.NET Core split the cache entries into blocks less than 85,000 bytes.

The following links show the ASP.NET Core approach to keeping objects under the LOH limit:

- ResponseCaching/Streams/StreamUtilities.cs
- ResponseCaching/MemoryResponseCache.cs

For more information, see:

- Large Object Heap Uncovered
- Large object heap

HttpClient

Incorrectly using HttpClient can result in a resource leak. System resources, such as database connections, sockets, file handles, etc.:

- Are more scarce than memory.
- Are more problematic when leaked than memory.

Experienced .NET developers know to call Dispose on objects that implement IDisposable. Not disposing objects that implement `IDisposable` typically results in leaked memory or leaked system resources.

`HttpClient` implements `IDisposable`, but should **not** be disposed on every invocation. Rather, `HttpClient` should be reused.

The following endpoint creates and disposes a new `HttpClient` instance on every request:

C#

```
[HttpGet("httpclient1")]
public async Task<int> GetHttpClient1(string url)
{
    using (var httpClient = new HttpClient())
    {
        var result = await httpClient.GetAsync(url);
        return (int)result.StatusCode;
    }
}
```

Under load, the following error messages are logged:

```
fail: Microsoft.AspNetCore.Server.Kestrel[13]
      Connection id "0HLG70PBE1CR1", Request id "0HLG70PBE1CR1:00000031":
      An unhandled exception was thrown by the application.
System.Net.Http.HttpRequestException: Only one usage of each socket address
    (protocol/network address/port) is normally permitted --->
    System.Net.Sockets.SocketException: Only one usage of each socket
address
    (protocol/network address/port) is normally permitted
   at System.Net.Http.ConnectHelper.ConnectAsync(String host, Int32 port,
    CancellationToken cancellationToken)
```

Even though the `HttpClient` instances are disposed, the actual network connection takes some time to be released by the operating system. By continuously creating new connections, *ports exhaustion* occurs. Each client connection requires its own client port.

One way to prevent port exhaustion is to reuse the same `HttpClient` instance:

```
C#
```

```
private static readonly HttpClient _httpClient = new HttpClient();

[HttpGet("httpclient2")]
public async Task<int> GetHttpClient2(string url)
{
    var result = await _httpClient.GetAsync(url);
    return (int)result.StatusCode;
}
```

The `HttpClient` instance is released when the app stops. This example shows that not every disposable resource should be disposed after each use.

See the following for a better way to handle the lifetime of an `HttpClient` instance:

- HttpClient and lifetime management
- HTTPClient factory blog

Object pooling

The previous example showed how the `HttpClient` instance can be made static and reused by all requests. Reuse prevents running out of resources.

Object pooling:

- Uses the reuse pattern.
- Is designed for objects that are expensive to create.

A pool is a collection of pre-initialized objects that can be reserved and released across threads. Pools can define allocation rules such as limits, predefined sizes, or growth rate.

The NuGet package Microsoft.Extensions.ObjectPool contains classes that help to manage such pools.

The following API endpoint instantiates a `byte` buffer that is filled with random numbers on each request:

```
C#
```

```
        [HttpGet("array/{size}")]
        public byte[] GetArray(int size)
        {
            var random = new Random();
            var array = new byte[size];
```

```
            random.NextBytes(array);

            return array;
        }
```

The following chart display calling the preceding API with moderate load:

In the preceding chart, generation 0 collections happen approximately once per second.

The preceding code can be optimized by pooling the `byte` buffer by using ArrayPool<T>. A static instance is reused across requests.

What's different with this approach is that a pooled object is returned from the API. That means:

- The object is out of your control as soon as you return from the method.
- You can't release the object.

To set up disposal of the object:

- Encapsulate the pooled array in a disposable object.
- Register the pooled object with HttpContext.Response.RegisterForDispose.

`RegisterForDispose` will take care of calling `Dispose` on the target object so that it's only released when the HTTP request is complete.

C#

```
private static ArrayPool<byte> _arrayPool = ArrayPool<byte>.Create();

private class PooledArray : IDisposable
{
```

```
    public byte[] Array { get; private set; }

    public PooledArray(int size)
    {
        Array = _arrayPool.Rent(size);
    }

    public void Dispose()
    {
        _arrayPool.Return(Array);
    }
}

[HttpGet("pooledarray/{size}")]
public byte[] GetPooledArray(int size)
{
    var pooledArray = new PooledArray(size);

    var random = new Random();
    random.NextBytes(pooledArray.Array);

    HttpContext.Response.RegisterForDispose(pooledArray);

    return pooledArray.Array;
}
```

Applying the same load as the non-pooled version results in the following chart:

The main difference is allocated bytes, and as a consequence much fewer generation 0 collections.

Deploying and scaling an ASP.NET Core app on Azure Container Apps

Article • 09/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Apps deployed to Azure that experience intermittent high demand benefit from scalability to meet demand. Scalable apps can scale out to ensure capacity during workload peaks and then scale down automatically when the peak drops, which can lower costs. Horizontal scaling (scaling out) adds new instances of a resource, such as VMs or database replicas. This article demonstrates how to deploy a horizontally scalable ASP.NET Core app to Azure container apps by completing the following tasks:

1. Set up the sample project
2. Deploy the app to Azure Container Apps
3. Scale and troubleshoot the app
4. Create the Azure Services
5. Connect the Azure services
6. Configure and redeploy the app

This article uses Razor Pages, but most of it applies to other ASP.NET Core apps.

In some cases, basic ASP.NET Core apps are able to scale without special considerations. However, apps that utilize certain framework features or architectural patterns require extra configurations, including the following:

- **Secure form submissions**: Razor Pages, MVC and Web API apps often rely on form submissions. By default these apps use cross site forgery tokens and internal data protection services to secure requests. When deployed to the cloud, these apps must be configured to manage data protection service concerns in a secure, centralized location.
- **SignalR circuits**: Blazor Server apps require the use of a centralized Azure SignalR service in order to securely scale. These services also utilize the data protection

services mentioned previously.

- **Centralized caching or state management services**: Scalable apps may use Azure Cache for Redis to provide distributed caching. Azure storage may be needed to store state for frameworks such as Microsoft Orleans, which can help write apps that manage state across many different app instances.

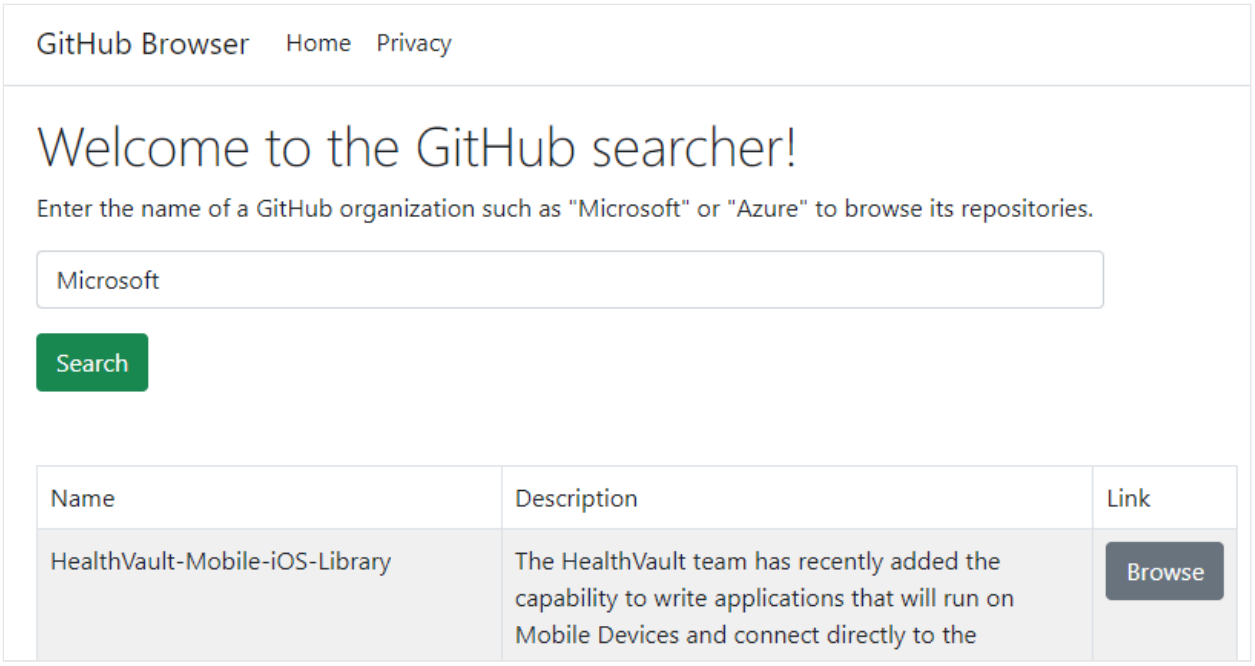
The steps in this article demonstrate how to properly address the preceding concerns by deploying a scalable app to Azure Container Apps. Most of the concepts in this tutorial also apply when scaling Azure App Service instances.

Set up the sample project

Use the GitHub Explorer sample app to follow along with this tutorial. Clone the app from GitHub using the following command:

.NET CLI

```
git clone "https://github.com/dotnet/AspNetCore.Docs.Samples.git"
```



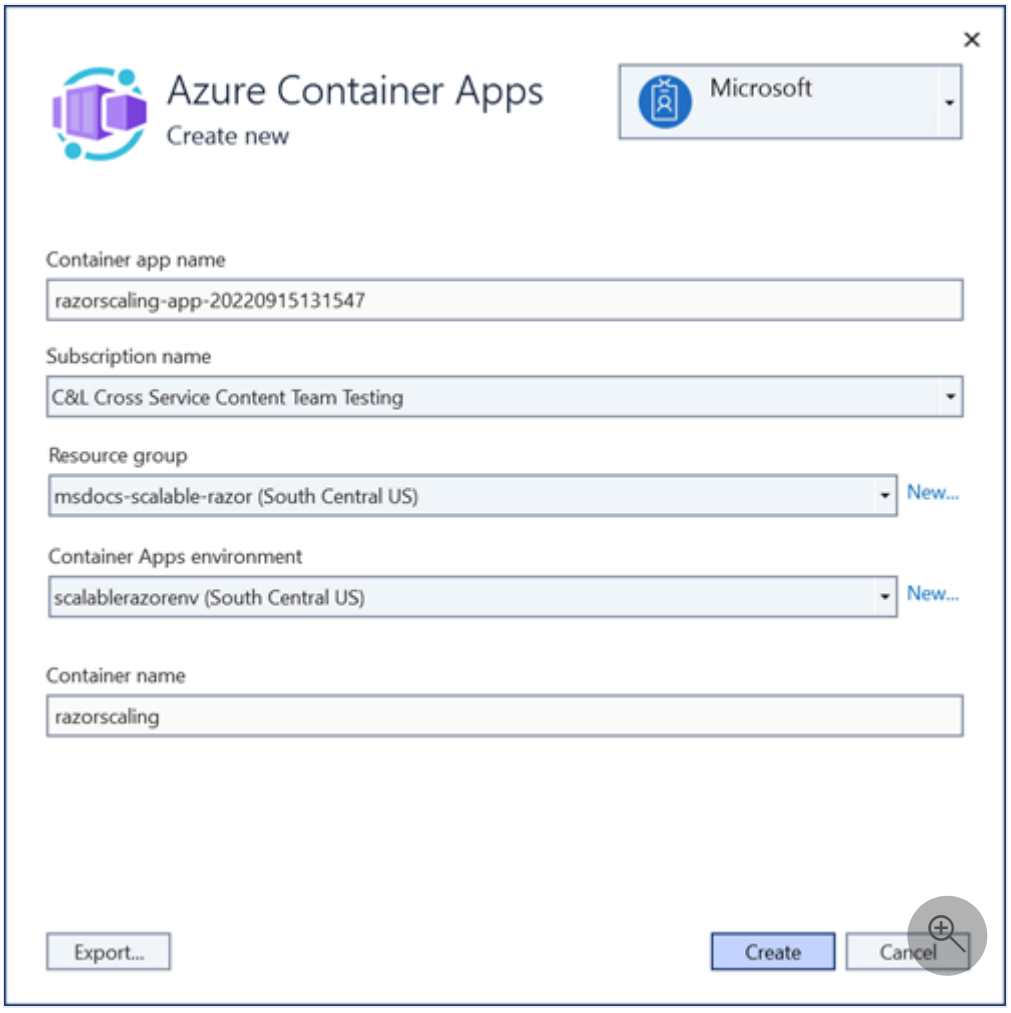
Navigate to the `/tutorials/scalable-razor-apps/start` folder and open the `ScalableRazor.csproj`.

The sample app uses a search form to browse GitHub repositories by name. The form relies on the built-in ASP.NET Core data protection services to handle antiforgery concerns. By default, when the app scales horizontally on Container Apps, the data protection service throws an exception.

Test the app

1. Launch the app in Visual Studio. The project includes a Docker file, which means that the arrow next to the run button can be selected to start the app using either a Docker Desktop setup or the standard ASP.NET Core local web server.

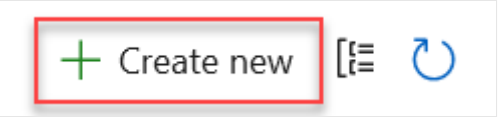
Use the search form to browse for GitHub repositories by name.



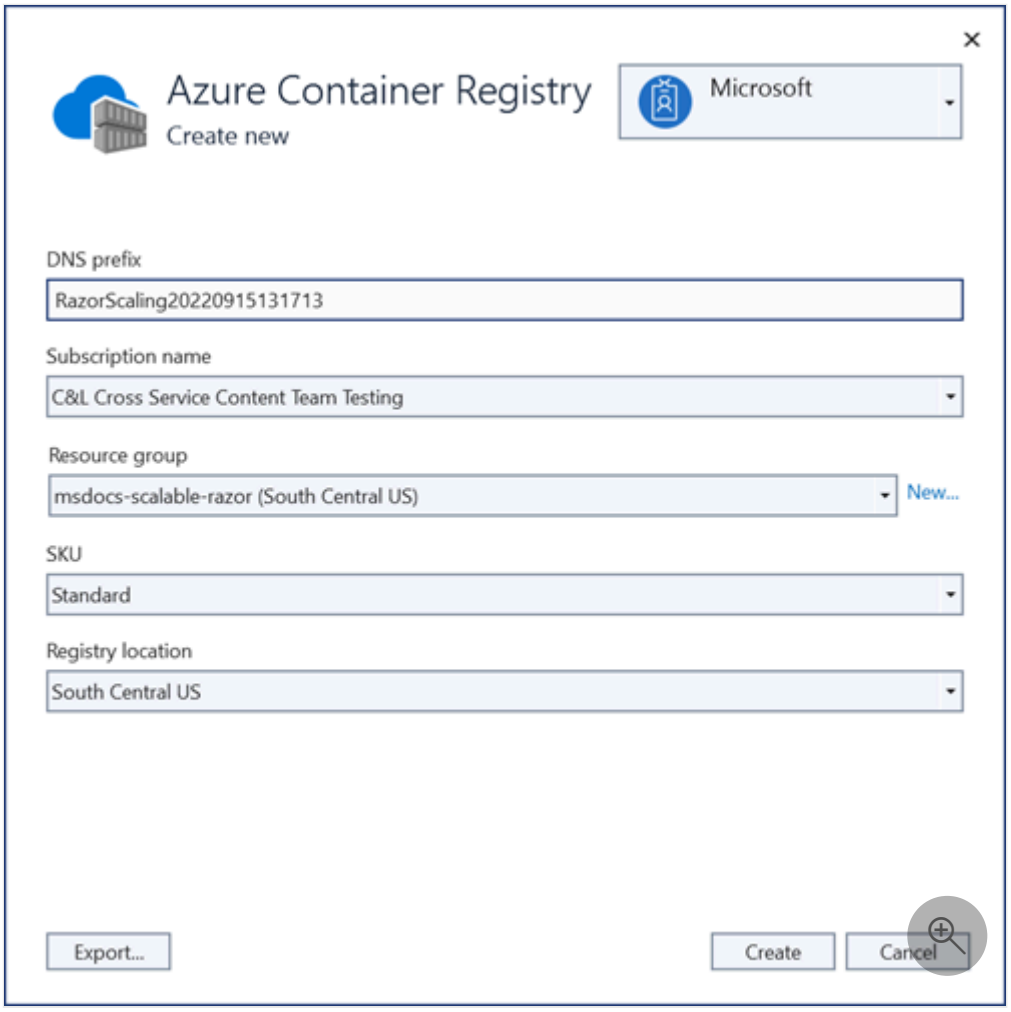
Deploy the app to Azure Container Apps

Visual Studio is used to deploy the app to Azure Container Apps. Container apps provide a managed service designed to simplify hosting containerized apps and microservices.

> ⓘ **Note**
>
> Many of the resources created for the app require a location. For this app, location isn't important. A real app should select a location closest to the clients. You may want to select a location near you.



1. In Visual Studio solution explorer, right click on the top level project node and select **Publish**.
2. In the publishing dialog, select **Azure** as the deployment target, and then select **Next**.
3. For the specific target, select **Azure Container Apps (Linux)**, and then select **Next**.
4. Create a new container app to deploy to. Select the green + icon to open a new dialog and enter the following values:



- **Container app name**: Leave the default value or enter a name.
- **Subscription name**: Select the subscription to deploy to.
- **Resource group**: Select **New** and create a new resource group called *msdocs-scalable-razor*.
- **Container apps environment**: Select **New** to open the container apps environment dialog and enter the following values:
  - **Environment name**: Keep the default value.
  - **Location**: Select a location near you.
  - **Azure Log Analytics Workspace**: Select **New** to open the log analytics workspace dialog.
    - **Name**: Leave the default value.
    - **Location**: Select a location near you and then select **Ok** to close the dialog.
  - Select **Ok** to close the container apps environment dialog.
- Select **Create** to close the original container apps dialog. Visual Studio creates the container app resource in Azure.

5. Once the resource is created, make sure it's selected in the list of container apps, and then select **Next**.

6. You'll need to create an Azure Container Registry to store the published image artifact for your app. Select the green + icon on the container registry screen.

7. Leave the default values, and then select **Create**.

8. After the container registry is created, make sure it's selected, and then select finish to close the dialog workflow and display a summary of the publishing profile.

   If Visual Studio prompts you to enable the Admin user to access the published docker container, select **Yes**.

9. Select **Publish** in the upper right of the publishing profile summary to deploy the app to Azure.

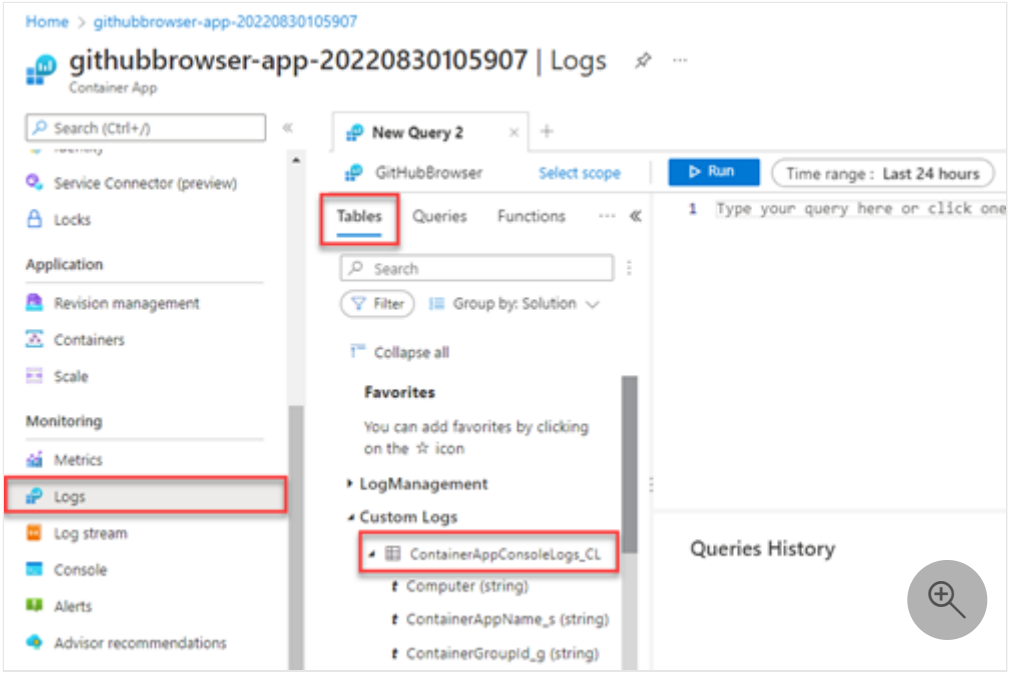
When the deployment finishes, Visual Studio launches the browser to display the hosted app. Search for `Microsoft` in the form field, and a list of repositories is displayed.

Scale and troubleshoot the app

The app is currently working without any issues, but we'd like to scale the app across more instances in anticipation of high traffic volumes.

1. In the Azure portal, search for the `razorscaling-app-****` container app in the top level search bar and select it from the results.
2. On the overview page, select **Scale** from the left navigation, and then select **+ Edit and deploy**.
3. On the revisions page, switch to the **Scale** tab.
4. Set both the min and max instances to **4** and then select **Create**. This configuration change guarantees your app is scaled horizontally across four instances.

Navigate back to the app. When the page loads, at first it appears everything is working correctly. However, when a search term is entered and submitted, an error may occur. If an error is not displayed, submit the form several more times.



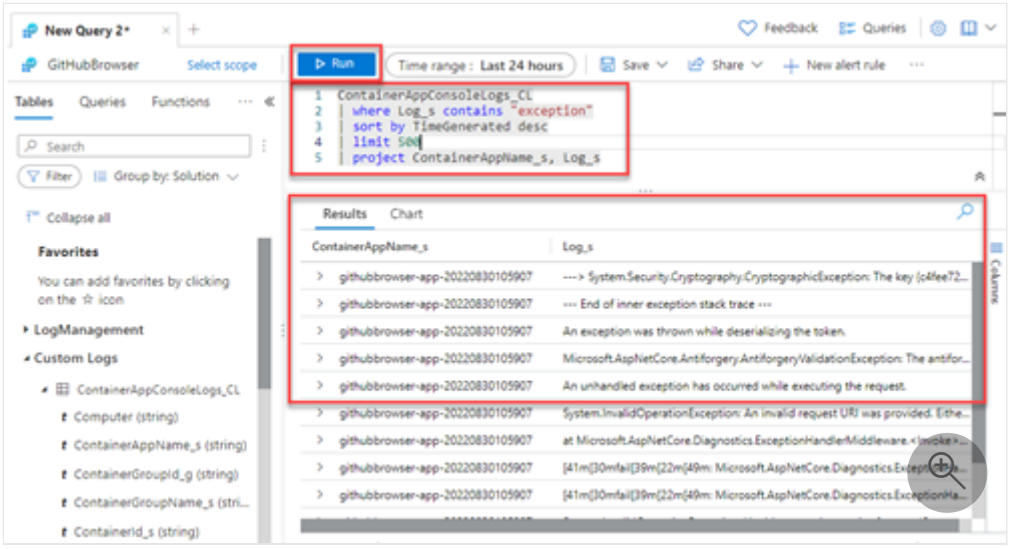
Troubleshooting the error

It's not immediately apparent why the search requests are failing. The browser tools indicate a 400 Bad Request response was sent back. However, you can use the logging features of container apps to diagnose errors occurring in your environment.

1. On the overview page of the container app, select **Logs** from the left navigation.

2. On the **Logs** page, close the pop-up that opens and navigate to the **Tables** tab.

3. Expand the **Custom Logs** item to reveal the **ContainerAppConsoleLogs_CL** node. This table holds various logs for the container app that can be queried to troubleshoot problems.



4. In the query editor, compose a basic query to search the **ContainerAppConsoleLogs_CL Logs** table for recent exceptions, such as the following script:

```KQL
ContainerAppConsoleLogs_CL
| where Log_s contains "exception"
| sort by TimeGenerated desc
| limit 500
| project ContainerAppName_s, Log_s
```

   The preceding query searches the **ContainerAppConsoleLogs_CL** table for any rows that contain the word exception. The results are ordered by the time generated, limited to 500 results, and only include the **ContainerAppName_s** and **Log_s** columns to make the results easier to read.

5. Select **Run**, a list of results is displayed. Read through the logs and note that most of them are related to antiforgery tokens and cryptography.

> **ⓘ Important**
>
> The errors in the app are caused by the .NET data protection services. When multiple instances of the app are running, there is no guarantee that the HTTP POST request to submit the form is routed to the same container that initially loaded the page from the HTTP GET request. If the requests are handled by different instances, the antiforgery tokens aren't handled correctly and an exception occurs.

   In the steps ahead, this issue is resolved by centralizing the data protection keys in an Azure storage service and protecting them with Key Vault.

Create the Azure Services

To resolve the preceding errors, the following services are created and connected to the app:

- Azure Storage Account: Handles storing data for the Data Protection Services. Provides a centralized location to store key data as the app scales. Storage accounts can also be used to hold documents, queue data, file shares, and almost any type of blob data.
- Azure KeyVault: This service stores secrets for an app, and is used to help manage encryption concerns for the Data Protection Services.

Create the storage account service

1. In the Azure portal search bar, enter `Storage accounts` and select the matching result.
2. On the storage accounts listing page, select **+ Create**.
3. On the **Basics** tab, enter the following values:

    - **Subscription**: Select the same subscription that you chose for the container app.
    - **Resource Group**: Select the *msdocs-scalable-razor* resource group you created previously.
    - **Storage account name**: Name the account *scalablerazorstorageXXXX* where the X's are random numbers of your choosing. This name must be unique across all of Azure.
    - **Region**: Select the same region you previously selected.

4. Leave the rest of the values at their default and select **Review**. After Azure validates the inputs, select **Create**.

Azure provisions the new storage account. When the task completes, choose **Go to resource** to view the new service.

Create the storage container

Create a Container to store the app's data protection keys.

1. On the overview page for the new storage account, select **Storage browser** on the left navigation.
2. Select **Blob containers**.
3. Select **+ Add container** to open the **New container** flyout menu.

4. Enter a name of *scalablerazorkeys*, leave the rest of the settings at their defaults, and then select **Create**.

The new containers appear on the page list.

Create the key vault service

Create a key vault to hold the keys that protect the data in the blob storage container.

1. In the Azure portal search bar, enter `Key Vault` and select the matching result.
2. On the key vault listing page, select **+ Create**.
3. On the **Basics** tab, enter the following values:

    - **Subscription**: Select the same subscription that was previously selected.
    - **Resource Group**: Select the *msdocs-scalable-razor* resource group previously created.
    - **Key Vault name**: Enter the name *scalablerazorvaultXXXX*.
    - **Region**: Select a region near your location.

4. Leave the rest of the settings at their default, and then select **Review + create**. Wait for Azure to validate your settings, and then select **Create**.

Azure provisions the new key vault. When the task completes, select **Go to resource** to view the new service.

Create the key

Create a secret key to protect the data in the blob storage account.

1. On the main overview page of the key vault, select **Keys** from the left navigation.
2. On the **Create a key** page, select **+ Generate/Import** to open the **Create a key** flyout menu.
3. Enter *razorkey* in the **Name** field. Leave the rest of the settings at their default values and then select **Create**. A new key appears on the key list page.

Connect the Azure Services

The Container App requires a secure connection to the storage account and the key vault services in order to resolve the data protection errors and scale correctly. The new services are connected together using the following steps:

> **ⓘ Important**

> Security role assignments through Service Connector and other tools typically take a minute or two to propagate, and in some rare cases can take up to eight minutes.

Connect the storage account

1. In the Azure portal, navigate to the Container App overview page.
2. On the left navigation, select **Service connector**
3. On the Service Connector page, choose **+ Create** to open the **Creation Connection** flyout panel and enter the following values:

    - **Container**: Select the Container App created previously.
    - **Service type**: Choose **Storage - blob**.
    - **Subscription**: Select the subscription previously used.
    - **Connection name**: Leave the default value.
    - **Storage account**: Select the storage account created previously.
    - **Client type**: Select **.NET**.

4. Select **Next: Authentication** to progress to the next step.
5. Select **System assigned managed identity** and choose **Next: Networking**.
6. Leave the default networking options selected, and then select **Review + Create**.
7. After Azure validates the settings, select **Create**.

The service connector enables a system-assigned managed identity on the container app. It also assigns a role of **Storage Blob Data Contributor** to the identity so it can perform data operations on the storage containers.

Connect the key vault

1. In the Azure portal, navigate to your Container App overview page.
2. On the left navigation, select **Service connector**.
3. On the Service Connector page, choose **+ Create** to open the **Creation Connection** flyout panel and enter the following values:

    - **Container**: Select the container app created previously.
    - **Service type**: Choose **Key Vault**.
    - **Subscription**: Select the subscription previously used.
    - **Connection name**: Leave the default value.
    - **Key vault**: Select the key vault created previously.
    - **Client type**: Select **.NET**.

4. Select **Next: Authentication** to progress to the next step.
5. Select **System assigned managed identity** and choose **Next: Networking**.

6. Leave the default networking options selected, and then select **Review + Create**.
7. After Azure validates the settings, select **Create**.

The service connector assigns a role to the identity so it can perform data operations on the key vault keys.

Configure and redeploy the app

The necessary Azure resources have been created. In this section the app code is configured to use the new resources.

1. Install the following NuGet packages:

    - **Azure.Identity**: Provides classes to work with the Azure identity and access management services.
    - **Microsoft.Extensions.Azure**: Provides helpful extension methods to perform core Azure configurations.
    - **Azure.Extensions.AspNetCore.DataProtection.Blobs**: Allows storing ASP.NET Core DataProtection keys in Azure Blob Storage so that keys can be shared across several instances of a web app.
    - **Azure.Extensions.AspNetCore.DataProtection.Keys**: Enables protecting keys at rest using the Azure Key Vault Key Encryption/Wrapping feature.

    .NET CLI

    ```
    dotnet add package Azure.Identity
    dotnet add package Microsoft.Extensions.Azure
    dotnet add package Azure.Extensions.AspNetCore.DataProtection.Blobs
    dotnet add package Azure.Extensions.AspNetCore.DataProtection.Keys
    ```

2. Update `Program.cs` with the following highlighted code:

    C#

    ```
    using Azure.Identity;
    using Microsoft.AspNetCore.DataProtection;
    using Microsoft.Extensions.Azure;
    var builder = WebApplication.CreateBuilder(args);
    var BlobStorageUri = builder.Configuration["AzureURIs:BlobStorage"];
    var KeyVaultURI = builder.Configuration["AzureURIs:KeyVault"];

    builder.Services.AddRazorPages();
    builder.Services.AddHttpClient();
    builder.Services.AddServerSideBlazor();
    ```

```
builder.Services.AddAzureClientsCore();

builder.Services.AddDataProtection()
                .PersistKeysToAzureBlobStorage(new Uri(BlobStorageUri),
                                               new
DefaultAzureCredential())
                .ProtectKeysWithAzureKeyVault(new Uri(KeyVaultURI),
                                               new
DefaultAzureCredential());
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The preceding changes allow the app to manage data protection using a centralized, scalable architecture. `DefaultAzureCredential` discovers the managed identity configurations enabled earlier when the app is redeployed.

Update the placeholders in `AzureURIs` section of the `appsettings.json` file to include the following:

1. Replace the `<storage-account-name>` placeholder with the name of the `scalablerazorstorageXXXX` storage account.
2. Replace the `<container-name>` placeholder with the name of the `scalablerazorkeys` storage container.
3. Replace the `<key-vault-name>` placeholder with the name of the `scalablerazorvaultXXXX` key vault.
4. Replace the `<key-name>` placeholder in the key vault URI with the `razorkey` name created previously.

```
C#
```

```
{
  "GitHubURL": "https://api.github.com",
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "AzureURIs": {
    "BlobStorage": "https://<storage-account-
name>.blob.core.windows.net/<container-name>/keys.xml",
    "KeyVault": "https://<key-vault-name>.vault.azure.net/keys/<key-
name>/"
  }
}
```

Redeploy the app

The app is now configured correctly to use the Azure services created previously. Redeploy the app for the code changes to be applied.

1. Right click on the project node in the solution explorer and select **Publish**.
2. On the publishing profile summary view, select the **Publish** button in the upper right corner.

Visual Studio redeploys the app to the container apps environment created previously. When the processes finished, the browser launches to the app home page.

Test the app again by searching for *Microsoft* in the search field. The page should now reload with the correct results every time you submit.

Configure roles for local development

The existing code and configuration of the app can also work while running locally during development. The `DefaultAzureCredential` class configured previously is able to pick up local environment credentials to authenticate to Azure Services. You'll need to assign the same roles to your own account that were assigned to your app's managed identity in order for the authentication to work. This should be the same account you use to log into Visual Studio or the Azure CLI.

Sign-in to your local development environment

You'll need to be signed in to the Azure CLI, Visual Studio, or Azure PowerShell for your credentials to be picked up by `DefaultAzureCredential`.

Azure CLI

Azure CLI

```
az login
```

Assign roles to your developer account

1. In the Azure portal, navigate to the `scalablerazor****` storage account created previously.
2. Select **Access Control (IAM)** from the left navigation.
3. Choose **+ Add** and then **Add role assignment** from the drop-down menu.
4. On the **Add role assignment** page, search for `Storage blob data contributor`, select the matching result, and then select **Next**.
5. Make sure **User, group, or service principal** is selected, and then select **+ Select members**.
6. In the **Select members** flyout, search for your own *user@domain* account and select it from the results.
7. Choose **Next** and then select **Review + assign**. After Azure validates the settings, select **Review + assign** again.

As previously stated, role assignment permissions might take a minute or two to propagate, or in rare cases up to eight minutes.

Repeat the previous steps to assign a role to your account so that it can access the key vault service and secret.

1. In the Azure portal, navigate to the `razorscalingkeys` key vault created previously.
2. Select **Access Control (IAM)** from the left navigation.
3. Choose **+ Add** and then **Add role assignment** from the drop-down menu.
4. On the **Add role assignment** page, search for `Key Vault Crypto Service Encryption User`, select the matching result, and then select **Next**.
5. Make sure **User, group, or service principal** is selected, and then select **+ Select members**.
6. In the **Select members** flyout, search for your own *user@domain* account and select it from the results.

7. Choose **Next** and then select **Review + assign**. After Azure validates your settings, select **Review + assign** again.

You may need to wait again for this role assignment to propagate.

You can then return to Visual Studio and run the app locally. The code should continue to function as expected. `DefaultAzureCredential` uses your existing credentials from Visual Studio or the Azure CLI.

Reliable web app patterns

See *The Reliable Web App Pattern for.NET* YouTube videos and article for guidance on creating a modern, reliable, performant, testable, cost-efficient, and scalable ASP.NET Core app, whether from scratch or refactoring an existing app.

Object reuse with ObjectPool in ASP.NET Core

Article • 06/17/2024

By Günther Foidl, Steve Gordon, and Samson Amaugo

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Microsoft.Extensions.ObjectPool is part of the ASP.NET Core infrastructure that supports keeping a group of objects in memory for reuse rather than allowing the objects to be garbage collected. All the static and instance methods in `Microsoft.Extensions.ObjectPool` are thread-safe.

Apps might want to use the object pool if the objects that are being managed are:

- Expensive to allocate/initialize.
- Represent a limited resource.
- Used predictably and frequently.

For example, the ASP.NET Core framework uses the object pool in some places to reuse StringBuilder instances. `StringBuilder` allocates and manages its own buffers to hold character data. ASP.NET Core regularly uses `StringBuilder` to implement features, and reusing them provides a performance benefit.

Object pooling doesn't always improve performance:

- Unless the initialization cost of an object is high, it's usually slower to get the object from the pool.
- Objects managed by the pool aren't de-allocated until the pool is de-allocated.

Use object pooling only after collecting performance data using realistic scenarios for your app or library.

NOTE: The ObjectPool doesn't place a limit on the number of objects that it allocates, it places a limit on the number of objects it retains.

ObjectPool concepts

When DefaultObjectPoolProvider is used and `T` implements `IDisposable`:

- Items that are ***not*** returned to the pool will be disposed.
- When the pool gets disposed by DI, all items in the pool are disposed.

NOTE: After the pool is disposed:

- Calling `Get` throws an `ObjectDisposedException`.
- Calling `Return` disposes the given item.

Important `ObjectPool` types and interfaces:

- ObjectPool<T> : The basic object pool abstraction. Used to get and return objects.
- PooledObjectPolicy<T> : Implement this to customize how an object is created and how it's reset when returned to the pool. This can be passed into an object pool that's constructed directly.
- IResettable : Automatically resets the object when returned to an object pool.

The ObjectPool can be used in an app in multiple ways:

- Instantiating a pool.
- Registering a pool in Dependency injection (DI) as an instance.
- Registering the `ObjectPoolProvider<>` in DI and using it as a factory.

How to use ObjectPool

Call Get to get an object and Return to return the object. There's no requirement to return every object. If an object isn't returned, it will be garbage collected.

ObjectPool sample

The following code:

- Adds `ObjectPoolProvider` to the Dependency injection (DI) container.
- Implements the `IResettable` interface to automatically clear the contents of the buffer when returned to the object pool.

C#

```
using Microsoft.Extensions.DependencyInjection.Extensions;
using Microsoft.Extensions.ObjectPool;
```

```
using System.Security.Cryptography;

var builder = WebApplication.CreateBuilder(args);

builder.Services.TryAddSingleton<ObjectPoolProvider,
DefaultObjectPoolProvider>();

builder.Services.TryAddSingleton<ObjectPool<ReusableBuffer>>(serviceProvider
=>
{
    var provider = serviceProvider.GetRequiredService<ObjectPoolProvider>();
    var policy = new DefaultPooledObjectPolicy<ReusableBuffer>();
    return provider.Create(policy);
});

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

// return the SHA256 hash of a word
// https://localhost:7214/hash/SamsonAmaugo
app.MapGet("/hash/{name}", (string name, ObjectPool<ReusableBuffer>
bufferPool) =>
{

    var buffer = bufferPool.Get();
    try
    {
        // Set the buffer data to the ASCII values of a word
        for (var i = 0; i < name.Length; i++)
        {
            buffer.Data[i] = (byte)name[i];
        }

        Span<byte> hash = stackalloc byte[32];
        SHA256.HashData(buffer.Data.AsSpan(0, name.Length), hash);
        return "Hash: " + Convert.ToHexString(hash);
    }
    finally
    {
        // Data is automatically reset because this type implemented
IResettable
        bufferPool.Return(buffer);
    }
});
app.Run();

public class ReusableBuffer : IResettable
{
    public byte[] Data { get; } = new byte[1024 * 1024]; // 1 MB

    public bool TryReset()
    {
        Array.Clear(Data);
        return true;
```

```
    }
}
```

NOTE: When the pooled type `T` doesn't implement `IResettable`, then a custom `PooledObjectPolicy<T>` can be used to reset the state of the objects before they are returned to the pool.

Response compression in ASP.NET Core

Article • 07/01/2024

Network bandwidth is a limited resource. Reducing the size of the response usually increases the responsiveness of an app, often dramatically. One way to reduce payload sizes is to compress an app's responses.

Compression with HTTPS

Compressed responses over secure connections can be controlled with the EnableForHttps option, which is disabled by default because of the security risk. Using compression with dynamically generated pages can expose the app to CRIME and BREACH attacks. CRIME and BREACH attacks can be mitigated in ASP.NET Core with antiforgery tokens. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core. For information on mitigating BREACH attacks, see mitigations at http://www.breachattack.com/

Even when `EnableForHttps` is disabled in the app, IIS, IIS Express, and Azure App Service can apply gzip at the IIS web server. When reviewing response headers, take note of the Server value. An unexpected `content-encoding` response header value may be the result of the web server and not the ASP.NET Core app configuration.

When to use Response Compression Middleware

Use server-based response compression technologies in IIS, Apache, or Nginx. The performance of the response compression middleware probably won't match that of the server modules. HTTP.sys server and Kestrel server don't currently offer built-in compression support.

Use Response Compression Middleware when the app is:

- Unable to use the following server-based compression technologies:
  - IIS Dynamic Compression module
  - Apache mod_deflate module
  - Nginx Compression and Decompression
- Hosting directly on:
  - HTTP.sys server
  - Kestrel server

Response compression

Usually, any response not natively compressed can benefit from response compression. Responses not natively compressed typically include CSS, JavaScript, HTML, XML, and JSON. Don't compress natively compressed assets, such as PNG files. When attempting to further compress a natively compressed response, any small extra reduction in size and transmission time will likely be overshadowed by the time it takes to process the compression. Don't compress files smaller than about 150-1000 bytes, depending on the file's content and the efficiency of compression. The overhead of compressing small files may produce a compressed file larger than the uncompressed file.

When a client can process compressed content, the client must inform the server of its capabilities by sending the Accept-Encoding header with the request. When a server sends compressed content, it must include information in the Content-Encoding header on how the compressed response is encoded. Content encoding designations supported by the response compression middleware are shown in the following table.

Expand table

Accept-Encoding header values	**Middleware Supported**	**Description**
`br`	Yes (default)	Brotli compressed data format
`deflate`	No	DEFLATE compressed data format
`exi`	No	W3C Efficient XML Interchange
`gzip`	Yes	Gzip file format
`identity`	Yes	"No encoding" identifier: The response must not be encoded.
`pack200-gzip`	No	Network Transfer Format for Java Archives
`*`	Yes	Any available content encoding not explicitly requested

For more information, see the IANA Official Content Coding List.

The response compression middleware allows adding additional compression providers for custom `Accept-Encoding` header values. For more information, see Custom Providers in this article.

The response compression middleware is capable of reacting to quality value (qvalue, `q`) weighting when sent by the client to prioritize compression schemes. For more

information, see RFC 9110: Accept-Encoding.

Compression algorithms are subject to a tradeoff between compression speed and the effectiveness of the compression. *Effectiveness* in this context refers to the size of the output after compression. The smallest size is achieved by the optimal compression.

The headers involved in requesting, sending, caching, and receiving compressed content are described in the following table.

Expand table

Header	Role
Accept-Encoding	Sent from the client to the server to indicate the content encoding schemes acceptable to the client.
Content-Encoding	Sent from the server to the client to indicate the encoding of the content in the payload.
Content-Length	When compression occurs, the `Content-Length` header is removed, since the body content changes when the response is compressed.
Content-MD5	When compression occurs, the `Content-MD5` header is removed, since the body content has changed and the hash is no longer valid.
Content-Type	Specifies the MIME type of the content. Every response should specify its `Content-Type`. The response compression middleware checks this value to determine if the response should be compressed. The response compression middleware specifies a set of default MIME types that it can encode, and they can bed replaced or added.
Vary	When sent by the server with a value of `Accept-Encoding` to clients and proxies, the `Vary` header indicates to the client or proxy that it should cache (vary) responses based on the value of the `Accept-Encoding` header of the request. The result of returning content with the `Vary: Accept-Encoding` header is that both compressed and uncompressed responses are cached separately.

Explore the features of the Response Compression Middleware with the sample app. The sample illustrates:

- The compression of app responses using Gzip and custom compression providers.
- How to add a MIME type to the default list of MIME types for compression.
- How to add a custom response compression provider.

Configuration

The following code shows how to enable the Response Compression Middleware for default MIME types and compression providers (Brotli and Gzip):

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCompression(options =>
{
    options.EnableForHttps = true;
});

var app = builder.Build();

app.UseResponseCompression();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Notes:

- Setting `EnableForHttps` to `true` is a security risk. See Compression with HTTPS in this article for more information.
- app.UseResponseCompression must be called ***before*** any middleware that compresses responses. For more information, see ASP.NET Core Middleware.
- Use a tool such as Firefox Browser Developer to set the `Accept-Encoding` request header and examine the response headers, size, and body.

Submit a request to the sample app without the `Accept-Encoding` header and observe that the response is uncompressed. The `Content-Encoding` header isn't in the Response Headers collection.

For example, in Firefox Developer:

- Select the network tab.
- Right click the request in the Network request list and select **Edit and resend**
- Change `Accept-Encoding:` from `gzip, deflate, br` to `none`.
- Select **Send**.

Submit a request to the sample app with a browser using the developer tools and observe that the response is compressed. The `Content-Encoding` and `Vary` headers are present on the response.

Providers

Brotli and Gzip compression providers

Use the BrotliCompressionProvider to compress responses with the Brotli compressed data format.

If no compression providers are explicitly added to the CompressionProviderCollection:

- The Brotli compression provider and Gzip compression provider are added by default to the array of compression providers.
- Compression defaults to Brotli compression when the Brotli compressed data format is supported by the client. If Brotli isn't supported by the client, compression defaults to Gzip when the client supports Gzip compression.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

When a compression provider is added, other providers aren't added. For example, if the Gzip compression provider is the only provider explicitly added, no other compression providers are added.

The following code:

- Enables response compression for HTTPS requests.
- Adds the Brotli and Gzip response compression providers.

C#

```
using System.IO.Compression;
using Microsoft.AspNetCore.ResponseCompression;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCompression(options =>
{
    options.EnableForHttps = true;
    options.Providers.Add<BrotliCompressionProvider>();
    options.Providers.Add<GzipCompressionProvider>();
});

builder.Services.Configure<BrotliCompressionProviderOptions>(options =>
```

```
{
    options.Level = CompressionLevel.Fastest;
});

builder.Services.Configure<GzipCompressionProviderOptions>(options =>
{
    options.Level = CompressionLevel.SmallestSize;
});

var app = builder.Build();

app.UseResponseCompression();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Set the compression level with BrotliCompressionProviderOptions and GzipCompressionProviderOptions. The Brotli and Gzip compression providers default to the fastest compression level, CompressionLevel.Fastest, which might not produce the most efficient compression. If the most efficient compression is desired, configure the response compression middleware for optimal compression.

See CompressionLevel Enum for values that indicate whether a compression operation emphasizes speed or compression size.

C#

```
using System.IO.Compression;
using Microsoft.AspNetCore.ResponseCompression;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCompression(options =>
{
    options.EnableForHttps = true;
    options.Providers.Add<BrotliCompressionProvider>();
    options.Providers.Add<GzipCompressionProvider>();
});

builder.Services.Configure<BrotliCompressionProviderOptions>(options =>
{
    options.Level = CompressionLevel.Fastest;
});

builder.Services.Configure<GzipCompressionProviderOptions>(options =>
{
    options.Level = CompressionLevel.SmallestSize;
});

var app = builder.Build();
```

```
app.UseResponseCompression();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Custom providers

Create custom compression implementations with ICompressionProvider. The EncodingName represents the content encoding that this `ICompressionProvider` produces. The response compression middleware uses this information to choose the provider based on the list specified in the `Accept-Encoding` header of the request.

Requests to the sample app with the `Accept-Encoding: mycustomcompression` header return a response with a `Content-Encoding: mycustomcompression` header. The client must be able to decompress the custom encoding in order for a custom compression implementation to work.

C#

```
using Microsoft.AspNetCore.ResponseCompression;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCompression(options =>
{
    options.Providers.Add<BrotliCompressionProvider>();
    options.Providers.Add<GzipCompressionProvider>();
    options.Providers.Add<CustomCompressionProvider>();
});

var app = builder.Build();

app.UseResponseCompression();

app.MapGet("/", () => "Hello World!");

app.Run();
```

C#

```
using Microsoft.AspNetCore.ResponseCompression;

public class CustomCompressionProvider : ICompressionProvider
{
    public string EncodingName => "mycustomcompression";
    public bool SupportsFlush => true;
```

```
    public Stream CreateStream(Stream outputStream)
    {
        // Replace with a custom compression stream wrapper.
        return outputStream;
    }
}
```

With the preceding code, the response body isn't compressed by the sample. However, the sample shows where to implement a custom compression algorithm.

MIME types

The response compression middleware specifies a default set of MIME types for compression. See the source code for a complete list of MIME types supported.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Replace or append MIME types with ResponseCompressionOptions.MimeTypes. Note that wildcard MIME types, such as `text/*` aren't supported. The sample app adds a MIME type for `image/svg+xml` and compresses and serves the ASP.NET Core banner image *banner.svg*.

C#

```
using Microsoft.AspNetCore.ResponseCompression;
using ResponseCompressionSample;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCompression(options =>
{
    options.EnableForHttps = true;
    options.Providers.Add<BrotliCompressionProvider>();
    options.Providers.Add<GzipCompressionProvider>();
    options.Providers.Add<CustomCompressionProvider>();
    options.MimeTypes =
    ResponseCompressionDefaults.MimeTypes.Concat(
        new[] { "image/svg+xml" });
});
```

```
var app = builder.Build();

app.UseResponseCompression();
```

Adding the Vary header

When compressing responses based on the Accept-Encoding request header, there are can be uncompressed and multiple compressed versions of the response. In order to instruct client and proxy caches that multiple versions exist and should be stored, the `Vary` header is added with an `Accept-Encoding` value. The response middleware adds the Vary header automatically when the response is compressed.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Middleware issue when behind an Nginx reverse proxy

When a request is proxied by Nginx, the `Accept-Encoding` header is removed. Removal of the `Accept-Encoding` header prevents the response compression middleware from compressing the response. For more information, see NGINX: Compression and Decompression. This issue is tracked by Figure out pass-through compression for Nginx (dotnet/aspnetcore#5989).

Disabling IIS dynamic compression

To disable IIS Dynamic Compression Module configured at the server level, see Disabling IIS modules.

Troubleshoot response compression

Use a tool like Firefox Browser Developer, which allows setting the `Accept-Encoding` request header and study the response headers, size, and body. By default, Response Compression Middleware compresses responses that meet the following conditions:

- The `Accept-Encoding` header is present with a value of `br`, `gzip`, `*`, or custom encoding that matches a custom compression provider. The value must not be `identity` or have a quality value (qvalue, `q`) setting of 0 (zero).
- The MIME type (`Content-Type`) must be set and must match a MIME type configured on the ResponseCompressionOptions.
- The request must not include the `Content-Range` header.
- The request must use insecure protocol (http), unless secure protocol (https) is configured in the Response Compression Middleware options. *Note the danger described above when enabling secure content compression.*

Azure deployed sample

The sample app deployed to Azure has the following `Program.cs` file:

C#

```
using Microsoft.AspNetCore.ResponseCompression;
using ResponseCompressionSample;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCompression(options =>
{
    options.EnableForHttps = true;
    options.Providers.Add<BrotliCompressionProvider>();
    options.Providers.Add<GzipCompressionProvider>();
    options.Providers.Add<CustomCompressionProvider>();
    options.MimeTypes =
    ResponseCompressionDefaults.MimeTypes.Concat(
        new[] { "image/svg+xml" });
});

var app = builder.Build();

app.UseResponseCompression();

app.Map("/trickle", async (HttpResponse httpResponse) =>
{
    httpResponse.ContentType = "text/plain;charset=utf-8";

    for (int i = 0; i < 20; i++)
    {
        await httpResponse.WriteAsync("a");
        await httpResponse.Body.FlushAsync();
```

```
        await Task.Delay(TimeSpan.FromMilliseconds(50));
    }
});

app.Map("/testfile1kb.txt", () => Results.File(

app.Environment.ContentRootFileProvider.GetFileInfo("testfile1kb.txt").Physi
calPath,
    "text/plain;charset=utf-8"));

app.Map("/banner.svg", () => Results.File(

app.Environment.ContentRootFileProvider.GetFileInfo("banner.svg").PhysicalPa
th,
    "image/svg+xml;charset=utf-8"));

app.MapFallback(() => LoremIpsum.Text);

app.Run();
```

Additional resources

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Performance Diagnostic Tools

Article • 06/17/2024

By Mike Rousos

This article lists tools for diagnosing performance issues in ASP.NET Core.

Visual Studio Diagnostic Tools

The profiling and diagnostic tools built into Visual Studio are a good place to start investigating performance issues. These tools are powerful and convenient to use from the Visual Studio development environment. The tooling allows analysis of CPU usage, memory usage, and performance events in ASP.NET Core apps. Being built-in makes profiling easy at development time.

More information is available in Visual Studio documentation.

Application Insights

Application Insights provides in-depth performance data for your app. Application Insights automatically collects data on response rates, failure rates, dependency response times, and more. Application Insights supports logging custom events and metrics specific to your app.

Azure Application Insights provides multiple ways to give insights on monitored apps:

- Application Map – helps spot performance bottlenecks or failure hot-spots across all components of distributed apps.
- Azure Metrics Explorer is a component of the Microsoft Azure portal that allows plotting charts, visually correlating trends, and investigating spikes and dips in metrics' values.
- Performance blade in Application Insights portal:
  - Shows performance details for different operations in the monitored app.
  - Allows drilling into a single operation to check all parts/dependencies that contribute to a long duration.
  - Profiler can be invoked from here to collect performance traces on-demand.
- Azure Application Insights Profiler allows regular and on-demand profiling of .NET apps. Azure portal shows captured performance traces with call stacks and hot

paths. The trace files can also be downloaded for deeper analysis using PerfView.

Application Insights can be used in a variety of environments:

- Optimized to work in Azure.
- Works in production, development, and staging.
- Works locally from Visual Studio or in other hosting environments.

For more information on code-based monitoring, see Application Insights for ASP.NET Core. For more information on codeless monitoring, see Monitor Azure App Service performance.

PerfView

PerfView is a performance analysis tool created by the .NET team specifically for diagnosing .NET performance issues. PerfView allows analysis of CPU usage, memory and GC behavior, performance events, and wall clock time.

For more about PerfView, see the user's guide available in the tool or on GitHub.

Windows Performance Toolkit

Windows Performance Toolkit (WPT) consists of two components: Windows Performance Recorder (WPR) and Windows Performance Analyzer (WPA). The tools produce in-depth performance profiles of Windows operating systems and apps. WPT has richer ways of visualizing data, but its data collecting is less powerful than PerfView's.

PerfCollect

While PerfView is a useful performance analysis tool for .NET scenarios, it only runs on Windows, so you can't use it to collect traces from ASP.NET Core apps running in Linux environments.

PerfCollect is a bash script that uses native Linux profiling tools (Perf and LTTng) to collect traces on Linux that can be analyzed by PerfView. PerfCollect is useful when performance problems show up in Linux environments where PerfView can't be used directly. Instead, PerfCollect can collect traces from .NET Core apps that are then analyzed on a Windows computer using PerfView.

More information about how to install and get started with PerfCollect is available on GitHub.

Other Third-party Performance Tools

The following lists some third-party performance tools that are useful in performance investigation of .NET Core applications.

- MiniProfiler
- dotTrace and dotMemory from JetBrains
- VTune from Intel

ASP.NET Core load/stress testing

Article • 03/07/2024

Load testing and stress testing are important to ensure a web app is performant and scalable. Load and stress testing have different goals even though they often share similar tests.

Load tests: Test whether the app can handle a specified load of users for a certain scenario while still satisfying the response goal. The app is run under normal conditions.

Stress tests: Test app stability when running under extreme conditions, often for a long period of time. The tests place high user load, either spikes or gradually increasing load on the app, or they limit the app's computing resources.

Stress tests determine if an app under stress can recover from failure and gracefully return to expected behavior. Under stress, the app is run at abnormally high stress.

Azure Load Testing is a fully managed load-testing service that enables you to generate high-scale load. The service simulates traffic for apps, regardless of where they're hosted. Azure Load Testing Preview enables you to use existing Apache JMeter scripts to generate high-scale load.

Visual Studio 2019 load testing has been deprecated. The corresponding Azure DevOps cloud-based load testing service has been closed.

Third-party tools

The following list contains third-party web performance tools with various feature sets:

- Apache JMeter
- ApacheBench (ab)
- Gatling
- jmeter-dotnet-dsl
- k6
- Locust
- West Wind WebSurge
- Netling
- Vegeta
- NBomber

Load and stress test with release builds

Load and stress tests should be done in release and production mode and not in debug and development mode. Release configurations are fully optimized with minimal logging. Debug configuration is not optimized. Development mode enables more information logging that can impact performance.

Tutorial: Measure performance using EventCounters in .NET Core

Article • 06/24/2023

This article applies to: ✔ .NET Core 3.0 SDK and later versions

In this tutorial, you'll learn how an EventCounter can be used to measure performance with a high frequency of events. You can use the available counters published by various official .NET Core packages, third-party providers, or create your own metrics for monitoring.

In this tutorial, you will:

- ✔ Implement an EventSource.
- ✔ Monitor counters with dotnet-counters.

Prerequisites

The tutorial uses:

- .NET Core 3.1 SDK or a later version.
- dotnet-counters to monitor event counters.
- A sample debug target app to diagnose.

Get the source

The sample application will be used as a basis for monitoring. The sample ASP.NET Core repository is available from the samples browser. You download the zip file, extract it once downloaded, and open it in your favorite IDE. Build and run the application to ensure that it works properly, then stop the application.

Implement an EventSource

For events that happen every few milliseconds, you'll want the overhead per event to be low (less than a millisecond). Otherwise, the impact on performance will be significant. Logging an event means you're going to write something to disk. If the disk is not fast enough, you will lose events. You need a solution other than logging the event itself.

When dealing with a large number of events, knowing the measure per event is not useful either. Most of the time all you need is just some statistics out of it. So you could

get the statistics within the process itself and then write an event once in a while to report the statistics, that's what EventCounter will do.

Below is an example of how to implement an System.Diagnostics.Tracing.EventSource. Create a new file named *MinimalEventCounterSource.cs* and use the code snippet as its source:

C#

```
using System.Diagnostics.Tracing;

[EventSource(Name = "Sample.EventCounter.Minimal")]
public sealed class MinimalEventCounterSource : EventSource
{
    public static readonly MinimalEventCounterSource Log = new
MinimalEventCounterSource();

    private EventCounter _requestCounter;

    private MinimalEventCounterSource() =>
        _requestCounter = new EventCounter("request-time", this)
        {
            DisplayName = "Request Processing Time",
            DisplayUnits = "ms"
        };

    public void Request(string url, long elapsedMilliseconds)
    {
        WriteEvent(1, url, elapsedMilliseconds);
        _requestCounter?.WriteMetric(elapsedMilliseconds);
    }

    protected override void Dispose(bool disposing)
    {
        _requestCounter?.Dispose();
        _requestCounter = null;

        base.Dispose(disposing);
    }
}
```

The EventSource.WriteEvent line is the EventSource part and is not part of EventCounter, it was written to show that you can log a message together with the event counter.

Add an action filter

The sample source code is an ASP.NET Core project. You can add an action filter globally that will log the total request time. Create a new file named *LogRequestTimeFilterAttribute.cs*, and use the following code:

C#

```
using System.Diagnostics;
using Microsoft.AspNetCore.Http.Extensions;
using Microsoft.AspNetCore.Mvc.Filters;

namespace DiagnosticScenarios
{
    public class LogRequestTimeFilterAttribute : ActionFilterAttribute
    {
        readonly Stopwatch _stopwatch = new Stopwatch();

        public override void OnActionExecuting(ActionExecutingContext
context) => _stopwatch.Start();

        public override void OnActionExecuted(ActionExecutedContext context)
        {
            _stopwatch.Stop();

            MinimalEventCounterSource.Log.Request(
                context.HttpContext.Request.GetDisplayUrl(),
_stopwatch.ElapsedMilliseconds);
        }
    }
}
```

The action filter starts a Stopwatch as the request begins, and stops after it has been completed, capturing the elapsed time. The total milliseconds are logged to the `MinimalEventCounterSource` singleton instance. For this filter to be applied, you need to add it to the filter collection. In the *Startup.cs* file, update the `ConfigureServices` method in include this filter.

C#

```
public void ConfigureServices(IServiceCollection services) =>
    services.AddControllers(options =>
options.Filters.Add<LogRequestTimeFilterAttribute>())
            .AddNewtonsoftJson();
```

Monitor event counter

With the implementation on an EventSource and the custom action filter, build and launch the application. You logged the metric to the EventCounter, but unless you access the statistics from of it, it is not useful. To get the statistics, you need to enable the EventCounter by creating a timer that fires as frequently as you want the events, as well as a listener to capture the events. To do that, you can use dotnet-counters.

Use the dotnet-counters ps command to display a list of .NET processes that can be monitored.

Console

```
dotnet-counters ps
```

Using the process identifier from the output of the `dotnet-counters ps` command, you can start monitoring the event counter with the following `dotnet-counters monitor` command:

Console

```
dotnet-counters monitor --process-id 2196 --counters
Sample.EventCounter.Minimal,Microsoft.AspNetCore.Hosting[total-
requests,requests-per-second],System.Runtime[cpu-usage]
```

While the `dotnet-counters monitor` command is running, hold F5 on the browser to start issuing continuous requests to the `https://localhost:5001/api/values` endpoint. After a few seconds stop by pressing q

Console

```
Press p to pause, r to resume, q to quit.
    Status: Running

[Microsoft.AspNetCore.Hosting]
    Request Rate / 1 sec                                 9
    Total Requests                                     134
[System.Runtime]
    CPU Usage (%)                                       13
[Sample.EventCounter.Minimal]
    Request Processing Time (ms)                      34.5
```

The `dotnet-counters monitor` command is great for active monitoring. However, you may want to collect these diagnostic metrics for post processing and analysis. For that, use the `dotnet-counters collect` command. The `collect` switch command is similar to the `monitor` command, but accepts a few additional parameters. You can specify the desired output file name and format. For a JSON file named *diagnostics.json* use the following command:

Console

```
dotnet-counters collect --process-id 2196 --format json -o diagnostics.json
--counters Sample.EventCounter.Minimal,Microsoft.AspNetCore.Hosting[total-
```

```
requests,requests-per-second],System.Runtime[cpu-usage]
```

Again, while the command is running, hold `F5` on the browser to start issuing continuous requests to the `https://localhost:5001/api/values` endpoint. After a few seconds stop by pressing `q`. The *diagnostics.json* file is written. The JSON file that is written is not indented, however; for readability it is indented here.

Globalization and localization in ASP.NET Core

Article • 10/25/2024

> **Important**
>

>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson, Damien Bowden, Bart Calixto, Nadeem Afana, and Hisham Bin Ateya

A multilingual website allows a website to reach a wider audience. ASP.NET Core provides services and middleware for localizing into different languages and cultures.

For Blazor localization guidance, which adds to or supersedes the guidance in this article, see ASP.NET Core Blazor globalization and localization.

Terms

- Globalization (G11N): The process of making an app support different languages and regions. The abbreviation comes from the first and last letters and the number of letters between them.
- Localization (L10N): The process of customizing a globalized app for specific languages and regions.
- Internationalization (I18N): Both globalization and localization.
- Culture: A language and, optionally, a region.
- Neutral culture: A culture that has a specified language, but not a region (for example "en", "es").
- Specific culture: A culture that has a specified language and region (for example, "en-US", "en-GB", "es-CL").
- Parent culture: The neutral culture that contains a specific culture (for example, "en" is the parent culture of "en-US" and "en-GB").
- Locale: A locale is the same as a culture.

Language and country/region codes

The RFC 4646 format for the culture name is `<language code>-<country/region code>`, where `<language code>` identifies the language and `<country/region code>` identifies the subculture. For example, `es-CL` for Spanish (Chile), `en-US` for English (United States), and `en-AU` for English (Australia). RFC 4646 is a combination of an ISO 639 two-letter lowercase culture code associated with a language and an ISO 3166 two-letter uppercase subculture code associated with a country or region. For more information, see System.Globalization.CultureInfo.

Tasks to localize an app

Globalizing and localizing an app involves the following tasks:

- Make an ASP.NET Core app's content localizable.
- Provide localized resources for the cultures the app supports
- Implement a strategy to select the culture for each request

View or download sample code (how to download)

Additional resources

- Url culture provider using middleware as filters in ASP.NET Core
- Applying the RouteDataRequest CultureProvider globally with middleware as filters
- IStringLocalizer : Uses the ResourceManager and ResourceReader to provide culture-specific resources at run time. The interface has an indexer and an `IEnumerable` for returning localized strings.
- IHtmlLocalizer: For resources that contain HTML.
- View and DataAnnotations
- Troubleshoot ASP.NET Core localization
- Globalizing and localizing .NET applications
- Resources in .resx Files
- Microsoft Multilingual App Toolkit
- Localization & Generics

Make an ASP.NET Core app's content localizable

Article • 10/25/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Hisham Bin Ateya, Damien Bowden, Bart Calixto and Nadeem Afana

One task for localizing an app is to wrap localizable content with code that facilitates replacing that content for different cultures.

`IStringLocalizer`

IStringLocalizer and IStringLocalizer<T> were architected to improve productivity when developing localized apps. `IStringLocalizer` uses the ResourceManager and ResourceReader to provide culture-specific resources at run time. The interface has an indexer and an `IEnumerable` for returning localized strings. `IStringLocalizer` doesn't require storing the default language strings in a resource file. You can develop an app targeted for localization and not need to create resource files early in development.

The following code example shows how to wrap the string "About Title" for localization.

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Localization;

namespace Localization.Controllers;

[Route("api/[controller]")]
public class AboutController : Controller
{
    private readonly IStringLocalizer<AboutController> _localizer;

    public AboutController(IStringLocalizer<AboutController> localizer)
    {
        _localizer = localizer;
```

```
    }

    [HttpGet]
    public string Get()
    {
        return _localizer["About Title"];
    }
}
```

In the preceding code, the `IStringLocalizer<T>` implementation comes from Dependency Injection. If the localized value of "About Title" isn't found, then the indexer key is returned, that is, the string "About Title".

You can leave the default language literal strings in the app and wrap them in the localizer, so that you can focus on developing the app. You develop an app with your default language and prepare it for the localization step without first creating a default resource file.

Alternatively, you can use the traditional approach and provide a key to retrieve the default language string. For many developers, the new workflow of not having a default language *.resx* file and simply wrapping the string literals can reduce the overhead of localizing an app. Other developers prefer the traditional work flow as it can be easier to work with long string literals and easier to update localized strings.

`IHtmlLocalizer`

Use the IHtmlLocalizer<TResource> implementation for resources that contain HTML. IHtmlLocalizer HTML-encodes arguments that are formatted in the resource string, but doesn't HTML-encode the resource string itself. In the following highlighted code, only the value of the `name` parameter is HTML-encoded.

C#

```
using System;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Localization;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.Localization;

namespace Localization.Controllers;

public class BookController : Controller
{
    private readonly IHtmlLocalizer<BookController> _localizer;

    public BookController(IHtmlLocalizer<BookController> localizer)
    {
```

```
        _localizer = localizer;
    }

    public IActionResult Hello(string name)
    {
        ViewData["Message"] = _localizer["<b>Hello</b><i> {0}</i>", name];

        return View();
    }
```

NOTE: Generally, only localize text, not HTML.

`IStringLocalizerFactory`

At the lowest level, IStringLocalizerFactory can be retrieved from of Dependency Injection:

C#

```
public class TestController : Controller
{
    private readonly IStringLocalizer _localizer;
    private readonly IStringLocalizer _localizer2;

    public TestController(IStringLocalizerFactory factory)
    {
        var type = typeof(SharedResource);
        var assemblyName = new
AssemblyName(type.GetTypeInfo().Assembly.FullName);
        _localizer = factory.Create(type);
        _localizer2 = factory.Create("SharedResource", assemblyName.Name);
    }

    public IActionResult About()
    {
        ViewData["Message"] = _localizer["Your application description
page."]
            + " loc 2: " + _localizer2["Your application description
page."];

        return View();
    }
```

The preceding code demonstrates each of the two factory create methods.

Shared resources

You can partition your localized strings by controller or area, or have just one container. In the sample app, a marker class named `SharedResource` is used for shared resources. The marker class is never called:

C#

```
// Dummy class to group shared resources

namespace Localization;

public class SharedResource
{
}
```

In the following sample, the `InfoController` and the `SharedResource` localizers are used:

C#

```
public class InfoController : Controller
{
    private readonly IStringLocalizer<InfoController> _localizer;
    private readonly IStringLocalizer<SharedResource> _sharedLocalizer;

    public InfoController(IStringLocalizer<InfoController> localizer,
                          IStringLocalizer<SharedResource> sharedLocalizer)
    {
        _localizer = localizer;
        _sharedLocalizer = sharedLocalizer;
    }

    public string TestLoc()
    {
        string msg = "Shared resx: " + _sharedLocalizer["Hello!"] +
                     " Info resx " + _localizer["Hello!"];
        return msg;
    }
```

View localization

The IViewLocalizer service provides localized strings for a view. The `ViewLocalizer` class implements this interface and finds the resource location from the view file path. The following code shows how to use the default implementation of `IViewLocalizer`:

CSHTML

```
@using Microsoft.AspNetCore.Mvc.Localization
```

```
@inject IViewLocalizer Localizer

@{
    ViewData["Title"] = Localizer["About"];
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<p>@Localizer["Use this area to provide additional information."]</p>
```

The default implementation of `IViewLocalizer` finds the resource file based on the view's file name. There's no option to use a global shared resource file. `ViewLocalizer` implements the localizer using `IHtmlLocalizer`, so Razor doesn't HTML-encode the localized string. You can parameterize resource strings, and `IViewLocalizer` HTML-encodes the parameters but not the resource string. Consider the following Razor markup:

CSHTML

```
@Localizer["<i>Hello</i> <b>{0}!</b>", UserManager.GetUserName(User)]
```

A French resource file could contain the following values:

Expand table

Key	Value
`<i>Hello</i> <b>{0}!</b>`	`<i>Bonjour</i> <b>{0} !</b>`

The rendered view would contain the HTML markup from the resource file.

Generally, ***only localize text***, not HTML.

To use a shared resource file in a view, inject `IHtmlLocalizer<T>`:

CSHTML

```
@using Microsoft.AspNetCore.Mvc.Localization
@using Localization.Services

@inject IViewLocalizer Localizer
@inject IHtmlLocalizer<SharedResource> SharedLocalizer

@{
    ViewData["Title"] = Localizer["About"];
}
<h2>@ViewData["Title"].</h2>
```

```
<h1>@SharedLocalizer["Hello!"]</h1>
```

DataAnnotations localization

DataAnnotations error messages are localized with `IStringLocalizer<T>`. Using the option `ResourcesPath = "Resources"`, the error messages in `RegisterViewModel` can be stored in either of the following paths:

- *Resources/ViewModels.Account.RegisterViewModel.fr.resx*
- *Resources/ViewModels/Account/RegisterViewModel.fr.resx*

C#

```
using System.ComponentModel.DataAnnotations;

namespace Localization.ViewModels.Account;

public class RegisterViewModel
{
    [Required(ErrorMessage = "The Email field is required.")]
    [EmailAddress(ErrorMessage = "The Email field is not a valid email
address.")]
    [Display(Name = "Email")]
    public string Email { get; set; }

    [Required(ErrorMessage = "The Password field is required.")]
    [StringLength(8, ErrorMessage = "The {0} must be at least {2} characters
long.",

MinimumLength = 6)]
    [DataType(DataType.Password)]
    [Display(Name = "Password")]
    public string Password { get; set; }

    [DataType(DataType.Password)]
    [Display(Name = "Confirm password")]
    [Compare("Password", ErrorMessage =
                            "The password and confirmation password do not
match.")]
    public string ConfirmPassword { get; set; }
}
```

Non-validation attributes are localized.

How to use one resource string for multiple classes

The following code shows how to use one resource string for validation attributes with multiple classes:

```
C#

    services.AddMvc()
        .AddDataAnnotationsLocalization(options => {
            options.DataAnnotationLocalizerProvider = (type, factory) =>
                factory.Create(typeof(SharedResource));
        });
```

In the preceding code, `SharedResource` is the class corresponding to the *.resx* file where the validation messages are stored. With this approach, DataAnnotations only uses `SharedResource`, rather than the resource for each class.

Configure localization services

Localization services are configured in `Program.cs`:

```
C#

builder.Services.AddLocalization(options => options.ResourcesPath =
"Resources");

builder.Services.AddMvc()
    .AddViewLocalization(LanguageViewLocationExpanderFormat.Suffix)
    .AddDataAnnotationsLocalization();
```

- AddLocalization adds the localization services to the services container, including implementations for `IStringLocalizer<T>` and `IStringLocalizerFactory`. The preceding code also sets the resources path to "Resources".
- AddViewLocalization adds support for localized view files. In this sample, view localization is based on the view file suffix. For example "fr" in the `Index.fr.cshtml` file.
- AddDataAnnotationsLocalization adds support for localized `DataAnnotations` validation messages through `IStringLocalizer` abstractions.

> **Note**
>
> You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and

non US-English date formats, you must take steps to globalize your app. See this GitHub comment 4076 for instructions on adding decimal comma.

Next steps

Localizing an app also involves the following tasks:

- Provide localized resources for the languages and cultures the app supports
- Implement a strategy to select the language/culture for each request

Provide localized resources for languages and cultures in an ASP.NET Core app

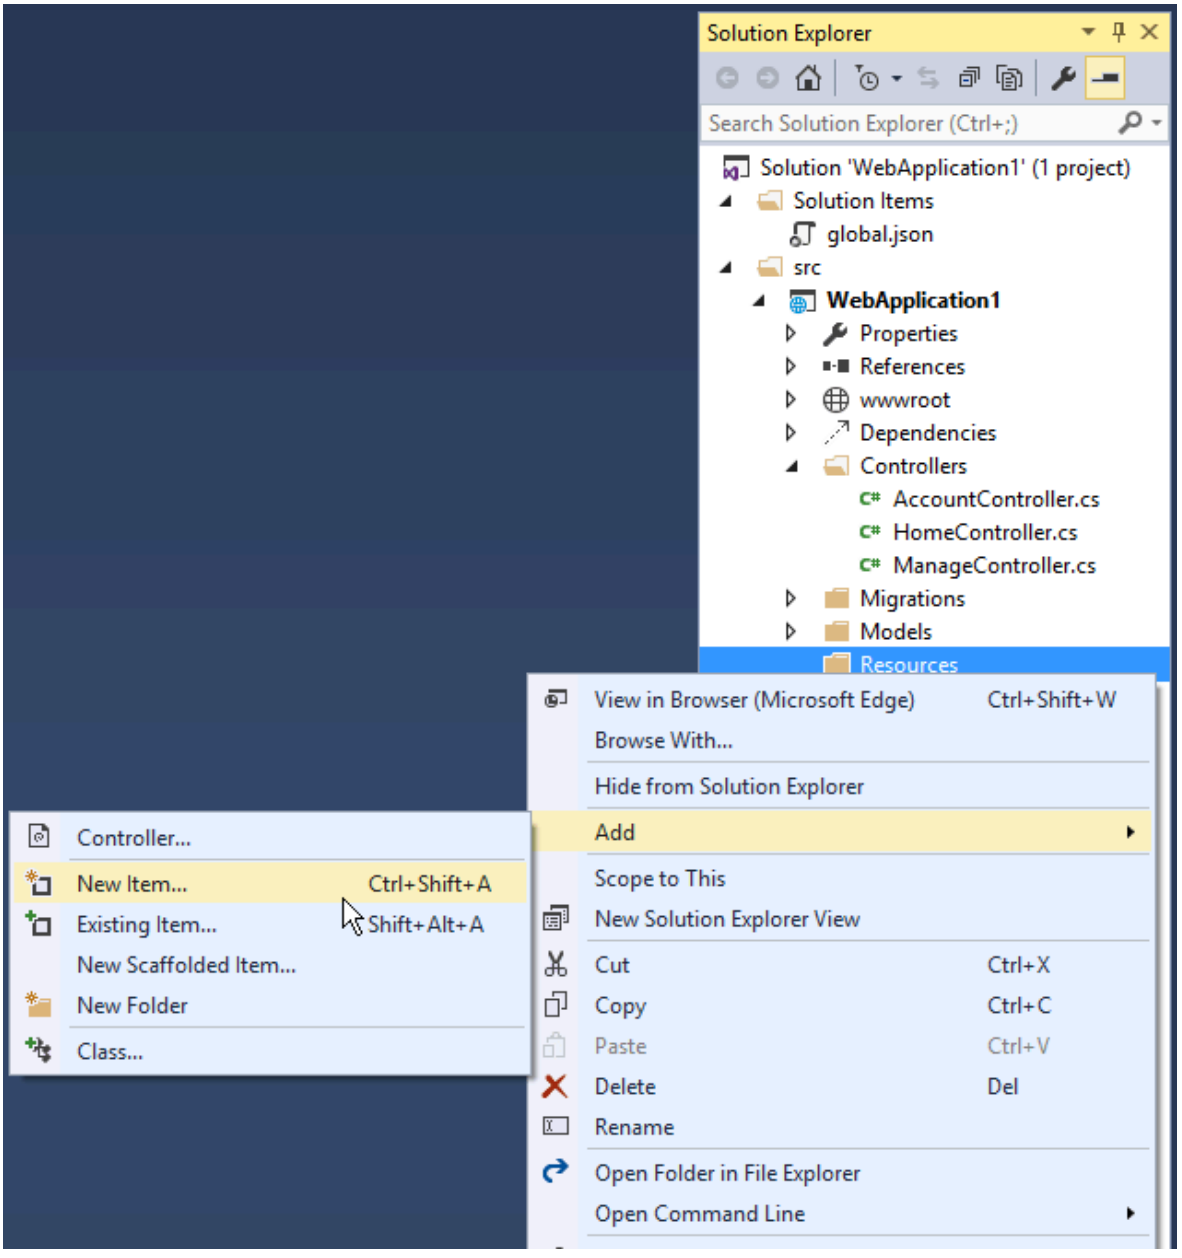
Article • 10/25/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson, Damien Bowden, Bart Calixto, Nadeem Afana, and Hisham Bin Ateya

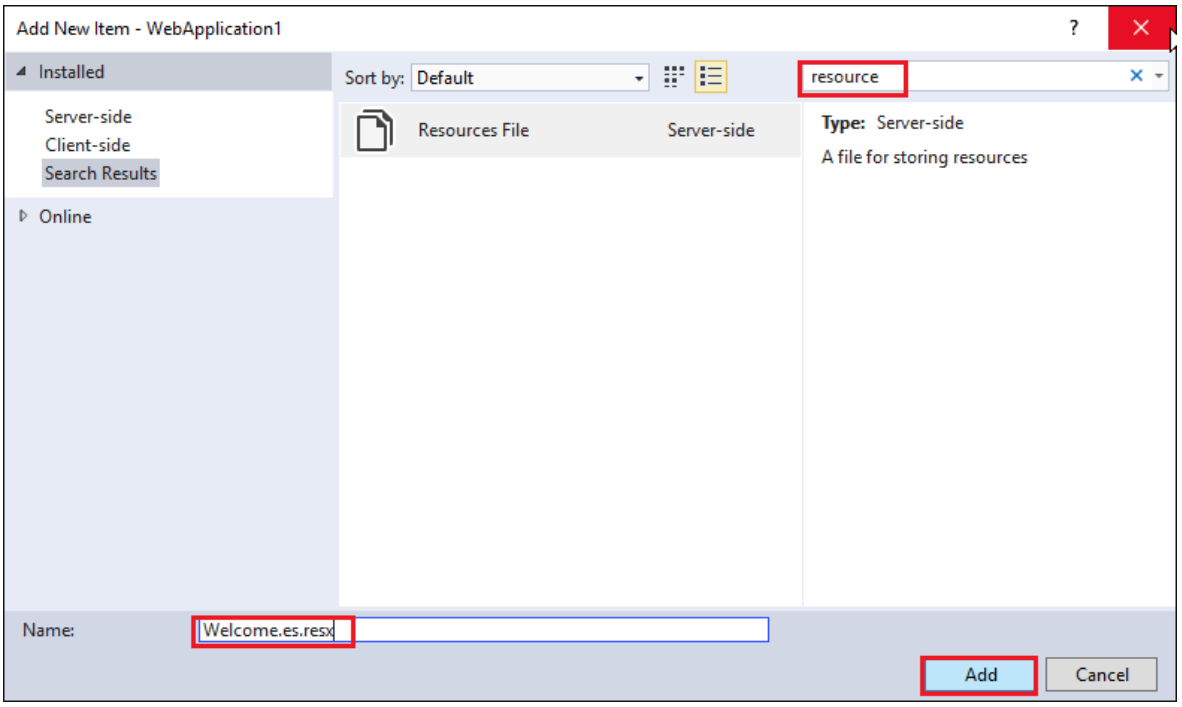
One task for localizing an app is to provide localized strings in resource files. This article is about working with resource files.

`SupportedCultures` and `SupportedUICultures`



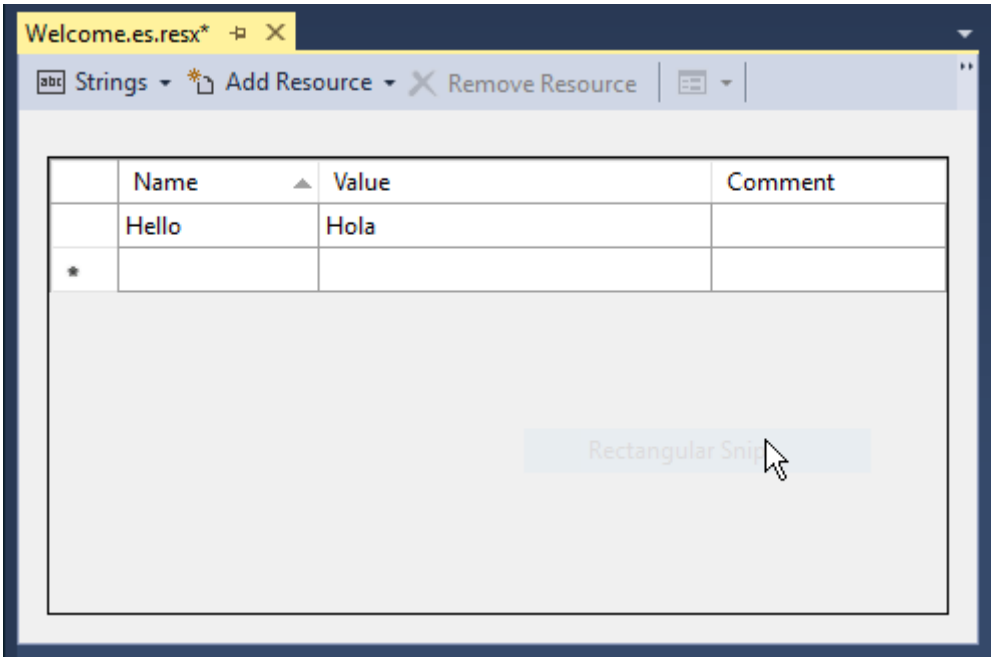
ASP.NET Core has two collections of culture values, `SupportedCultures` and `SupportedUICultures`. The CultureInfo object for `SupportedCultures` determines the results of culture-dependent functions, such as date, time, number, and currency formatting. `SupportedCultures` also determines the sorting order of text, casing conventions, and string comparisons. See StringComparer.CurrentCulture for more info on how the server gets the culture. The `SupportedUICultures` determines which translated strings (from *.resx* files) are looked up by the ResourceManager. The `ResourceManager` simply looks up culture-specific strings that are determined by `CurrentUICulture`. Every thread in .NET has `CurrentCulture` and `CurrentUICulture` objects. ASP.NET Core inspects these values when rendering culture-dependent functions. For example, if the current thread's culture is set to "en-US" (English, United States), `DateTime.Now.ToLongDateString()` displays "Thursday, February 18, 2016", but if `CurrentCulture` is set to "es-ES" (Spanish, Spain) the output will be "jueves, 18 de febrero de 2016".

Resource files

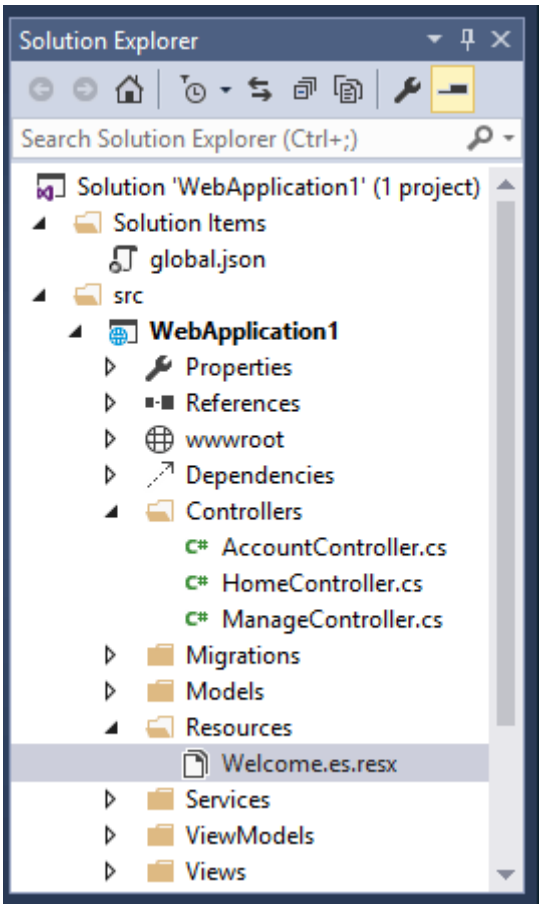


NOTE: ResX Viewer and Editor provides an alternate mechanism to work with resource files using Visual Studio Code.

A resource file is a useful mechanism for separating localizable strings from code. Translated strings for the non-default language are isolated in *.resx* resource files. For example, you might want to create a Spanish resource file named *Welcome.es.resx* containing translated strings. "es" is the language code for Spanish. To create this resource file in Visual Studio:



1. In **Solution Explorer**, right click on the folder that will contain the resource file, and then select **Add** > **New Item**.



2. In the **Search installed templates** box, enter "resource" and name the file.

3. Enter the key value (native string) in the **Name** column and the translated string in the **Value** column.

Visual Studio shows the *Welcome.es.resx* file.

Resource file naming

Resources are named for the full type name of their class minus the assembly name. For example, a French resource in a project whose main assembly is `LocalizationWebsite.Web.dll` for the class `LocalizationWebsite.Web.Startup` would be named *Startup.fr.resx*. A resource for the class `LocalizationWebsite.Web.Controllers.HomeController` would be named *Controllers.HomeController.fr.resx*. If your targeted class's namespace isn't the same as the assembly name you will need the full type name. For example, in the sample project a resource for the type `ExtraNamespace.Tools` would be named *ExtraNamespace.Tools.fr.resx*.

In the sample project, the `ConfigureServices` method sets the `ResourcesPath` to "Resources", so the project relative path for the home controller's French resource file is *Resources/Controllers.HomeController.fr.resx*. Alternatively, you can use folders to organize resource files. For the home controller, the path would be *Resources/Controllers/HomeController.fr.resx*. If you don't use the `ResourcesPath` option, the *.resx* file would go in the project base directory. The resource file for `HomeController` would be named *Controllers.HomeController.fr.resx*. The choice of using the dot or path naming convention depends on how you want to organize your resource files.

Expand table

Resource name	Dot or path naming
Resources/Controllers.HomeController.fr.resx	Dot
Resources/Controllers/HomeController.fr.resx	Path

Resource files using `@inject IViewLocalizer` in Razor views follow a similar pattern. The resource file for a view can be named using either dot naming or path naming. Razor view resource files mimic the path of their associated view file. Assuming we set the `ResourcesPath` to "Resources", the French resource file associated with the `Views/Home/About.cshtml` view could be either of the following:

- Resources/Views/Home/About.fr.resx
- Resources/Views.Home.About.fr.resx

If you don't use the `ResourcesPath` option, the *.resx* file for a view would be located in the same folder as the view.

RootNamespaceAttribute

The RootNamespaceAttribute attribute provides the root namespace of an assembly when the root namespace of an assembly is different than the assembly name.

> ⚠ **Warning**
>
> This can occur when a project's name is not a valid .NET identifier. For instance `my-project-name.csproj` will use the root namespace `my_project_name` and the assembly name `my-project-name` leading to this error.

If the root namespace of an assembly is different than the assembly name:

- Localization does not work by default.
- Localization fails due to the way resources are searched for within the assembly. `RootNamespace` is a build-time value which is not available to the executing process.

If the `RootNamespace` is different from the `AssemblyName`, include the following in `AssemblyInfo.cs` (with parameter values replaced with the actual values):

```
C#
```

```
using System.Reflection;
using Microsoft.Extensions.Localization;

[assembly: ResourceLocation("Resource Folder Name")]
[assembly: RootNamespace("App Root Namespace")]
```

The preceding code enables the successful resolution of resx files.

Culture fallback behavior

When searching for a resource, localization engages in "culture fallback". Starting from the requested culture, if not found, it reverts to the parent culture of that culture. As an aside, the CultureInfo.Parent property represents the parent culture. This usually (but not always) means removing the national signifier from the language-and-culture code. For example, the dialect of Spanish spoken in Mexico is "es-MX". It has the parent "es"—Spanish non-specific to any country.

Imagine your site receives a request for a "Welcome" resource using culture "fr-CA". The localization system looks for the following resources, in order, and selects the first match:

- *Welcome.fr-CA.resx*
- *Welcome.fr.resx*
- *Welcome.resx* (if the `NeutralResourcesLanguage` is "fr-CA")

As an example, if you remove the ".fr" culture designator and you have the culture set to French, the default resource file is read and strings are localized. The Resource manager designates a default or fallback resource for when nothing meets your requested culture. If you want to just return the key when missing a resource for the requested culture you must not have a default resource file.

Generate resource files with Visual Studio

If you create a resource file in Visual Studio without a culture in the file name (for example, *Welcome.resx*), Visual Studio will create a C# class with a property for each string. That's usually not what you want with ASP.NET Core. You typically don't have a default *.resx* resource file (a *.resx* file without the culture name). We suggest you create the *.resx* file with a culture name (for example *Welcome.fr.resx*). When you create a *.resx* file with a culture name, Visual Studio won't generate the class file.

Add other cultures

Each language and culture combination (other than the default language) requires a unique resource file. You create resource files for different cultures and locales by creating new resource files in which the language codes are part of the file name (for example, **en-us**, **fr-ca**, and **en-gb**). These codes are placed between the file name and the *.resx* file extension, as in *Welcome.es-MX.resx* (Spanish/Mexico).

Next steps

Localizing an app also involves the following tasks:

- Make the app's content localizable.
- Implement a strategy to select the language/culture for each request

Implement a strategy to select the language/culture for each request in a localized ASP.NET Core app

Article • 10/25/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Hisham Bin Ateya, Damien Bowden, Bart Calixto, Nadeem Afana, and Rick Anderson

One task for localizing an app is to implement a strategy for selecting the appropriate culture for each response the app returns.

Configure Localization middleware

The current culture on a request is set in the localization Middleware. The localization middleware is enabled in `Program.cs`. The localization middleware must be configured before any middleware that might check the request culture (for example, `app.UseMvcWithDefaultRoute()`).

C#

```
builder.Services.Configure<RequestLocalizationOptions>(options =>
{
    var supportedCultures = new[] { "en-US", "fr" };
    options.SetDefaultCulture(supportedCultures[0])
        .AddSupportedCultures(supportedCultures)
        .AddSupportedUICultures(supportedCultures);
});
```

UseRequestLocalization initializes a RequestLocalizationOptions object. On every request the list of RequestCultureProvider in the RequestLocalizationOptions is enumerated and the first provider that can successfully determine the request culture is used. The default providers come from the `RequestLocalizationOptions` class:

1. QueryStringRequestCultureProvider
2. CookieRequestCultureProvider
3. AcceptLanguageHeaderRequestCultureProvider

The default list goes from most specific to least specific. Later in the article you'll see how you can change the order and even add a custom culture provider. If none of the providers can determine the request culture, the DefaultRequestCulture is used.

QueryStringRequestCultureProvider

Some apps will use a query string to set the CultureInfo. For apps that use the cookie or Accept-Language header approach, adding a query string to the URL is useful for debugging and testing code. By default, the QueryStringRequestCultureProvider is registered as the first localization provider in the `RequestCultureProvider` list. You pass the query string parameters `culture` and `ui-culture`. The following example sets the specific culture (language and region) to Spanish/Mexico:

```
http://localhost:5000/?culture=es-MX&ui-culture=es-MX
```

If only `culture` or `ui-culture` is passed in, the query string provider sets both values using the one passed in. For example, setting just the culture will set both the `Culture` and the `UICulture`:

```
http://localhost:5000/?culture=es-MX
```

CookieRequestCultureProvider

Production apps will often provide a mechanism to set the culture with the ASP.NET Core culture cookie. Use the MakeCookieValue method to create a cookie.

The CookieRequestCultureProvider DefaultCookieName returns the default cookie name used to track the user's preferred culture information. The default cookie name is `.AspNetCore.Culture`.

The cookie format is `c=%LANGCODE%|uic=%LANGCODE%`, where `c` is `Culture` and `uic` is `UICulture`, for example:

```
c=en-UK|uic=en-US
```

If only one of culture info or UI culture is provided, the provided culture is used for both culture info and UI culture.

The Accept-Language HTTP header

The Accept-Language header is settable in most browsers and was originally intended to specify the user's language. This setting indicates what the browser has been set to send or has inherited from the underlying operating system. The Accept-Language HTTP header from a browser request isn't an infallible way to detect the user's preferred language (see Setting language preferences in a browser). A production app should include a way for a user to customize their choice of culture.

Set the Accept-Language HTTP header in Edge

1. Search **Settings** for **Preferred languages**.
2. The preferred languages are listed in the **Preferred languages** box.
3. Select **Add languages** to add to the list.
4. Select **More actions ...** next to a language to change the order of preference.

The Content-Language HTTP header

The Content-Language entity header:

- Is used to describe the language(s) intended for the audience.
- Allows a user to differentiate according to the users' own preferred language.

Entity headers are used in both HTTP requests and responses.

The `Content-Language` header can be added by setting the property ApplyCurrentCultureToResponseHeaders.

Adding the Content-Language header:

- Allows the RequestLocalizationMiddleware to set the `Content-Language` header with the `CurrentUICulture`.
- Eliminates the need to set the response header `Content-Language` explicitly.

C#

```
app.UseRequestLocalization(new RequestLocalizationOptions
{
    ApplyCurrentCultureToResponseHeaders = true
});
```

Apply the RouteDataRequest CultureProvider

The RouteDataRequestCultureProvider sets the culture based on the value of the `culture` route value. See Url culture provider using middleware as filters for information on:

- Using the middleware as filters feature of ASP.NET Core.
- How to use `RouteDataRequestCultureProvider` to set the culture of an app from the url.

See Applying the RouteDataRequest CultureProvider globally with middleware as filters for information on how to apply the `RouteDataRequestCultureProvider` globally.

Use a custom provider

Suppose you want to let your customers store their language and culture in your databases. You could write a provider to look up these values for the user. The following code shows how to add a custom provider:

C#

```
private const string enUSCulture = "en-US";

services.Configure<RequestLocalizationOptions>(options =>
{
    var supportedCultures = new[]
    {
        new CultureInfo(enUSCulture),
        new CultureInfo("fr")
    };

    options.DefaultRequestCulture = new RequestCulture(culture: enUSCulture,
uiCulture: enUSCulture);
    options.SupportedCultures = supportedCultures;
    options.SupportedUICultures = supportedCultures;

    options.AddInitialRequestCultureProvider(new
CustomRequestCultureProvider(async context =>
    {
```

```
        // My custom request culture logic
        return await Task.FromResult(new ProviderCultureResult("en"));
    }));
});
```

Use `RequestLocalizationOptions` to add or remove localization providers.

Change request culture providers order

RequestLocalizationOptions has three default request culture providers: QueryStringRequestCultureProvider, CookieRequestCultureProvider, and AcceptLanguageHeaderRequestCultureProvider. Use RequestLocalizationOptions.RequestCultureProviders property to change the order of these providers as shown in the following below:

C#

```
    app.UseRequestLocalization(options =>
    {
        var questStringCultureProvider = options.RequestCultureProviders[0];
        options.RequestCultureProviders.RemoveAt(0);
        options.RequestCultureProviders.Insert(1,
questStringCultureProvider);
    });
```

In the preceding example, the order of `QueryStringRequestCultureProvider` and `CookieRequestCultureProvider` is switched, so the `RequestLocalizationMiddleware` looks for the cultures from the cookies first, then the query string.

As previously mentioned, add a custom provider via AddInitialRequestCultureProvider which sets the order to `0`, so this provider takes the precedence over the others.

User override culture

The RequestLocalizationOptions.CultureInfoUseUserOverride property allows the app to decide whether or not to use non-default Windows settings for the CultureInfo DateTimeFormat and NumberFormat properties. This has ***no*** impact on Linux. This directly corresponds to UseUserOverride.

C#

```
    app.UseRequestLocalization(options =>
    {
```

```
        options.CultureInfoUseUserOverride = false;
    });
```

Set the culture programmatically

This sample **Localization.StarterWeb** project on GitHub contains UI to set the `Culture`. The `Views/Shared/_SelectLanguagePartial.cshtml` file allows you to select the culture from the list of supported cultures:

CSHTML

```
@using Microsoft.AspNetCore.Builder
@using Microsoft.AspNetCore.Http.Features
@using Microsoft.AspNetCore.Localization
@using Microsoft.AspNetCore.Mvc.Localization
@using Microsoft.Extensions.Options

@inject IViewLocalizer Localizer
@inject IOptions<RequestLocalizationOptions> LocOptions

@{
    var requestCulture = Context.Features.Get<IRequestCultureFeature>();
    var cultureItems = LocOptions.Value.SupportedUICultures
        .Select(c => new SelectListItem { Value = c.Name, Text =
c.DisplayName })
        .ToList();
    var returnUrl = string.IsNullOrEmpty(Context.Request.Path) ? "~/" : $"~
{Context.Request.Path.Value}";
}

<div title="@Localizer["Request culture provider:"]
@requestCulture?.Provider?.GetType().Name">
    <form id="selectLanguage" asp-controller="Home"
          asp-action="SetLanguage" asp-route-returnUrl="@returnUrl"
          method="post" class="form-horizontal" role="form">
        <label asp-
for="@requestCulture.RequestCulture.UICulture.Name">@Localizer["Language:"]
</label> <select name="culture"
          onchange="this.form.submit();"
          asp-for="@requestCulture.RequestCulture.UICulture.Name" asp-
items="cultureItems">
        </select>
    </form>
</div>
```

The `Views/Shared/_SelectLanguagePartial.cshtml` file is added to the `footer` section of the layout file so it will be available to all views:

CSHTML

```
<div class="container body-content" style="margin-top:60px">
    @RenderBody()
    <hr>
    <footer>
        <div class="row">
            <div class="col-md-6">
                <p>&copy; @System.DateTime.Now.Year - Localization</p>
            </div>
            <div class="col-md-6 text-right">
                @await Html.PartialAsync("_SelectLanguagePartial")
            </div>
        </div>
    </footer>
</div>
```

The `SetLanguage` method sets the culture cookie.

C#

```
[HttpPost]
public IActionResult SetLanguage(string culture, string returnUrl)
{
    Response.Cookies.Append(
        CookieRequestCultureProvider.DefaultCookieName,
        CookieRequestCultureProvider.MakeCookieValue(new
RequestCulture(culture)),
        new CookieOptions { Expires = DateTimeOffset.UtcNow.AddYears(1) }
    );

    return LocalRedirect(returnUrl);
}
```

You can't plug in the `_SelectLanguagePartial.cshtml` to sample code for this project. The **Localization.StarterWeb** project on GitHub has code to flow the `RequestLocalizationOptions` to a Razor partial through the Dependency Injection container.

Model binding route data and query strings

See Globalization behavior of model binding route data and query strings.

Next steps

Localizing an app also involves the following tasks:

- Make the app's content localizable.

- Provide localized resources for the languages and cultures the app supports

Configure portable object localization in ASP.NET Core

Article • 08/07/2024

By Hisham Bin Ateya and Sébastien Ros.

This article walks through the steps for using Portable Object (PO) files in an ASP.NET Core application with the Orchard Core framework.

Note: Orchard Core isn't a Microsoft product. Microsoft provides no support for this feature.

View or download sample code (how to download)

What is a PO file?

PO files are distributed as text files containing the translated strings for a given language. Some advantages of using PO files instead of *.resx* files include:

- PO files support pluralization; *.resx* files don't support pluralization.
- PO files aren't compiled like *.resx* files. As such, specialized tooling and build steps aren't required.
- PO files work well with collaborative online editing tools.

Example

The following sample PO file contains the translation for two strings in French, including one with its plural form:

fr.po

text

```
#: Pages/Index.cshtml:13
msgid "Hello world!"
msgstr "Bonjour le monde!"

msgid "There is one item."
msgid_plural "There are {0} items."
msgstr[0] "Il y a un élément."
msgstr[1] "Il y a {0} éléments."
```

This example uses the following syntax:

- `#:`: A comment indicating the context of the string to be translated. The same string might be translated differently depending on where it's being used.
- `msgid`: The untranslated string.
- `msgstr`: The translated string.

For pluralization support, more entries can be defined.

- `msgid_plural`: The untranslated plural string.
- `msgstr[0]`: The translated string for the case 0.
- `msgstr[N]`: The translated string for the case N.

The PO file specification can be found here.

Configuring PO file support in ASP.NET Core

This example is based on an ASP.NET Core Web application generated from a Visual Studio 2022 project template.

Referencing the package

Add a reference to the `OrchardCore.Localization.Core` NuGet package.

The `.csproj` file now contains a line similar to the following (version number may vary):

XML

```xml
<PackageReference Include="OrchardCore.Localization.Core" Version="1.5.0" />
```

Registering the service

Add the required services to `Program.cs`:

C#

```
builder.Services.AddPortableObjectLocalization();

builder.Services
    .Configure<RequestLocalizationOptions>(options => options
        .AddSupportedCultures("fr", "cs")
        .AddSupportedUICultures("fr", "cs"));

builder.Services
```

```
    .AddRazorPages()
    .AddViewLocalization();
```

Add the following code to your Razor page of choice. `Index.cshtml` is used in this example.

CSHTML

```
@page
@using Microsoft.AspNetCore.Mvc.Localization
@inject IViewLocalizer Localizer
@{
    ViewData["Title"] = "Home";
}

<div class="text-center">
    <h1 class="display-4">Welcome</h1>
    <p>Learn about <a href="https://docs.microsoft.com/aspnet/core">building
Web apps with ASP.NET Core</a>.</p>
</div>

<p>@Localizer["Hello world!"]</p>
```

An `IViewLocalizer` instance is injected and used to translate the text "Hello world!".

Creating a PO file

Create a file named *<culture code>.po* in your application root folder. In this example, the file name is *fr.po* because the French language is used:

text

```
msgid "Hello world!"
msgstr "Bonjour le monde!"
```

This file stores both the string to translate and the French-translated string. Translations revert to their parent culture, if necessary. In this example, the *fr.po* file is used if the requested culture is `fr-FR` or `fr-CA`.

Testing the application

Run your application, the text **Hello world!** is displayed.

Navigate to the URL `/Index?culture=fr-FR`. The text **Bonjour le monde!** is displayed.

Pluralization

PO files support pluralization forms, which is useful when the same string needs to be translated differently based on a cardinality. This task is made complicated by the fact that each language defines custom rules to select which string to use based on the cardinality.

The Orchard Localization package provides an API to invoke these different plural forms automatically.

Creating pluralization PO files

Add the following content to the previously mentioned *fr.po* file:

```text
msgid "There is one item."
msgid_plural "There are {0} items."
msgstr[0] "Il y a un élément."
msgstr[1] "Il y a {0} éléments."
```

See What is a PO file? for an explanation of what each entry in this example represents.

Adding a language using different pluralization forms

English and French strings were used in the previous example. English and French have only two pluralization forms and share the same form rules, which is that a cardinality of one is mapped to the first plural form. Any other cardinality is mapped to the second plural form.

Not all languages share the same rules. This is illustrated with the Czech language, which has three plural forms.

Create the `cs.po` file as follows, and note how the pluralization needs three different translations:

```text
msgid "Hello world!"
msgstr "Ahoj světe!!"

msgid "There is one item."
msgid_plural "There are {0} items."
msgstr[0] "Existuje jedna položka."
```

```
msgstr[1] "Existují {0} položky."
msgstr[2] "Existuje {0} položek."
```

To accept Czech localizations, add `"cs"` to the list of supported cultures in the `Configure` method:

C#

```
builder.Services
    .Configure<RequestLocalizationOptions>(options => options
        .AddSupportedCultures("fr", "cs")
        .AddSupportedUICultures("fr", "cs"));
```

Edit the `Pages/Index.cshtml` file to render localized, plural strings for several cardinalities:

CSHTML

```
<p>@Localizer.Plural(1, "There is one item.", "There are {0} items.")</p>
<p>@Localizer.Plural(2, "There is one item.", "There are {0} items.")</p>
<p>@Localizer.Plural(5, "There is one item.", "There are {0} items.")</p>
```

Note: In a real world scenario, a variable would be used to represent the count. Here, we repeat the same code with three different values to expose a specific case.

Upon switching cultures, you see the following:

For `/Index`:

HTML

```
There is one item.
There are 2 items.
There are 5 items.
```

For `/Index?culture=fr`:

HTML

```
Il y a un élément.
Il y a 2 éléments.
Il y a 5 éléments.
```

For `/Index?culture=cs`:

```
```

HTML

```
Existuje jedna položka.
Existují 2 položky.
Existuje 5 položek.
```

For the Czech culture, the three translations are different. The French and English cultures share the same construction for the two last translated strings.

Advanced tasks

Using additional arguments

The argument at index zero `{0}` always represents the count value. When invoking the `Plural` method it is possible to add additional arguments and their index will then start at one (`1`).

CSHTML

```
<p>@Localizer.Plural(count, "There is one item with the color {1}.", "There
are {0} items. The main color is {1}.", color)</p>
```

Contextualizing strings

Applications often contain the strings to be translated in several places. The same string may have a different translation in certain locations within an app (Razor views or class files). A PO file supports the notion of a file context, which can be used to categorize the string being represented. Using a file context, a string can be translated differently, depending on the file context (or lack of a file context).

The PO localization services use the name of the full class or the view that's used when translating a string. This is accomplished by setting the value on the `msgctxt` entry.

Consider a minor addition to the previous *fr.po* example. A Razor page located at `Pages/Index.cshtml` can be defined as the file context by setting the reserved `msgctxt` entry's value:

text

```
msgctxt "Views.Home.About"
msgid "Hello world!"
```

```
msgstr "Bonjour le monde!"
```

With the `msgctxt` set as such, text translation occurs when navigating to `/Index?culture=fr-FR`. The translation doesn't occur when navigating to `/Privacy?culture=fr-FR`.

When no specific entry is matched with a given file context, Orchard Core's fallback mechanism looks for an appropriate PO file without a context. Assuming there's no specific file context defined for `Pages/Privacy.cshtml`, navigating to `/Privacy?culture=fr-FR` loads a PO file such as:

text

```
msgid "Hello world!"
msgstr "Bonjour le monde!"
```

Changing the location of PO files

The default location of PO files can be changed in `Programs.cs`:

C#

```
services.AddPortableObjectLocalization(options => options.ResourcesPath =
"Localization");
```

In this example, the PO files are loaded from the *Localization* folder.

Implementing a custom logic for finding localization files

When more complex logic is needed to locate PO files, the `OrchardCore.Localization.PortableObject.ILocalizationFileLocationProvider` interface can be implemented and registered as a service. This is useful when PO files can be stored in varying locations or when the files have to be found within a hierarchy of folders.

Using a different default pluralized language

The package includes a `Plural` extension method that's specific to two plural forms. For languages requiring more plural forms, create an extension method. With an extension method, you won't need to provide any localization file for the default language — the original strings are already available directly in the code.

You can use the more generic `Plural(int count, string[] pluralForms, params object[] arguments)` overload which accepts a string array of translations.

Localization Extensibility

By Hisham Bin Ateya

This article:

- Lists the extensibility points on the localization APIs.
- Provides instructions on how to extend ASP.NET Core app localization.

Extensible Points in Localization APIs

ASP.NET Core localization APIs are built to be extensible. Extensibility allows developers to customize the localization according to their needs. For instance, OrchardCore has a `POStringLocalizer`. `POStringLocalizer` describes in detail using Portable Object localization to use `PO` files to store localization resources.

This article lists the two main extensibility points that localization APIs provide:

- RequestCultureProvider
- IStringLocalizer

Localization Culture Providers

ASP.NET Core localization APIs have four default providers that can determine the current culture of an executing request:

- QueryStringRequestCultureProvider
- CookieRequestCultureProvider
- AcceptLanguageHeaderRequestCultureProvider
- CustomRequestCultureProvider

The preceding providers are described in detail in the Localization Middleware documentation. If the default providers don't meet your needs, build a custom provider using one of the following approaches:

Use CustomRequestCultureProvider

CustomRequestCultureProvider provides a custom RequestCultureProvider that uses a simple delegate to determine the current localization culture:

C#

```
options.AddInitialRequestCultureProvider(new
CustomRequestCultureProvider(async context =>
{
    var currentCulture = "en";
    var segments = context.Request.Path.Value.Split(new char[] { '/' },
        StringSplitOptions.RemoveEmptyEntries);

    if (segments.Length > 1 && segments[0].Length == 2)
    {
        currentCulture = segments[0];
    }

    var requestCulture = new ProviderCultureResult(currentCulture);

    return Task.FromResult(requestCulture);
}));
```

Use a new implementation of RequestCultureProvider

A new implementation of RequestCultureProvider can be created that determines the request culture information from a custom source. For example, the custom source can be a configuration file or database.

The following example shows `AppSettingsRequestCultureProvider`, which extends the RequestCultureProvider to determine the request culture information from `appsettings.json`:

C#

```
public class AppSettingsRequestCultureProvider : RequestCultureProvider
{
    public string CultureKey { get; set; } = "culture";

    public string UICultureKey { get; set; } = "ui-culture";

    public override Task<ProviderCultureResult>
```

```
DetermineProviderCultureResult(HttpContext httpContext)
    {
        if (httpContext == null)
        {
            throw new ArgumentNullException();
        }

        var configuration =
httpContext.RequestServices.GetService<IConfigurationRoot>();
        var culture = configuration[CultureKey];
        var uiCulture = configuration[UICultureKey];

        if (culture == null && uiCulture == null)
        {
            return Task.FromResult((ProviderCultureResult)null);
        }

        if (culture != null && uiCulture == null)
        {
            uiCulture = culture;
        }

        if (culture == null && uiCulture != null)
        {
            culture = uiCulture;
        }

        var providerResultCulture = new ProviderCultureResult(culture,
uiCulture);

        return Task.FromResult(providerResultCulture);
    }
}
```

Localization resources

ASP.NET Core localization provides ResourceManagerStringLocalizer. ResourceManagerStringLocalizer is an implementation of IStringLocalizer that uses `resx` to store localization resources.

You aren't limited to using `resx` files. By implementing `IStringLocalizer`, any data source can be used.

The following example projects implement IStringLocalizer:

- EFStringLocalizer
- JsonStringLocalizer
- SqlLocalizer

Troubleshoot ASP.NET Core localization

Article • 05/03/2024

By Hisham Bin Ateya

This article provides instructions on how to diagnose ASP.NET Core app localization issues.

Localization configuration issues

Localization middleware order
The app may not localize because the localization middleware isn't ordered as expected.

To resolve this issue, ensure that localization middleware is registered before MVC middleware. Otherwise, the localization middleware isn't applied.

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddLocalization(options => options.ResourcesPath =
"Resources");

    services.AddMvc();
}
```

Localization resources path not found

Supported Cultures in RequestCultureProvider don't match with registered once

Resource file naming issues

ASP.NET Core has predefined rules and guidelines for localization resources file naming, which are described in Globalization and localization in ASP.NET Core.

Missing resources

Common causes of resources not being found include:

- Resource names are misspelled in either the .NET XML resource file (`.resx`) or the localizer request.

- The resource is missing from the resource file for some languages, but exists in others.
- If you're still having trouble, check the localization log messages (logged at the `Debug` log level) for more details about the missing resources.

> **Tip**
>
> When using **CookieRequestCultureProvider**, verify single quotes aren't used with the cultures inside the localization cookie value. For example, `c='en-UK'|uic='en-US'` is an invalid cookie value, while `c=en-UK|uic=en-US` is valid.

Resources and class libraries issues

ASP.NET Core by default provides a way to allow the class libraries to find their resource files via ResourceLocationAttribute.

Common issues with class libraries include:

- Missing the ResourceLocationAttribute in a class library prevents ResourceManagerStringLocalizerFactory from discovering the resources.
- Resource file naming. For more information, see the Resource file naming issues section.
- Changing the root namespace of the class library. For more information, see the Root namespace issues section.

`CustomRequestCultureProvider` doesn't work as expected

The RequestLocalizationOptions class has three default providers:

- QueryStringRequestCultureProvider
- CookieRequestCultureProvider
- AcceptLanguageHeaderRequestCultureProvider

The CustomRequestCultureProvider allows you to customize how the localization culture is provided. The CustomRequestCultureProvider is used when the default providers don't meet your requirements.

A common reason for a custom provider not working properly is that it isn't the first provider in the RequestCultureProviders list. To resolve this issue:

- Insert the custom provider at position zero in the RequestCultureProviders list:

```
C#
```

```
options.AddInitialRequestCultureProvider(
    new CustomRequestCultureProvider(async context =>
    {
        // My custom request culture logic
        return new ProviderCultureResult("en");
    }));
```

- Use the AddInitialRequestCultureProvider extension method to set the custom provider as the initial provider.

Root namespace issues

When the root namespace of an assembly is different than the assembly name, localization doesn't work by default. To avoid this issue use the RootNamespace attribute, which is described in Globalization and localization in ASP.NET Core.

> ⚠ **Warning**
>
> A root namespace issue can occur when a project's name isn't a valid .NET identifier. For instance, `my-project-name.csproj` uses the root namespace `my_project_name` and the assembly name `my-project-name`, which results in this error.

Resources and build action

If you use resource files for localization, it's important that they have an appropriate build action. Use **Embedded Resource**; otherwise, the `ResourceStringLocalizer` isn't able to find these resources.

Location override using "Sensors" pane in developer tools

When using the location override using the **Sensors** pane in Google Chrome or Microsoft Edge developer tools, the fallback language is reset after prerendering. Avoid setting the language using the **Sensors** pane when testing. Set the language using the browser's language settings.

For more information, see Blazor Localization does not work with InteractiveServer (dotnet/aspnetcore #53707).

Model Binding in ASP.NET Core

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains what model binding is, how it works, and how to customize its behavior.

What is Model binding

Controllers and Razor pages work with data that comes from HTTP requests. For example, route data may provide a record key, and posted form fields may provide values for the properties of the model. Writing code to retrieve each of these values and convert them from strings to .NET types would be tedious and error-prone. Model binding automates this process. The model binding system:

- Retrieves data from various sources such as route data, form fields, and query strings.
- Provides the data to controllers and Razor pages in method parameters and public properties.
- Converts string data to .NET types.
- Updates properties of complex types.

Example

Suppose you have the following action method:

C#

```
[HttpGet("{id}")]
public ActionResult<Pet> GetById(int id, bool dogsOnly)
```

And the app receives a request with this URL:

HTTP

```
https://contoso.com/api/pets/2?DogsOnly=true
```

Model binding goes through the following steps after the routing system selects the action method:

- Finds the first parameter of `GetById`, an integer named `id`.
- Looks through the available sources in the HTTP request and finds `id` = "2" in route data.
- Converts the string "2" into integer 2.
- Finds the next parameter of `GetById`, a boolean named `dogsOnly`.
- Looks through the sources and finds "DogsOnly=true" in the query string. Name matching is not case-sensitive.
- Converts the string "true" into boolean `true`.

The framework then calls the `GetById` method, passing in 2 for the `id` parameter, and `true` for the `dogsOnly` parameter.

In the preceding example, the model binding targets are method parameters that are simple types. Targets may also be the properties of a complex type. After each property is successfully bound, model validation occurs for that property. The record of what data is bound to the model, and any binding or validation errors, is stored in ControllerBase.ModelState or PageModel.ModelState. To find out if this process was successful, the app checks the ModelState.IsValid flag.

Targets

Model binding tries to find values for the following kinds of targets:

- Parameters of the controller action method that a request is routed to.
- Parameters of the Razor Pages handler method that a request is routed to.
- Public properties of a controller or `PageModel` class, if specified by attributes.

[BindProperty] attribute

Can be applied to a public property of a controller or `PageModel` class to cause model binding to target that property:

C#

```
public class EditModel : PageModel
{
    [BindProperty]
    public Instructor? Instructor { get; set; }

    // ...
}
```

[BindProperties] attribute

Can be applied to a controller or `PageModel` class to tell model binding to target all public properties of the class:

C#

```
[BindProperties]
public class CreateModel : PageModel
{
    public Instructor? Instructor { get; set; }

    // ...
}
```

Model binding for HTTP GET requests

By default, properties are not bound for HTTP GET requests. Typically, all you need for a GET request is a record ID parameter. The record ID is used to look up the item in the database. Therefore, there is no need to bind a property that holds an instance of the model. In scenarios where you do want properties bound to data from GET requests, set the `SupportsGet` property to `true`:

C#

```
[BindProperty(Name = "ai_user", SupportsGet = true)]
public string? ApplicationInsightsCookie { get; set; }
```

Model binding simple and complex types

Model binding uses specific definitions for the types it operates on. A *simple type* is converted from a single string using TypeConverter or a `TryParse` method. A *complex type* is converted from multiple input values. The framework determines the difference based on the existence of a `TypeConverter` or `TryParse`. We recommend creating a type

converter or using `TryParse` for a `string` to `SomeType` conversion that doesn't require external resources or multiple inputs.

Sources

By default, model binding gets data in the form of key-value pairs from the following sources in an HTTP request:

1. Form fields
2. The request body (For controllers that have the [ApiController] attribute.)
3. Route data
4. Query string parameters
5. Uploaded files

For each target parameter or property, the sources are scanned in the order indicated in the preceding list. There are a few exceptions:

- Route data and query string values are used only for simple types.
- Uploaded files are bound only to target types that implement `IFormFile` or `IEnumerable<IFormFile>`.

If the default source is not correct, use one of the following attributes to specify the source:

- [FromQuery] - Gets values from the query string.
- [FromRoute] - Gets values from route data.
- [FromForm] - Gets values from posted form fields.
- [FromBody] - Gets values from the request body.
- [FromHeader] - Gets values from HTTP headers.

These attributes:

- Are added to model properties individually and not to the model class, as in the following example:

```
C#

public class Instructor
{
    public int Id { get; set; }

    [FromQuery(Name = "Note")]
    public string? NoteFromQueryString { get; set; }
```

```
    // ...
}
```

- Optionally accept a model name value in the constructor. This option is provided in case the property name doesn't match the value in the request. For instance, the value in the request might be a header with a hyphen in its name, as in the following example:

```
C#

public void OnGet([FromHeader(Name = "Accept-Language")] string
language)
```

[FromBody] attribute

Apply the `[FromBody]` attribute to a parameter to populate its properties from the body of an HTTP request. The ASP.NET Core runtime delegates the responsibility of reading the body to an input formatter. Input formatters are explained later in this article.

When `[FromBody]` is applied to a complex type parameter, any binding source attributes applied to its properties are ignored. For example, the following `Create` action specifies that its `pet` parameter is populated from the body:

```
C#

public ActionResult<Pet> Create([FromBody] Pet pet)
```

The `Pet` class specifies that its `Breed` property is populated from a query string parameter:

```
C#

public class Pet
{
    public string Name { get; set; } = null!;

    [FromQuery] // Attribute is ignored.
    public string Breed { get; set; } = null!;
}
```

In the preceding example:

- The `[FromQuery]` attribute is ignored.

- The `Breed` property is not populated from a query string parameter.

Input formatters read only the body and don't understand binding source attributes. If a suitable value is found in the body, that value is used to populate the `Breed` property.

Don't apply `[FromBody]` to more than one parameter per action method. Once the request stream is read by an input formatter, it's no longer available to be read again for binding other `[FromBody]` parameters.

Additional sources

Source data is provided to the model binding system by *value providers*. You can write and register custom value providers that get data for model binding from other sources. For example, you might want data from cookies or session state. To get data from a new source:

- Create a class that implements `IValueProvider`.
- Create a class that implements `IValueProviderFactory`.
- Register the factory class in `Program.cs`.

The sample includes a value provider and factory example that gets values from cookies. Register custom value provider factories in `Program.cs`:

```
C#

builder.Services.AddControllers(options =>
{
    options.ValueProviderFactories.Add(new CookieValueProviderFactory());
});
```

The preceding code puts the custom value provider after all built-in value providers. To make it the first in the list, call `Insert(0, new CookieValueProviderFactory())` instead of `Add`.

No source for a model property

By default, a model state error isn't created if no value is found for a model property. The property is set to null or a default value:

- Nullable simple types are set to `null`.
- Non-nullable value types are set to `default(T)`. For example, a parameter `int id` is set to 0.

- For complex Types, model binding creates an instance by using the default constructor, without setting properties.
- Arrays are set to `Array.Empty<T>()`, except that `byte[]` arrays are set to `null`.

If model state should be invalidated when nothing is found in form fields for a model property, use the [BindRequired] attribute.

Note that this `[BindRequired]` behavior applies to model binding from posted form data, not to JSON or XML data in a request body. Request body data is handled by input formatters.

Type conversion errors

If a source is found but can't be converted into the target type, model state is flagged as invalid. The target parameter or property is set to null or a default value, as noted in the previous section.

In an API controller that has the `[ApiController]` attribute, invalid model state results in an automatic HTTP 400 response.

In a Razor page, redisplay the page with an error message:

C#

```
public IActionResult OnPost()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    // ...

    return RedirectToPage("./Index");
}
```

When the page is redisplayed by the preceding code, the invalid input isn't shown in the form field. This is because the model property has been set to null or a default value. The invalid input does appear in an error message. If you want to redisplay the bad data in the form field, consider making the model property a string and doing the data conversion manually.

The same strategy is recommended if you don't want type conversion errors to result in model state errors. In that case, make the model property a string.

Simple types

See Model binding simple and complex types for explanation of simple and complex types.

The simple types that the model binder can convert source strings into include the following:

- Boolean
- Byte, SByte
- Char
- DateOnly
- DateTime
- DateTimeOffset
- Decimal
- Double
- Enum
- Guid
- Int16, Int32, Int64
- Single
- TimeOnly
- TimeSpan
- UInt16, UInt32, UInt64
- Uri
- Version

Bind with `IParsable<T>.TryParse`

The IParsable<TSelf>.TryParse API supports binding controller action parameter values:

C#

```
public static bool TryParse (string? s, IFormatProvider? provider, out TSelf
result);
```

The following `DateRange` class implements IParsable<TSelf> to support binding a date range:

C#

```
public class DateRange : IParsable<DateRange>
{
    public DateOnly? From { get; init; }
```

```
    public DateOnly? To { get; init; }

    public static DateRange Parse(string value, IFormatProvider? provider)
    {
        if (!TryParse(value, provider, out var result))
        {
           throw new ArgumentException("Could not parse supplied value.",
nameof(value));
        }

        return result;
    }

    public static bool TryParse(string? value,
                                IFormatProvider? provider, out DateRange
dateRange)
    {
        var segments = value?.Split(',',
StringSplitOptions.RemoveEmptyEntries
                                    | StringSplitOptions.TrimEntries);

        if (segments?.Length == 2
            && DateOnly.TryParse(segments[0], provider, out var fromDate)
            && DateOnly.TryParse(segments[1], provider, out var toDate))
        {
            dateRange = new DateRange { From = fromDate, To = toDate };
            return true;
        }

        dateRange = new DateRange { From = default, To = default };
        return false;
    }
}
```

The preceding code:

- Converts a string representing two dates to a `DateRange` object
- The model binder uses the IParsable<TSelf>.TryParse method to bind the `DateRange`.

The following controller action uses the `DateRange` class to bind a date range:

C#

```
// GET /WeatherForecast/ByRange?range=7/24/2022,07/26/2022
public IActionResult ByRange([FromQuery] DateRange range)
{
    if (!ModelState.IsValid)
        return View("Error", ModelState.Values.SelectMany(v => v.Errors));

    var weatherForecasts = Enumerable
        .Range(1, 5).Select(index => new WeatherForecast
```

```
        {
            Date = DateTime.Now.AddDays(index),
            TemperatureC = Random.Shared.Next(-20, 55),
            Summary = Summaries[Random.Shared.Next(Summaries.Length)]
        })
        .Where(wf => DateOnly.FromDateTime(wf.Date) >= range.From
                    && DateOnly.FromDateTime(wf.Date) <= range.To)
        .Select(wf => new WeatherForecastViewModel
        {
            Date = wf.Date.ToString("d"),
            TemperatureC = wf.TemperatureC,
            TemperatureF = 32 + (int)(wf.TemperatureC / 0.5556),
            Summary = wf.Summary
        });

    return View("Index", weatherForecasts);
}
```

The following `Locale` class implements IParsable<TSelf> to support binding to `CultureInfo`:

C#

```
public class Locale : CultureInfo, IParsable<Locale>
{
    public Locale(string culture) : base(culture)
    {
    }

    public static Locale Parse(string value, IFormatProvider? provider)
    {
        if (!TryParse(value, provider, out var result))
        {
           throw new ArgumentException("Could not parse supplied value.",
nameof(value));
        }

        return result;
    }

    public static bool TryParse([NotNullWhen(true)] string? value,
                                IFormatProvider? provider, out Locale
locale)
    {
        if (value is null)
        {
            locale = new Locale(CurrentCulture.Name);
            return false;
        }

        try
        {
            locale = new Locale(value);
```

```
            return true;
        }
        catch (CultureNotFoundException)
        {
            locale = new Locale(CurrentCulture.Name);
            return false;
        }
    }
}
```

The following controller action uses the `Locale` class to bind a `CultureInfo` string:

C#

```
// GET /en-GB/WeatherForecast
public IActionResult Index([FromRoute] Locale locale)
{
    var weatherForecasts = Enumerable
        .Range(1, 5).Select(index => new WeatherForecast
        {
            Date = DateTime.Now.AddDays(index),
            TemperatureC = Random.Shared.Next(-20, 55),
            Summary = Summaries[Random.Shared.Next(Summaries.Length)]
        })
        .Select(wf => new WeatherForecastViewModel
        {
            Date = wf.Date.ToString("d", locale),
            TemperatureC = wf.TemperatureC,
            TemperatureF = 32 + (int)(wf.TemperatureC / 0.5556),
            Summary = wf.Summary
        });

    return View(weatherForecasts);
}
```

The following controller action uses the `DateRange` and `Locale` classes to bind a date range with `CultureInfo`:

C#

```
// GET /af-ZA/WeatherForecast/RangeByLocale?range=2022-07-24,2022-07-29
public IActionResult RangeByLocale([FromRoute] Locale locale, [FromQuery]
string range)
{
    if (!ModelState.IsValid)
        return View("Error", ModelState.Values.SelectMany(v => v.Errors));

    if (!DateRange.TryParse(range, locale, out DateRange rangeResult))
    {
        ModelState.TryAddModelError(nameof(range),
            $"Invalid date range: {range} for locale {locale.DisplayName}");
```

```
        return View("Error", ModelState.Values.SelectMany(v => v.Errors));
    }

    var weatherForecasts = Enumerable
        .Range(1, 5).Select(index => new WeatherForecast
        {
            Date = DateTime.Now.AddDays(index),
            TemperatureC = Random.Shared.Next(-20, 55),
            Summary = Summaries[Random.Shared.Next(Summaries.Length)]
        })
        .Where(wf => DateOnly.FromDateTime(wf.Date) >= rangeResult.From
                    && DateOnly.FromDateTime(wf.Date) <= rangeResult.To)
        .Select(wf => new WeatherForecastViewModel
        {
            Date = wf.Date.ToString("d", locale),
            TemperatureC = wf.TemperatureC,
            TemperatureF = 32 + (int) (wf.TemperatureC / 0.5556),
            Summary = wf.Summary
        });

    return View("Index", weatherForecasts);
}
```

The API sample app on GitHub shows the preceding sample for an API controller.

Bind with `TryParse`

The `TryParse` API supports binding controller action parameter values:

C#

```
public static bool TryParse(string value, T out result);
public static bool TryParse(string value, IFormatProvider provider, T out
result);
```

IParsable<T>.TryParse is the recommended approach for parameter binding because unlike `TryParse`, it doesn't depend on reflection.

The following `DateRangeTP` class implements `TryParse`:

C#

```
public class DateRangeTP
{
    public DateOnly? From { get; }
    public DateOnly? To { get; }

    public DateRangeTP(string from, string to)
```

```
    {
        if (string.IsNullOrEmpty(from))
            throw new ArgumentNullException(nameof(from));
        if (string.IsNullOrEmpty(to))
            throw new ArgumentNullException(nameof(to));

        From = DateOnly.Parse(from);
        To = DateOnly.Parse(to);
    }

    public static bool TryParse(string? value, out DateRangeTP? result)
    {
        var range = value?.Split(',', StringSplitOptions.RemoveEmptyEntries
| StringSplitOptions.TrimEntries);
        if (range?.Length != 2)
        {
            result = default;
            return false;
        }

        result = new DateRangeTP(range[0], range[1]);
        return true;
    }
}
```

The following controller action uses the `DateRangeTP` class to bind a date range:

C#

```
// GET /WeatherForecast/ByRangeTP?range=7/24/2022,07/26/2022
public IActionResult ByRangeTP([FromQuery] DateRangeTP range)
{
    if (!ModelState.IsValid)
        return View("Error", ModelState.Values.SelectMany(v => v.Errors));

    var weatherForecasts = Enumerable
        .Range(1, 5).Select(index => new WeatherForecast
        {
            Date = DateTime.Now.AddDays(index),
            TemperatureC = Random.Shared.Next(-20, 55),
            Summary = Summaries[Random.Shared.Next(Summaries.Length)]
        })
        .Where(wf => DateOnly.FromDateTime(wf.Date) >= range.From
                    && DateOnly.FromDateTime(wf.Date) <= range.To)
        .Select(wf => new WeatherForecastViewModel
        {
            Date = wf.Date.ToString("d"),
            TemperatureC = wf.TemperatureC,
            TemperatureF = 32 + (int)(wf.TemperatureC / 0.5556),
            Summary = wf.Summary
        });
```

```
    return View("Index", weatherForecasts);
}
```

Complex types

A complex type must have a public default constructor and public writable properties to bind. When model binding occurs, the class is instantiated using the public default constructor.

For each property of the complex type, model binding looks through the sources for the name pattern *prefix.property_name*. If nothing is found, it looks for just *property_name* without the prefix. The decision to use the prefix isn't made per property. For example, with a query containing `?Instructor.Id=100&Name=foo`, bound to method `OnGet(Instructor instructor)`, the resulting object of type `Instructor` contains:

- `Id` set to `100`.
- `Name` set to `null`. Model binding expects `Instructor.Name` because `Instructor.Id` was used in the preceding query parameter.

For binding to a parameter, the prefix is the parameter name. For binding to a `PageModel` public property, the prefix is the public property name. Some attributes have a `Prefix` property that lets you override the default usage of parameter or property name.

For example, suppose the complex type is the following `Instructor` class:

C#

```
public class Instructor
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstName { get; set; }
}
```

Prefix = parameter name

If the model to be bound is a parameter named `instructorToUpdate`:

C#

```
public IActionResult OnPost(int? id, Instructor instructorToUpdate)
```

Model binding starts by looking through the sources for the key `instructorToUpdate.ID`. If that isn't found, it looks for `ID` without a prefix.

Prefix = property name

If the model to be bound is a property named `Instructor` of the controller or `PageModel` class:

```
C#

[BindProperty]
public Instructor Instructor { get; set; }
```

Model binding starts by looking through the sources for the key `Instructor.ID`. If that isn't found, it looks for `ID` without a prefix.

Custom prefix

If the model to be bound is a parameter named `instructorToUpdate` and a `Bind` attribute specifies `Instructor` as the prefix:

```
C#

public IActionResult OnPost(
    int? id, [Bind(Prefix = "Instructor")] Instructor instructorToUpdate)
```

Model binding starts by looking through the sources for the key `Instructor.ID`. If that isn't found, it looks for `ID` without a prefix.

Attributes for complex type targets

Several built-in attributes are available for controlling model binding of complex types:

- [Bind]
- [BindRequired]
- [BindNever]

> ⚠ **Warning**
>
> These attributes affect model binding when posted form data is the source of values. They do ***not*** affect input formatters, which process posted JSON and XML

request bodies. Input formatters are explained later in this article.

[Bind] attribute

Can be applied to a class or a method parameter. Specifies which properties of a model should be included in model binding. `[Bind]` does ***not*** affect input formatters.

In the following example, only the specified properties of the `Instructor` model are bound when any handler or action method is called:

```
C#

[Bind("LastName,FirstMidName,HireDate")]
public class Instructor
```

In the following example, only the specified properties of the `Instructor` model are bound when the `OnPost` method is called:

```
C#

[HttpPost]
public IActionResult OnPost(
    [Bind("LastName,FirstMidName,HireDate")] Instructor instructor)
```

The `[Bind]` attribute can be used to protect against overposting in *create* scenarios. It doesn't work well in edit scenarios because excluded properties are set to null or a default value instead of being left unchanged. For protection against overposting, view models are recommended rather than the `[Bind]` attribute. For more information, see Security note about overposting.

[ModelBinder] attribute

ModelBinderAttribute can be applied to types, properties, or parameters. It allows specifying the type of model binder used to bind the specific instance or type. For example:

```
C#

[HttpPost]
public IActionResult OnPost(
    [ModelBinder<MyInstructorModelBinder>] Instructor instructor)
```

The `[ModelBinder]` attribute can also be used to change the name of a property or parameter when it's being model bound:

C#

```
public class Instructor
{
    [ModelBinder(Name = "instructor_id")]
    public string Id { get; set; }

    // ...
}
```

[BindRequired] attribute

Causes model binding to add a model state error if binding cannot occur for a model's property. Here's an example:

C#

```
public class InstructorBindRequired
{
    // ...

    [BindRequired]
    public DateTime HireDate { get; set; }
}
```

See also the discussion of the `[Required]` attribute in Model validation.

[BindNever] attribute

Can be applied to a property or a type. Prevents model binding from setting a model's property. When applied to a type, the model binding system excludes all properties the type defines. Here's an example:

C#

```
public class InstructorBindNever
{
    [BindNever]
    public int Id { get; set; }

    // ...
}
```

Collections

For targets that are collections of simple types, model binding looks for matches to *parameter_name* or *property_name*. If no match is found, it looks for one of the supported formats without the prefix. For example:

- Suppose the parameter to be bound is an array named `selectedCourses`:

  ```
  C#

  public IActionResult OnPost(int? id, int[] selectedCourses)
  ```

- Form or query string data can be in one of the following formats:

  ```

  selectedCourses=1050&selectedCourses=2000
  ```

  ```

  selectedCourses[0]=1050&selectedCourses[1]=2000
  ```

  ```

  [0]=1050&[1]=2000
  ```

  ```

  selectedCourses[a]=1050&selectedCourses[b]=2000&selectedCourses.index=a
  &selectedCourses.index=b
  ```

  ```

  [a]=1050&[b]=2000&index=a&index=b
  ```

  Avoid binding a parameter or a property named `index` or `Index` if it is adjacent to a collection value. Model binding attempts to use `index` as the index for the collection which might result in incorrect binding. For example, consider the following action:

  ```
  C#
  ```

```
public IActionResult Post(string index, List<Product> products)
```

In the preceding code, the `index` query string parameter binds to the `index` method parameter and also is used to bind the product collection. Renaming the `index` parameter or using a model binding attribute to configure binding avoids this issue:

```
C#

public IActionResult Post(string productIndex, List<Product> products)
```

- The following format is supported only in form data:

```

selectedCourses[]=1050&selectedCourses[]=2000
```

- For all of the preceding example formats, model binding passes an array of two items to the `selectedCourses` parameter:
  - selectedCourses[0]=1050
  - selectedCourses[1]=2000

  Data formats that use subscript numbers (... [0] ... [1] ...) must ensure that they are numbered sequentially starting at zero. If there are any gaps in subscript numbering, all items after the gap are ignored. For example, if the subscripts are 0 and 2 instead of 0 and 1, the second item is ignored.

Dictionaries

For `Dictionary` targets, model binding looks for matches to *parameter_name* or *property_name*. If no match is found, it looks for one of the supported formats without the prefix. For example:

- Suppose the target parameter is a `Dictionary<int, string>` named `selectedCourses`:

```
C#

public IActionResult OnPost(int? id, Dictionary<int, string>
selectedCourses)
```

- The posted form or query string data can look like one of the following examples:

```
selectedCourses[1050]=Chemistry&selectedCourses[2000]=Economics
```

```
[1050]=Chemistry&selectedCourses[2000]=Economics
```

```
selectedCourses[0].Key=1050&selectedCourses[0].Value=Chemistry&
selectedCourses[1].Key=2000&selectedCourses[1].Value=Economics
```

```
[0].Key=1050&[0].Value=Chemistry&[1].Key=2000&[1].Value=Economics
```

- For all of the preceding example formats, model binding passes a dictionary of two items to the `selectedCourses` parameter:
  - selectedCourses["1050"]="Chemistry"
  - selectedCourses["2000"]="Economics"

Constructor binding and record types

Model binding requires that complex types have a parameterless constructor. Both `System.Text.Json` and `Newtonsoft.Json` based input formatters support deserialization of classes that don't have a parameterless constructor.

Record types are a great way to succinctly represent data over the network. ASP.NET Core supports model binding and validating record types with a single constructor:

C#

```
public record Person(
    [Required] string Name, [Range(0, 150)] int Age, [BindNever] int Id);

public class PersonController
{
    public IActionResult Index() => View();

    [HttpPost]
    public IActionResult Index(Person person)
```

```
    {
        // ...
    }
}
```

`Person/Index.cshtml`:

CSHTML

```
@model Person

<label>Name: <input asp-for="Name" /></label>
<br />
<label>Age: <input asp-for="Age" /></label>
```

When validating record types, the runtime searches for binding and validation metadata specifically on parameters rather than on properties.

The framework allows binding to and validating record types:

C#

```
public record Person([Required] string Name, [Range(0, 100)] int Age);
```

For the preceding to work, the type must:

- Be a record type.
- Have exactly one public constructor.
- Contain parameters that have a property with the same name and type. The names must not differ by case.

POCOs without parameterless constructors

POCOs that do not have parameterless constructors can't be bound.

The following code results in an exception saying that the type must have a parameterless constructor:

C#

```
public class Person(string Name)

public record Person([Required] string Name, [Range(0, 100)] int Age)
{
```

```
    public Person(string Name) : this (Name, 0);
}
```

Record types with manually authored constructors

Record types with manually authored constructors that look like primary constructors work

C#

```
public record Person
{
    public Person([Required] string Name, [Range(0, 100)] int Age)
        => (this.Name, this.Age) = (Name, Age);

    public string Name { get; set; }
    public int Age { get; set; }
}
```

Record types, validation and binding metadata

For record types, validation and binding metadata on parameters is used. Any metadata on properties is ignored

C#

```
public record Person (string Name, int Age)
{
   [BindProperty(Name = "SomeName")] // This does not get used
   [Required] // This does not get used
   public string Name { get; init; }
}
```

Validation and metadata

Validation uses metadata on the parameter but uses the property to read the value. In the ordinary case with primary constructors, the two would be identical. However, there are ways to defeat it:

C#

```
public record Person([Required] string Name)
{
    private readonly string _name;
```

```
    // The following property is never null.
    // However this object could have been constructed as "new
Person(null)".
    public string Name { get; init => _name = value ?? string.Empty; }
}
```

TryUpdateModel does not update parameters on a record type

C#

```
public record Person(string Name)
{
    public int Age { get; set; }
}

var person = new Person("initial-name");
TryUpdateModel(person, ...);
```

In this case, MVC will not attempt to bind `Name` again. However, `Age` is allowed to be updated

Globalization behavior of model binding route data and query strings

The ASP.NET Core route value provider and query string value provider:

- Treat values as invariant culture.
- Expect that URLs are culture-invariant.

In contrast, values coming from form data undergo a culture-sensitive conversion. This is by design so that URLs are shareable across locales.

To make the ASP.NET Core route value provider and query string value provider undergo a culture-sensitive conversion:

- Inherit from IValueProviderFactory
- Copy the code from QueryStringValueProviderFactory or RouteValueValueProviderFactory
- Replace the culture value passed to the value provider constructor with CultureInfo.CurrentCulture
- Replace the default value provider factory in MVC options with your new one:

C#

```
public class CultureQueryStringValueProviderFactory : IValueProviderFactory
{
    public Task CreateValueProviderAsync(ValueProviderFactoryContext
context)
    {
        _ = context ?? throw new ArgumentNullException(nameof(context));

        var query = context.ActionContext.HttpContext.Request.Query;
        if (query?.Count > 0)
        {
            context.ValueProviders.Add(
                new QueryStringValueProvider(
                    BindingSource.Query,
                    query,
                    CultureInfo.CurrentCulture));
        }

        return Task.CompletedTask;
    }
}
```

C#

```
builder.Services.AddControllers(options =>
{
    var index = options.ValueProviderFactories.IndexOf(

options.ValueProviderFactories.OfType<QueryStringValueProviderFactory>()
            .Single());

    options.ValueProviderFactories[index] =
        new CultureQueryStringValueProviderFactory();
});
```

Special data types

There are some special data types that model binding can handle.

IFormFile and IFormFileCollection

An uploaded file included in the HTTP request. Also supported is `IEnumerable<IFormFile>` for multiple files.

CancellationToken

Actions can optionally bind a `CancellationToken` as a parameter. This binds RequestAborted that signals when the connection underlying the HTTP request is aborted. Actions can use this parameter to cancel long running async operations that are executed as part of the controller actions.

FormCollection

Used to retrieve all the values from posted form data.

Input formatters

Data in the request body can be in JSON, XML, or some other format. To parse this data, model binding uses an *input formatter* that is configured to handle a particular content type. By default, ASP.NET Core includes JSON based input formatters for handling JSON data. You can add other formatters for other content types.

ASP.NET Core selects input formatters based on the Consumes attribute. If no attribute is present, it uses the Content-Type header.

To use the built-in XML input formatters:

- In `Program.cs`, call AddXmlSerializerFormatters or AddXmlDataContractSerializerFormatters.

  C#

  ```
  builder.Services.AddControllers()
      .AddXmlSerializerFormatters();
  ```

- Apply the `Consumes` attribute to controller classes or action methods that should expect XML in the request body.

  C#

  ```
  [HttpPost]
  [Consumes("application/xml")]
  public ActionResult<Pet> Create(Pet pet)
  ```

  For more information, see Introducing XML Serialization.

Customize model binding with input formatters

An input formatter takes full responsibility for reading data from the request body. To customize this process, configure the APIs used by the input formatter. This section describes how to customize the `System.Text.Json`-based input formatter to understand a custom type named `ObjectId`.

Consider the following model, which contains a custom `ObjectId` property:

```
C#

public class InstructorObjectId
{
    [Required]
    public ObjectId ObjectId { get; set; } = null!;
}
```

To customize the model binding process when using `System.Text.Json`, create a class derived from JsonConverter<T>:

```
C#

internal class ObjectIdConverter : JsonConverter<ObjectId>
{
    public override ObjectId Read(
        ref Utf8JsonReader reader, Type typeToConvert, JsonSerializerOptions
options)
        => new(JsonSerializer.Deserialize<int>(ref reader, options));

    public override void Write(
        Utf8JsonWriter writer, ObjectId value, JsonSerializerOptions
options)
        => writer.WriteNumberValue(value.Id);
}
```

To use a custom converter, apply the JsonConverterAttribute attribute to the type. In the following example, the `ObjectId` type is configured with `ObjectIdConverter` as its custom converter:

```
C#

[JsonConverter(typeof(ObjectIdConverter))]
public record ObjectId(int Id);
```

For more information, see How to write custom converters.

Exclude specified types from model binding

The model binding and validation systems' behavior is driven by ModelMetadata. You can customize `ModelMetadata` by adding a details provider to MvcOptions.ModelMetadataDetailsProviders. Built-in details providers are available for disabling model binding or validation for specified types.

To disable model binding on all models of a specified type, add an ExcludeBindingMetadataProvider in `Program.cs`. For example, to disable model binding on all models of type `System.Version`:

C#

```
builder.Services.AddRazorPages()
    .AddMvcOptions(options =>
    {
        options.ModelMetadataDetailsProviders.Add(
            new ExcludeBindingMetadataProvider(typeof(Version)));
        options.ModelMetadataDetailsProviders.Add(
            new SuppressChildValidationMetadataProvider(typeof(Guid)));
    });
```

To disable validation on properties of a specified type, add a SuppressChildValidationMetadataProvider in `Program.cs`. For example, to disable validation on properties of type `System.Guid`:

C#

```
builder.Services.AddRazorPages()
    .AddMvcOptions(options =>
    {
        options.ModelMetadataDetailsProviders.Add(
            new ExcludeBindingMetadataProvider(typeof(Version)));
        options.ModelMetadataDetailsProviders.Add(
            new SuppressChildValidationMetadataProvider(typeof(Guid)));
    });
```

Custom model binders

You can extend model binding by writing a custom model binder and using the `[ModelBinder]` attribute to select it for a given target. Learn more about custom model binding.

Manual model binding

Model binding can be invoked manually by using the TryUpdateModelAsync method. The method is defined on both `ControllerBase` and `PageModel` classes. Method overloads let you specify the prefix and value provider to use. The method returns `false` if model binding fails. Here's an example:

```
C#

if (await TryUpdateModelAsync(
    newInstructor,
    "Instructor",
    x => x.Name, x => x.HireDate!))
{
    _instructorStore.Add(newInstructor);
    return RedirectToPage("./Index");
}

return Page();
```

TryUpdateModelAsync uses value providers to get data from the form body, query string, and route data. `TryUpdateModelAsync` is typically:

- Used with Razor Pages and MVC apps using controllers and views to prevent over-posting.
- Not used with a web API unless consumed from form data, query strings, and route data. Web API endpoints that consume JSON use Input formatters to deserialize the request body into an object.

For more information, see TryUpdateModelAsync.

[FromServices] attribute

This attribute's name follows the pattern of model binding attributes that specify a data source. But it's not about binding data from a value provider. It gets an instance of a type from the dependency injection container. Its purpose is to provide an alternative to constructor injection for when you need a service only if a particular method is called.

If an instance of the type isn't registered in the dependency injection container, the app throws an exception when attempting to bind the parameter. To make the parameter optional, use one of the following approaches:

- Make the parameter nullable.
- Set a default value for the parameter.

For nullable parameters, ensure that the parameter isn't `null` before accessing it.

Custom Model Binding in ASP.NET Core

Article • 04/03/2024

By Kirk Larkin

Model binding allows controller actions to work directly with model types (passed in as method arguments), rather than HTTP requests. Mapping between incoming request data and application models is handled by model binders. Developers can extend the built-in model binding functionality by implementing custom model binders (though typically, you don't need to write your own provider).

View or download sample code (how to download)

Default model binder limitations

The default model binders support most of the common .NET Core data types and should meet most developers' needs. They expect to bind text-based input from the request directly to model types. You might need to transform the input prior to binding it. For example, when you have a key that can be used to look up model data. You can use a custom model binder to fetch data based on the key.

Model binding simple and complex types

Model binding uses specific definitions for the types it operates on. A *simple type* is converted from a single string using TypeConverter or a `TryParse` method. A *complex type* is converted from multiple input values. The framework determines the difference based on the existence of a `TypeConverter` or `TryParse`. We recommend creating a type converter or using `TryParse` for a `string` to `SomeType` conversion that doesn't require external resources or multiple inputs.

See Simple types for a list of types that the model binder can convert from strings.

Before creating your own custom model binder, it's worth reviewing how existing model binders are implemented. Consider the ByteArrayModelBinder which can be used to convert base64-encoded strings into byte arrays. The byte arrays are often stored as files or database BLOB fields.

Working with the ByteArrayModelBinder

Base64-encoded strings can be used to represent binary data. For example, an image can be encoded as a string. The sample includes an image as a base64-encoded string in Base64String.txt.

ASP.NET Core MVC can take a base64-encoded string and use a `ByteArrayModelBinder` to convert it into a byte array. The ByteArrayModelBinderProvider maps `byte[]` arguments to `ByteArrayModelBinder`:

C#

```
public IModelBinder GetBinder(ModelBinderProviderContext context)
{
    if (context == null)
    {
        throw new ArgumentNullException(nameof(context));
    }

    if (context.Metadata.ModelType == typeof(byte[]))
    {
        var loggerFactory =
context.Services.GetRequiredService<ILoggerFactory>();
        return new ByteArrayModelBinder(loggerFactory);
    }

    return null;
}
```

When creating your own custom model binder, you can implement your own `IModelBinderProvider` type, or use the ModelBinderAttribute.

The following example shows how to use `ByteArrayModelBinder` to convert a base64-encoded string to a `byte[]` and save the result to a file:

C#

```
[HttpPost]
public void Post([FromForm] byte[] file, string filename)
{
    // Don't trust the file name sent by the client. Use
    // Path.GetRandomFileName to generate a safe random
    // file name. _targetFilePath receives a value
    // from configuration (the appsettings.json file in
    // the sample app).
    var trustedFileName = Path.GetRandomFileName();
    var filePath = Path.Combine(_targetFilePath, trustedFileName);

    if (System.IO.File.Exists(filePath))
    {
        return;
```

```
    }

    System.IO.File.WriteAllBytes(filePath, file);
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

You can POST a base64-encoded string to the previous api method using a tool like curl.

As long as the binder can bind request data to appropriately named properties or arguments, model binding will succeed. The following example shows how to use `ByteArrayModelBinder` with a view model:

C#

```
[HttpPost("Profile")]
public void SaveProfile([FromForm] ProfileViewModel model)
{
    // Don't trust the file name sent by the client. Use
    // Path.GetRandomFileName to generate a safe random
    // file name. _targetFilePath receives a value
    // from configuration (the appsettings.json file in
    // the sample app).
    var trustedFileName = Path.GetRandomFileName();
    var filePath = Path.Combine(_targetFilePath, trustedFileName);

    if (System.IO.File.Exists(filePath))
    {
        return;
    }

    System.IO.File.WriteAllBytes(filePath, model.File);
}

public class ProfileViewModel
{
    public byte[] File { get; set; }
    public string FileName { get; set; }
}
```

Custom model binder sample

In this section we'll implement a custom model binder that:

- Converts incoming request data into strongly typed key arguments.
- Uses Entity Framework Core to fetch the associated entity.

- Passes the associated entity as an argument to the action method.

The following sample uses the `ModelBinder` attribute on the `Author` model:

C#

```
using CustomModelBindingSample.Binders;
using Microsoft.AspNetCore.Mvc;

namespace CustomModelBindingSample.Data
{
    [ModelBinder(BinderType = typeof(AuthorEntityBinder))]
    public class Author
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public string GitHub { get; set; }
        public string Twitter { get; set; }
        public string BlogUrl { get; set; }
    }
}
```

In the preceding code, the `ModelBinder` attribute specifies the type of `IModelBinder` that should be used to bind `Author` action parameters.

The following `AuthorEntityBinder` class binds an `Author` parameter by fetching the entity from a data source using Entity Framework Core and an `authorId`:

C#

```
public class AuthorEntityBinder : IModelBinder
{
    private readonly AuthorContext _context;

    public AuthorEntityBinder(AuthorContext context)
    {
        _context = context;
    }

    public Task BindModelAsync(ModelBindingContext bindingContext)
    {
        if (bindingContext == null)
        {
            throw new ArgumentNullException(nameof(bindingContext));
        }

        var modelName = bindingContext.ModelName;

        // Try to fetch the value of the argument by name
        var valueProviderResult =
bindingContext.ValueProvider.GetValue(modelName);
```

```
        if (valueProviderResult == ValueProviderResult.None)
        {
            return Task.CompletedTask;
        }

        bindingContext.ModelState.SetModelValue(modelName,
valueProviderResult);

        var value = valueProviderResult.FirstValue;

        // Check if the argument value is null or empty
        if (string.IsNullOrEmpty(value))
        {
            return Task.CompletedTask;
        }

        if (!int.TryParse(value, out var id))
        {
            // Non-integer arguments result in model state errors
            bindingContext.ModelState.TryAddModelError(
                modelName, "Author Id must be an integer.");

            return Task.CompletedTask;
        }

        // Model will be null if not found, including for
        // out of range id values (0, -3, etc.)
        var model = _context.Authors.Find(id);
        bindingContext.Result = ModelBindingResult.Success(model);
        return Task.CompletedTask;
    }
}
```

> **Note**
>
> The preceding `AuthorEntityBinder` class is intended to illustrate a custom model binder. The class isn't intended to illustrate best practices for a lookup scenario. For lookup, bind the `authorId` and query the database in an action method. This approach separates model binding failures from `NotFound` cases.

The following code shows how to use the `AuthorEntityBinder` in an action method:

C#

```
[HttpGet("get/{author}")]
public IActionResult Get(Author author)
{
    if (author == null)
    {
```

```
        return NotFound();
    }

    return Ok(author);
}
```

The `ModelBinder` attribute can be used to apply the `AuthorEntityBinder` to parameters that don't use default conventions:

C#

```
[HttpGet("{id}")]
public IActionResult GetById([ModelBinder(Name = "id")] Author author)
{
    if (author == null)
    {
        return NotFound();
    }

    return Ok(author);
}
```

In this example, since the name of the argument isn't the default `authorId`, it's specified on the parameter using the `ModelBinder` attribute. Both the controller and action method are simplified compared to looking up the entity in the action method. The logic to fetch the author using Entity Framework Core is moved to the model binder. This can be a considerable simplification when you have several methods that bind to the `Author` model.

You can apply the `ModelBinder` attribute to individual model properties (such as on a viewmodel) or to action method parameters to specify a certain model binder or model name for just that type or action.

Implementing a ModelBinderProvider

Instead of applying an attribute, you can implement `IModelBinderProvider`. This is how the built-in framework binders are implemented. When you specify the type your binder operates on, you specify the type of argument it produces, **not** the input your binder accepts. The following binder provider works with the `AuthorEntityBinder`. When it's added to MVC's collection of providers, you don't need to use the `ModelBinder` attribute on `Author` or `Author`-typed parameters.

C#

```
using CustomModelBindingSample.Data;
using Microsoft.AspNetCore.Mvc.ModelBinding;
using Microsoft.AspNetCore.Mvc.ModelBinding.Binders;
using System;

namespace CustomModelBindingSample.Binders
{
    public class AuthorEntityBinderProvider : IModelBinderProvider
    {
        public IModelBinder GetBinder(ModelBinderProviderContext context)
        {
            if (context == null)
            {
                throw new ArgumentNullException(nameof(context));
            }

            if (context.Metadata.ModelType == typeof(Author))
            {
                return new
BinderTypeModelBinder(typeof(AuthorEntityBinder));
            }

            return null;
        }
    }
}
```

> Note: The preceding code returns a `BinderTypeModelBinder`. `BinderTypeModelBinder` acts as a factory for model binders and provides dependency injection (DI). The `AuthorEntityBinder` requires DI to access EF Core. Use `BinderTypeModelBinder` if your model binder requires services from DI.

To use a custom model binder provider, add it in `ConfigureServices`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<AuthorContext>(options =>
options.UseInMemoryDatabase("Authors"));

    services.AddControllers(options =>
    {
        options.ModelBinderProviders.Insert(0, new
AuthorEntityBinderProvider());
    });
}
```

When evaluating model binders, the collection of providers is examined in order. The first provider that returns a binder that matches the input model is used. Adding your provider to the end of the collection may thus result in a built-in model binder being called before your custom binder has a chance. In this example, the custom provider is added to the beginning of the collection to ensure it's always used for `Author` action arguments.

Polymorphic model binding

Binding to different models of derived types is known as polymorphic model binding. Polymorphic custom model binding is required when the request value must be bound to the specific derived model type. Polymorphic model binding:

- Isn't typical for a REST API that's designed to interoperate with all languages.
- Makes it difficult to reason about the bound models.

However, if an app requires polymorphic model binding, an implementation might look like the following code:

C#

```
public abstract class Device
{
    public string Kind { get; set; }
}

public class Laptop : Device
{
    public string CPUIndex { get; set; }
}

public class SmartPhone : Device
{
    public string ScreenSize { get; set; }
}

public class DeviceModelBinderProvider : IModelBinderProvider
{
    public IModelBinder GetBinder(ModelBinderProviderContext context)
    {
        if (context.Metadata.ModelType != typeof(Device))
        {
            return null;
        }

        var subclasses = new[] { typeof(Laptop), typeof(SmartPhone), };

        var binders = new Dictionary<Type, (ModelMetadata, IModelBinder)>();
        foreach (var type in subclasses)
```

```
        {
            var modelMetadata =
context.MetadataProvider.GetMetadataForType(type);
            binders[type] = (modelMetadata,
context.CreateBinder(modelMetadata));
        }

        return new DeviceModelBinder(binders);
    }
}

public class DeviceModelBinder : IModelBinder
{
    private Dictionary<Type, (ModelMetadata, IModelBinder)> binders;

    public DeviceModelBinder(Dictionary<Type, (ModelMetadata, IModelBinder)>
binders)
    {
        this.binders = binders;
    }

    public async Task BindModelAsync(ModelBindingContext bindingContext)
    {
        var modelKindName =
ModelNames.CreatePropertyModelName(bindingContext.ModelName,
nameof(Device.Kind));
        var modelTypeValue =
bindingContext.ValueProvider.GetValue(modelKindName).FirstValue;

        IModelBinder modelBinder;
        ModelMetadata modelMetadata;
        if (modelTypeValue == "Laptop")
        {
            (modelMetadata, modelBinder) = binders[typeof(Laptop)];
        }
        else if (modelTypeValue == "SmartPhone")
        {
            (modelMetadata, modelBinder) = binders[typeof(SmartPhone)];
        }
        else
        {
            bindingContext.Result = ModelBindingResult.Failed();
            return;
        }

        var newBindingContext =
DefaultModelBindingContext.CreateBindingContext(
            bindingContext.ActionContext,
            bindingContext.ValueProvider,
            modelMetadata,
            bindingInfo: null,
            bindingContext.ModelName);

        await modelBinder.BindModelAsync(newBindingContext);
        bindingContext.Result = newBindingContext.Result;
```

```
        if (newBindingContext.Result.IsModelSet)
        {
            // Setting the ValidationState ensures properties on derived
types are correctly
            bindingContext.ValidationState[newBindingContext.Result.Model] =
new ValidationStateEntry
            {
                Metadata = modelMetadata,
            };
        }
    }
}
```

Recommendations and best practices

Custom model binders:

- Shouldn't attempt to set status codes or return results (for example, 404 Not Found). If model binding fails, an action filter or logic within the action method itself should handle the failure.
- Are most useful for eliminating repetitive code and cross-cutting concerns from action methods.
- Typically shouldn't be used to convert a string into a custom type, a TypeConverter is usually a better option.

Model validation in ASP.NET Core MVC and Razor Pages

Article • 08/30/2024

This article explains how to validate user input in an ASP.NET Core MVC or Razor Pages app.

View or download sample code (how to download).

Model state

Model state represents errors that come from two subsystems: model binding and model validation. Errors that originate from model binding are generally data conversion errors. For example, an "x" is entered in an integer field. Model validation occurs after model binding and reports errors where data doesn't conform to business rules. For example, a 0 is entered in a field that expects a rating between 1 and 5.

Both model binding and model validation occur before the execution of a controller action or a Razor Pages handler method. For web apps, it's the app's responsibility to inspect `ModelState.IsValid` and react appropriately. Web apps typically redisplay the page with an error message, as shown in the following Razor Pages example:

C#

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movies.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

For ASP.NET Core MVC with controllers and views, the following example shows how to check `ModelState.IsValid` inside of a controller action:

C#

```
public async Task<IActionResult> Create(Movie movie)
{
    if (!ModelState.IsValid)
    {
        return View(movie);
    }

    _context.Movies.Add(movie);
    await _context.SaveChangesAsync();

    return RedirectToAction(nameof(Index));
}
```

Web API controllers don't have to check `ModelState.IsValid` if they have the [ApiController] attribute. In that case, an automatic HTTP 400 response containing error details is returned when model state is invalid. For more information, see Automatic HTTP 400 responses.

Rerun validation

Validation is automatic, but you might want to repeat it manually. For example, you might compute a value for a property and want to rerun validation after setting the property to the computed value. To rerun validation, call ModelStateDictionary.ClearValidationState to clear validation specific to the model being validated followed by `TryValidateModel`:

C#

```
public async Task<IActionResult> OnPostTryValidateAsync()
{
    var modifiedReleaseDate = DateTime.Now.Date;
    Movie.ReleaseDate = modifiedReleaseDate;

    ModelState.ClearValidationState(nameof(Movie));
    if (!TryValidateModel(Movie, nameof(Movie)))
    {
        return Page();
    }

    _context.Movies.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

Validation attributes

Validation attributes let you specify validation rules for model properties. The following example from the sample app shows a model class that is annotated with validation attributes. The `[ClassicMovie]` attribute is a custom validation attribute and the others are built in. Not shown is `[ClassicMovieWithClientValidator]`, which shows an alternative way to implement a custom attribute.

C#

```
public class Movie
{
    public int Id { get; set; }

    [Required]
    [StringLength(100)]
    public string Title { get; set; } = null!;

    [ClassicMovie(1960)]
    [DataType(DataType.Date)]
    [Display(Name = "Release Date")]
    public DateTime ReleaseDate { get; set; }

    [Required]
    [StringLength(1000)]
    public string Description { get; set; } = null!;

    [Range(0, 999.99)]
    public decimal Price { get; set; }

    public Genre Genre { get; set; }

    public bool Preorder { get; set; }
}
```

Built-in attributes

Here are some of the built-in validation attributes:

- [ValidateNever]: Indicates that a property or parameter should be excluded from validation.
- [CreditCard]: Validates that the property has a credit card format. Requires jQuery Validation Additional Methods.
- [Compare]: Validates that two properties in a model match.
- [EmailAddress]: Validates that the property has an email format.
- [Phone]: Validates that the property has a telephone number format.

- [Range]: Validates that the property value falls within a specified range.
- [RegularExpression]: Validates that the property value matches a specified regular expression.
- [Required]: Validates that the field isn't null. See [Required] attribute for details about this attribute's behavior.
- [StringLength]: Validates that a string property value doesn't exceed a specified length limit.
- [Url]: Validates that the property has a URL format.
- [Remote]: Validates input on the client by calling an action method on the server. See [Remote] attribute for details about this attribute's behavior.

A complete list of validation attributes can be found in the System.ComponentModel.DataAnnotations namespace.

Error messages

Validation attributes let you specify the error message to be displayed for invalid input. For example:

```
C#

[StringLength(8, ErrorMessage = "Name length can't be more than 8.")]
```

Internally, the attributes call String.Format with a placeholder for the field name and sometimes additional placeholders. For example:

```
C#

[StringLength(8, ErrorMessage = "{0} length must be between {2} and {1}.",
MinimumLength = 6)]
```

When applied to a `Name` property, the error message created by the preceding code would be "Name length must be between 6 and 8.".

To find out which parameters are passed to `String.Format` for a particular attribute's error message, see the DataAnnotations source code.

Use JSON property names in validation errors

By default, when a validation error occurs, model validation produces a ModelStateDictionary with the property name as the error key. Some apps, such as single page apps, benefit from using JSON property names for validation errors

generated from Web APIs. The following code configures validation to use the SystemTextJsonValidationMetadataProvider to use JSON property names:

C#

```
using Microsoft.AspNetCore.Mvc.ModelBinding.Metadata;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers(options =>
{
    options.ModelMetadataDetailsProviders.Add(new
SystemTextJsonValidationMetadataProvider());
});

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

The following code configures validation to use the NewtonsoftJsonValidationMetadataProvider to use JSON property name when using Json.NET:

C#

```
using Microsoft.AspNetCore.Mvc.NewtonsoftJson;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers(options =>
{
    options.ModelMetadataDetailsProviders.Add(new
NewtonsoftJsonValidationMetadataProvider());
}).AddNewtonsoftJson();

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

For an example of the policy to use camel-casing, see Program.cs on GitHub.

Non-nullable reference types and [Required] attribute

The validation system treats non-nullable parameters or bound properties as if they had a `[Required(AllowEmptyStrings = true)]` attribute. By enabling Nullable contexts, MVC implicitly starts validating non-nullable properties or parameters as if they had been attributed with the `[Required(AllowEmptyStrings = true)]` attribute. Consider the following code:

```
C#

public class Person
{
    public string Name { get; set; }
}
```

If the app was built with `<Nullable>enable</Nullable>`, a missing value for `Name` in a JSON or form post results in a validation error. This may seem contradictory since the `[Required(AllowEmptyStrings = true)]` attribute is implied, but this is expected behavior because empty strings are converted to null by default. Use a nullable reference type to allow null or missing values to be specified for the `Name` property:

```
C#

public class Person
{
    public string? Name { get; set; }
}
```

This behavior can be disabled by configuring SuppressImplicitRequiredAttributeForNonNullableReferenceTypes in `Program.cs`:

```
C#

builder.Services.AddControllers(
    options =>
options.SuppressImplicitRequiredAttributeForNonNullableReferenceTypes =
true);
```

[Required] validation on the server

On the server, a required value is considered missing if the property is null. A non-nullable field is always valid, and the `[Required]` attribute's error message is never displayed.

However, model binding for a non-nullable property may fail, resulting in an error message such as `The value '' is invalid`. To specify a custom error message for server-side validation of non-nullable types, you have the following options:

- Make the field nullable (for example, `decimal?` instead of `decimal`). Nullable<T> value types are treated like standard nullable types.
- Specify the default error message to be used by model binding, as shown in the following example:

  C#

  ```
  builder.Services.AddRazorPages()
      .AddMvcOptions(options =>
      {
          options.MaxModelValidationErrors = 50;

  options.ModelBindingMessageProvider.SetValueMustNotBeNullAccessor(
              _ => "The field is required.");
      });

  builder.Services.AddSingleton
      <IValidationAttributeAdapterProvider,
  CustomValidationAttributeAdapterProvider>();
  ```

  For more information about model binding errors that you can set default messages for, see DefaultModelBindingMessageProvider.

[Required] validation on the client

Non-nullable types and strings are handled differently on the client compared to the server. On the client:

- A value is considered present only if input is entered for it. Therefore, client-side validation handles non-nullable types the same as nullable types.
- Whitespace in a string field is considered valid input by the jQuery Validation required method. Server-side validation considers a required string field invalid if only whitespace is entered.

As noted earlier, non-nullable types are treated as though they had a `[Required(AllowEmptyStrings = true)]` attribute. That means you get client-side

validation even if you don't apply the `[Required(AllowEmptyStrings = true)]` attribute. But if you don't use the attribute, you get a default error message. To specify a custom error message, use the attribute.

[Remote] attribute

The [Remote] attribute implements client-side validation that requires calling a method on the server to determine whether field input is valid. For example, the app may need to verify whether a user name is already in use.

To implement remote validation:

1. Create an action method for JavaScript to call. The jQuery Validation remote method expects a JSON response:

   - `true` means the input data is valid.
   - `false`, `undefined`, or `null` means the input is invalid. Display the default error message.
   - Any other string means the input is invalid. Display the string as a custom error message.

   Here's an example of an action method that returns a custom error message:

   C#

   ```
   [AcceptVerbs("GET", "POST")]
   public IActionResult VerifyEmail(string email)
   {
       if (!_userService.VerifyEmail(email))
       {
           return Json($"Email {email} is already in use.");
       }

       return Json(true);
   }
   ```

2. In the model class, annotate the property with a `[Remote]` attribute that points to the validation action method, as shown in the following example:

   C#

   ```
   [Remote(action: "VerifyEmail", controller: "Users")]
   public string Email { get; set; } = null!;
   ```

Server side validation also needs to be implemented for clients that have disabled JavaScript.

Additional fields

The AdditionalFields property of the `[Remote]` attribute lets you validate combinations of fields against data on the server. For example, if the `User` model had `FirstName` and `LastName` properties, you might want to verify that no existing users already have that pair of names. The following example shows how to use `AdditionalFields`:

C#

```
[Remote(action: "VerifyName", controller: "Users", AdditionalFields =
nameof(LastName))]
[Display(Name = "First Name")]
public string FirstName { get; set; } = null!;

[Remote(action: "VerifyName", controller: "Users", AdditionalFields =
nameof(FirstName))]
[Display(Name = "Last Name")]
public string LastName { get; set; } = null!;
```

`AdditionalFields` could be set explicitly to the strings "FirstName" and "LastName", but using the nameof operator simplifies later refactoring. The action method for this validation must accept both `firstName` and `lastName` arguments:

C#

```
[AcceptVerbs("GET", "POST")]
public IActionResult VerifyName(string firstName, string lastName)
{
    if (!_userService.VerifyName(firstName, lastName))
    {
        return Json($"A user named {firstName} {lastName} already exists.");
    }

    return Json(true);
}
```

When the user enters a first or last name, JavaScript makes a remote call to see if that pair of names has been taken.

To validate two or more additional fields, provide them as a comma-delimited list. For example, to add a `MiddleName` property to the model, set the `[Remote]` attribute as shown in the following example:

C#

```
[Remote(action: "VerifyName", controller: "Users",
    AdditionalFields = nameof(FirstName) + "," + nameof(LastName))]
public string MiddleName { get; set; }
```

`AdditionalFields`, like all attribute arguments, must be a constant expression. Therefore, don't use an interpolated string or call Join to initialize `AdditionalFields`.

Alternatives to built-in attributes

If you need validation not provided by built-in attributes, you can:

- Create custom attributes.
- Implement IValidatableObject.

Custom attributes

For scenarios that the built-in validation attributes don't handle, you can create custom validation attributes. Create a class that inherits from ValidationAttribute, and override the IsValid method.

The `IsValid` method accepts an object named *value*, which is the input to be validated. An overload also accepts a ValidationContext object, which provides additional information, such as the model instance created by model binding.

The following example validates that the release date for a movie in the *Classic* genre isn't later than a specified year. The `[ClassicMovie]` attribute:

- Is only run on the server.
- For Classic movies, validates the release date:

C#

```
public class ClassicMovieAttribute : ValidationAttribute
{
    public ClassicMovieAttribute(int year)
        => Year = year;

    public int Year { get; }

    public string GetErrorMessage() =>
        $"Classic movies must have a release year no later than {Year}.";

    protected override ValidationResult? IsValid(
```

```
        object? value, ValidationContext validationContext)
    {
        var movie = (Movie)validationContext.ObjectInstance;
        var releaseYear = ((DateTime)value!).Year;

        if (movie.Genre == Genre.Classic && releaseYear > Year)
        {
            return new ValidationResult(GetErrorMessage());
        }

        return ValidationResult.Success;
    }
}
```

The `movie` variable in the preceding example represents a `Movie` object that contains the data from the form submission. When validation fails, a ValidationResult with an error message is returned.

IValidatableObject

The preceding example works only with `Movie` types. Another option for class-level validation is to implement IValidatableObject in the model class, as shown in the following example:

C#

```
public class ValidatableMovie : IValidatableObject
{
    private const int _classicYear = 1960;

    public int Id { get; set; }

    [Required]
    [StringLength(100)]
    public string Title { get; set; } = null!;

    [DataType(DataType.Date)]
    [Display(Name = "Release Date")]
    public DateTime ReleaseDate { get; set; }

    [Required]
    [StringLength(1000)]
    public string Description { get; set; } = null!;

    [Range(0, 999.99)]
    public decimal Price { get; set; }

    public Genre Genre { get; set; }

    public bool Preorder { get; set; }
```

```
    public IEnumerable<ValidationResult> Validate(ValidationContext
validationContext)
    {
        if (Genre == Genre.Classic && ReleaseDate.Year > _classicYear)
        {
            yield return new ValidationResult(
                $"Classic movies must have a release year no later than
{_classicYear}.",
                new[] { nameof(ReleaseDate) });
        }
    }
}
```

Custom validation

The following code shows how to add a model error after examining the model:

C#

```
if (Contact.Name == Contact.ShortName)
{
    ModelState.AddModelError("Contact.ShortName",
                             "Short name can't be the same as Name.");
}
```

The following code implements the validation test in a controller:

C#

```
if (contact.Name == contact.ShortName)
{
    ModelState.AddModelError(nameof(contact.ShortName),
                             "Short name can't be the same as Name.");
}
```

The following code verifies the phone number and email are unique:

C#

```
public async Task<IActionResult> OnPostAsync()
{
    // Attach Validation Error Message to the Model on validation failure.

    if (Contact.Name == Contact.ShortName)
    {
        ModelState.AddModelError("Contact.ShortName",
                                 "Short name can't be the same as Name.");
```

```
    }

    if (_context.Contact.Any(i => i.PhoneNumber == Contact.PhoneNumber))
    {
        ModelState.AddModelError("Contact.PhoneNumber",
                                 "The Phone number is already in use.");
    }
    if (_context.Contact.Any(i => i.Email == Contact.Email))
    {
        ModelState.AddModelError("Contact.Email", "The Email is already in
use.");
    }

    if (!ModelState.IsValid || _context.Contact == null || Contact == null)
    {
        // if model is invalid, return the page with the model state errors.
        return Page();
    }
    _context.Contact.Add(Contact);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

The following code implements the validation test in a controller:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult>
Create([Bind("Id,Name,ShortName,Email,PhoneNumber")] Contact contact)
{
    // Attach Validation Error Message to the Model on validation failure.
    if (contact.Name == contact.ShortName)
    {
        ModelState.AddModelError(nameof(contact.ShortName),
                                 "Short name can't be the same as Name.");
    }

    if (_context.Contact.Any(i => i.PhoneNumber == contact.PhoneNumber))
    {
        ModelState.AddModelError(nameof(contact.PhoneNumber),
                                 "The Phone number is already in use.");
    }
    if (_context.Contact.Any(i => i.Email == contact.Email))
    {
        ModelState.AddModelError(nameof(contact.Email), "The Email is
already in use.");
    }

    if (ModelState.IsValid)
    {
```

```
            _context.Add(contact);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        return View(contact);
    }
```

Checking for a unique phone number or email is typically also done with remote validation.

ValidationResult

Consider the following custom `ValidateNameAttribute`:

C#

```
public class ValidateNameAttribute : ValidationAttribute
{
    public ValidateNameAttribute()
    {
        const string defaultErrorMessage = "Error with Name";
        ErrorMessage ??= defaultErrorMessage;
    }

    protected override ValidationResult? IsValid(object? value,
                                        ValidationContext
validationContext)
    {
        if (value == null || string.IsNullOrWhiteSpace(value.ToString()))
        {
            return new ValidationResult("Name is required.");
        }

        if (value.ToString()!.ToLower().Contains("zz"))
        {

            return new ValidationResult(
                        FormatErrorMessage(validationContext.DisplayName));
        }

        return ValidationResult.Success;
    }
}
```

In the following code, the custom `[ValidateName]` attribute is applied:

C#

```
public class Contact
{
    public Guid Id { get; set; }

    [ValidateName(ErrorMessage = "Name must not contain `zz`")]
    public string? Name { get; set; }
    public string? Email { get; set; }
    public string? PhoneNumber { get; set; }
}
```

When the model contains `zz`, a new ValidationResult is returned.

Top-level node validation

Top-level nodes include:

- Action parameters
- Controller properties
- Page handler parameters
- Page model properties

Model-bound top-level nodes are validated in addition to validating model properties. In the following example from the sample app, the `VerifyPhone` method uses the RegularExpressionAttribute to validate the `phone` action parameter:

C#

```
[AcceptVerbs("GET", "POST")]
public IActionResult VerifyPhone(
    [RegularExpression(@"^\d{3}-\d{3}-\d{4}$")] string phone)
{
    if (!ModelState.IsValid)
    {
        return Json($"Phone {phone} has an invalid format. Format: ###-###-
####");
    }

    return Json(true);
}
```

Top-level nodes can use BindRequiredAttribute with validation attributes. In the following example from the sample app, the `CheckAge` method specifies that the `age` parameter must be bound from the query string when the form is submitted:

C#

```
[HttpPost]
public IActionResult CheckAge([BindRequired, FromQuery] int age)
{
```

In the Check Age page (`CheckAge.cshtml`), there are two forms. The first form submits an `Age` value of `99` as a query string parameter: `https://localhost:5001/Users/CheckAge?Age=99`.

When a properly formatted `age` parameter from the query string is submitted, the form validates.

The second form on the Check Age page submits the `Age` value in the body of the request, and validation fails. Binding fails because the `age` parameter must come from a query string.

Maximum errors

Validation stops when the maximum number of errors is reached (200 by default). You can configure this number with the following code in `Program.cs`:

C#

```
builder.Services.AddRazorPages()
    .AddMvcOptions(options =>
    {
        options.MaxModelValidationErrors = 50;
        options.ModelBindingMessageProvider.SetValueMustNotBeNullAccessor(
            _ => "The field is required.");
    });

builder.Services.AddSingleton
    <IValidationAttributeAdapterProvider,
CustomValidationAttributeAdapterProvider>();
```

Maximum recursion

ValidationVisitor traverses the object graph of the model being validated. For models that are deep or are infinitely recursive, validation may result in stack overflow. MvcOptions.MaxValidationDepth provides a way to stop validation early if the visitor recursion exceeds a configured depth. The default value of `MvcOptions.MaxValidationDepth` is 32.

Automatic short-circuit

Validation is automatically short-circuited (skipped) if the model graph doesn't require validation. Objects that the runtime skips validation for include collections of primitives (such as `byte[]`, `string[]`, `Dictionary<string, string>`) and complex object graphs that don't have any validators.

Client-side validation

Client-side validation prevents submission until the form is valid. The Submit button runs JavaScript that either submits the form or displays error messages.

Client-side validation avoids an unnecessary round trip to the server when there are input errors on a form. The following script references in `_Layout.cshtml` and `_ValidationScriptsPartial.cshtml` support client-side validation:

CSHTML

```
<script src="https://cdnjs.cloudflare.com/ajax/libs/jquery/3.6.0/jquery.js">
</script>
```

CSHTML

```
<script src="https://cdnjs.cloudflare.com/ajax/libs/jquery-
validate/1.19.3/jquery.validate.js"></script>
<script src="https://cdnjs.cloudflare.com/ajax/libs/jquery-validation-
unobtrusive/3.2.12/jquery.validate.unobtrusive.js"></script>
```

The jQuery Unobtrusive Validation script is a custom Microsoft front-end library that builds on the popular jQuery Validation plugin. Without jQuery Unobtrusive Validation, you would have to code the same validation logic in two places: once in the server-side validation attributes on model properties, and then again in client-side scripts. Instead, Tag Helpers and HTML helpers use the validation attributes and type metadata from model properties to render HTML 5 `data-` attributes for the form elements that need validation. jQuery Unobtrusive Validation parses the `data-` attributes and passes the logic to jQuery Validation, effectively "copying" the server-side validation logic to the client. You can display validation errors on the client using tag helpers as shown here:

CSHTML

```
<div class="form-group">
    <label asp-for="Movie.ReleaseDate" class="control-label"></label>
    <input asp-for="Movie.ReleaseDate" class="form-control" />
    <span asp-validation-for="Movie.ReleaseDate" class="text-danger"></span>
</div>
```

The preceding tag helpers render the following HTML:

HTML

```
<div class="form-group">
    <label class="control-label" for="Movie_ReleaseDate">Release
Date</label>
    <input class="form-control" type="date" data-val="true"
        data-val-required="The Release Date field is required."
        id="Movie_ReleaseDate" name="Movie.ReleaseDate" value="">
    <span class="text-danger field-validation-valid"
        data-valmsg-for="Movie.ReleaseDate" data-valmsg-replace="true">
</span>
</div>
```

Notice that the `data-` attributes in the HTML output correspond to the validation attributes for the `Movie.ReleaseDate` property. The `data-val-required` attribute contains an error message to display if the user doesn't fill in the release date field. jQuery Unobtrusive Validation passes this value to the jQuery Validation required() method, which then displays that message in the accompanying **** element.

Data type validation is based on the .NET type of a property, unless that is overridden by a [DataType] attribute. Browsers have their own default error messages, but the jQuery Validation Unobtrusive Validation package can override those messages. `[DataType]` attributes and subclasses such as [EmailAddress] let you specify the error message.

Unobtrusive validation

For information on unobtrusive validation, see this GitHub issue.

Add Validation to Dynamic Forms

jQuery Unobtrusive Validation passes validation logic and parameters to jQuery Validation when the page first loads. Therefore, validation doesn't work automatically on dynamically generated forms. To enable validation, tell jQuery Unobtrusive Validation to parse the dynamic form immediately after you create it. For example, the following code sets up client-side validation on a form added via AJAX.

JavaScript

```
$.get({
    url: "https://url/that/returns/a/form",
    dataType: "html",
    error: function(jqXHR, textStatus, errorThrown) {
        alert(textStatus + ": Couldn't add form. " + errorThrown);
    },
    success: function(newFormHTML) {
        var container = document.getElementById("form-container");
        container.insertAdjacentHTML("beforeend", newFormHTML);
        var forms = container.getElementsByTagName("form");
        var newForm = forms[forms.length - 1];
        $.validator.unobtrusive.parse(newForm);
    }
})
```

The `$.validator.unobtrusive.parse()` method accepts a jQuery selector for its one argument. This method tells jQuery Unobtrusive Validation to parse the `data-` attributes of forms within that selector. The values of those attributes are then passed to the jQuery Validation plugin.

Add Validation to Dynamic Controls

The `$.validator.unobtrusive.parse()` method works on an entire form, not on individual dynamically generated controls, such as `<input>` and `<select/>`. To reparse the form, remove the validation data that was added when the form was parsed earlier, as shown in the following example:

JavaScript

```
$.get({
    url: "https://url/that/returns/a/control",
    dataType: "html",
    error: function(jqXHR, textStatus, errorThrown) {
        alert(textStatus + ": Couldn't add control. " + errorThrown);
    },
    success: function(newInputHTML) {
        var form = document.getElementById("my-form");
        form.insertAdjacentHTML("beforeend", newInputHTML);
        $(form).removeData("validator")    // Added by jQuery Validation
               .removeData("unobtrusiveValidation");   // Added by jQuery
Unobtrusive Validation
        $.validator.unobtrusive.parse(form);
    }
})
```

Custom client-side validation

Custom client-side validation is done by generating `data-` HTML attributes that work with a custom jQuery Validation adapter. The following sample adapter code was written for the `[ClassicMovie]` and `[ClassicMovieWithClientValidator]` attributes that were introduced earlier in this article:

JavaScript

```
$.validator.addMethod('classicmovie', function (value, element, params) {
    var genre = $(params[0]).val(), year = params[1], date = new
Date(value);

    // The Classic genre has a value of '0'.
    if (genre && genre.length > 0 && genre[0] === '0') {
        // The release date for a Classic is valid if it's no greater than
the given year.
        return date.getUTCFullYear() <= year;
    }

    return true;
});

$.validator.unobtrusive.adapters.add('classicmovie', ['year'], function
(options) {
    var element = $(options.form).find('select#Movie_Genre')[0];

    options.rules['classicmovie'] = [element,
parseInt(options.params['year'])];
    options.messages['classicmovie'] = options.message;
});
```

For information about how to write adapters, see the jQuery Validation documentation.

The use of an adapter for a given field is triggered by `data-` attributes that:

- Flag the field as being subject to validation (`data-val="true"`).
- Identify a validation rule name and error message text (for example, `data-val-rulename="Error message."`).
- Provide any additional parameters the validator needs (for example, `data-val-rulename-param1="value"`).

The following example shows the `data-` attributes for the sample app's `ClassicMovie` attribute:

HTML

```
<input class="form-control" type="date"
    data-val="true"
    data-val-classicmovie="Classic movies must have a release year no later
than 1960."
    data-val-classicmovie-year="1960"
    data-val-required="The Release Date field is required."
    id="Movie_ReleaseDate" name="Movie.ReleaseDate" value="">
```

As noted earlier, Tag Helpers and HTML helpers use information from validation attributes to render `data-` attributes. There are two options for writing code that results in the creation of custom `data-` HTML attributes:

- Create a class that derives from AttributeAdapterBase<TAttribute> and a class that implements IValidationAttributeAdapterProvider, and register your attribute and its adapter in DI. This method follows the single responsibility principle in that server-related and client-related validation code is in separate classes. The adapter also has the advantage that since it's registered in DI, other services in DI are available to it if needed.
- Implement IClientModelValidator in your ValidationAttribute class. This method might be appropriate if the attribute doesn't do any server-side validation and doesn't need any services from DI.

AttributeAdapter for client-side validation

This method of rendering `data-` attributes in HTML is used by the `ClassicMovie` attribute in the sample app. To add client validation by using this method:

1. Create an attribute adapter class for the custom validation attribute. Derive the class from AttributeAdapterBase<TAttribute>. Create an `AddValidation` method that adds `data-` attributes to the rendered output, as shown in this example:

   C#

   ```
   public class ClassicMovieAttributeAdapter :
   AttributeAdapterBase<ClassicMovieAttribute>
   {
       public ClassicMovieAttributeAdapter(
           ClassicMovieAttribute attribute, IStringLocalizer?
   stringLocalizer)
           : base(attribute, stringLocalizer)
       {

       }

       public override void AddValidation(ClientModelValidationContext
   ```

```
context)
    {
        MergeAttribute(context.Attributes, "data-val", "true");
        MergeAttribute(context.Attributes, "data-val-classicmovie",
GetErrorMessage(context));

        var year =
Attribute.Year.ToString(CultureInfo.InvariantCulture);
        MergeAttribute(context.Attributes, "data-val-classicmovie-
year", year);
    }

    public override string GetErrorMessage(ModelValidationContextBase
validationContext)
        => Attribute.GetErrorMessage();
}
```

2. Create an adapter provider class that implements IValidationAttributeAdapterProvider. In the GetAttributeAdapter method pass in the custom attribute to the adapter's constructor, as shown in this example:

C#

```
public class CustomValidationAttributeAdapterProvider :
IValidationAttributeAdapterProvider
{
    private readonly IValidationAttributeAdapterProvider baseProvider =
        new ValidationAttributeAdapterProvider();

    public IAttributeAdapter? GetAttributeAdapter(
        ValidationAttribute attribute, IStringLocalizer?
stringLocalizer)
    {
        if (attribute is ClassicMovieAttribute classicMovieAttribute)
        {
            return new
ClassicMovieAttributeAdapter(classicMovieAttribute, stringLocalizer);
        }

        return baseProvider.GetAttributeAdapter(attribute,
stringLocalizer);
    }
}
```

3. Register the adapter provider for DI in `Program.cs`:

C#

```
builder.Services.AddRazorPages()
    .AddMvcOptions(options =>
    {
```

```
        options.MaxModelValidationErrors = 50;

options.ModelBindingMessageProvider.SetValueMustNotBeNullAccessor(
            _ => "The field is required.");
    });

builder.Services.AddSingleton
    <IValidationAttributeAdapterProvider,
CustomValidationAttributeAdapterProvider>();
```

IClientModelValidator for client-side validation

This method of rendering `data-` attributes in HTML is used by the `ClassicMovieWithClientValidator` attribute in the sample app. To add client validation by using this method:

- In the custom validation attribute, implement the IClientModelValidator interface and create an AddValidation method. In the `AddValidation` method, add `data-` attributes for validation, as shown in the following example:

C#

```
public class ClassicMovieWithClientValidatorAttribute :
    ValidationAttribute, IClientModelValidator
{
    public ClassicMovieWithClientValidatorAttribute(int year)
        => Year = year;

    public int Year { get; }

    public void AddValidation(ClientModelValidationContext context)
    {
        MergeAttribute(context.Attributes, "data-val", "true");
        MergeAttribute(context.Attributes, "data-val-classicmovie",
GetErrorMessage());

        var year = Year.ToString(CultureInfo.InvariantCulture);
        MergeAttribute(context.Attributes, "data-val-classicmovie-
year", year);
    }

    public string GetErrorMessage() =>
        $"Classic movies must have a release year no later than
{Year}.";

    protected override ValidationResult? IsValid(
        object? value, ValidationContext validationContext)
    {
        var movie = (Movie)validationContext.ObjectInstance;
        var releaseYear = ((DateTime)value!).Year;
```

```
        if (movie.Genre == Genre.Classic && releaseYear > Year)
        {
            return new ValidationResult(GetErrorMessage());
        }

        return ValidationResult.Success;
    }

    private static bool MergeAttribute(IDictionary<string, string>
attributes, string key, string value)
    {
        if (attributes.ContainsKey(key))
        {
            return false;
        }

        attributes.Add(key, value);
        return true;
    }
}
```

Disable client-side validation

The following code disables client validation in Razor Pages:

C#

```
builder.Services.AddRazorPages()
    .AddViewOptions(options =>
    {
        options.HtmlHelperOptions.ClientValidationEnabled = false;
    });
```

Other options to disable client-side validation:

- Comment out the reference to `_ValidationScriptsPartial` in all the `.cshtml` files.
- Remove the contents of the *Pages\Shared_ValidationScriptsPartial.cshtml* file.

The preceding approach won't prevent client-side validation of ASP.NET Core Identity Razor class library. For more information, see Scaffold Identity in ASP.NET Core projects.

Problem details

Problem Details are not the only response format to describe an HTTP API error, however, they are commonly used to report errors for HTTP APIs.

The problem details service implements the IProblemDetailsService interface, which supports creating problem details in ASP.NET Core. The AddProblemDetails(IServiceCollection) extension method on IServiceCollection registers the default `IProblemDetailsService` implementation.

In ASP.NET Core apps, the following middleware generates problem details HTTP responses when `AddProblemDetails` is called, except when the Accept request HTTP header doesn't include one of the content types supported by the registered IProblemDetailsWriter (default: `application/json`):

- ExceptionHandlerMiddleware: Generates a problem details response when a custom handler is not defined.
- StatusCodePagesMiddleware: Generates a problem details response by default.
- DeveloperExceptionPageMiddleware: Generates a problem details response in development when the `Accept` request HTTP header doesn't include `text/html`.

Compatibility version for ASP.NET Core MVC

Article • 06/03/2022

By Rick Anderson

The SetCompatibilityVersion method is a no-op for ASP.NET Core 3.0 apps. That is, calling `SetCompatibilityVersion` with any value of CompatibilityVersion has no impact on the application.

- The next minor version of ASP.NET Core may provide a new `CompatibilityVersion` value.
- `CompatibilityVersion` values `Version_2_0` through `Version_2_2` are marked `[Obsolete(...)]`.
- See Breaking API changes in Antiforgery, CORS, Diagnostics, Mvc, and Routing. This list includes breaking changes for compatibility switches.

To see how `SetCompatibilityVersion` works with ASP.NET Core 2.x apps, select the ASP.NET Core 2.2 version of this article.

Write custom ASP.NET Core middleware

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Fiyaz Hasan, Rick Anderson, and Steve Smith

Middleware is software that's assembled into an app pipeline to handle requests and responses. ASP.NET Core provides a rich set of built-in middleware components, but in some scenarios you might want to write a custom middleware.

This topic describes how to write *convention-based* middleware. For an approach that uses strong typing and per-request activation, see Factory-based middleware activation in ASP.NET Core.

Middleware class

Middleware is generally encapsulated in a class and exposed with an extension method. Consider the following inline middleware, which sets the culture for the current request from a query string:

C#

```
using System.Globalization;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.UseHttpsRedirection();
```

```
app.Use(async (context, next) =>
{
    var cultureQuery = context.Request.Query["culture"];
    if (!string.IsNullOrWhiteSpace(cultureQuery))
    {
        var culture = new CultureInfo(cultureQuery);

        CultureInfo.CurrentCulture = culture;
        CultureInfo.CurrentUICulture = culture;
    }

    // Call the next delegate/middleware in the pipeline.
    await next(context);
});

app.Run(async (context) =>
{
    await context.Response.WriteAsync(
        $"CurrentCulture.DisplayName:
{CultureInfo.CurrentCulture.DisplayName}");
});

app.Run();
```

The preceding highlighted inline middleware is used to demonstrate creating a middleware component by calling Microsoft.AspNetCore.Builder.UseExtensions.Use. The preceding `Use` extension method adds a middleware delegate defined in-line to the application's request pipeline.

There are two overloads available for the `Use` extension:

- One takes a HttpContext and a `Func<Task>`. Invoke the `Func<Task>` without any parameters.
- The other takes a `HttpContext` and a RequestDelegate. Invoke the `RequestDelegate` by passing the `HttpContext`.

Prefer using the later overload as it saves two internal per-request allocations that are required when using the other overload.

Test the middleware by passing in the culture. For example, request `https://localhost:5001/?culture=es-es`.

For ASP.NET Core's built-in localization support, see Globalization and localization in ASP.NET Core.

The following code moves the middleware delegate to a class:

```
C#
```

```
using System.Globalization;

namespace Middleware.Example;

public class RequestCultureMiddleware
{
    private readonly RequestDelegate _next;

    public RequestCultureMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task InvokeAsync(HttpContext context)
    {
        var cultureQuery = context.Request.Query["culture"];
        if (!string.IsNullOrWhiteSpace(cultureQuery))
        {
            var culture = new CultureInfo(cultureQuery);

            CultureInfo.CurrentCulture = culture;
            CultureInfo.CurrentUICulture = culture;
        }

        // Call the next delegate/middleware in the pipeline.
        await _next(context);
    }
}
```

The middleware class must include:

- A public constructor with a parameter of type RequestDelegate.
- A public method named `Invoke` or `InvokeAsync`. This method must:
  - Return a `Task`.
  - Accept a first parameter of type HttpContext.

Additional parameters for the constructor and `Invoke`/`InvokeAsync` are populated by dependency injection (DI).

Typically, an extension method is created to expose the middleware through IApplicationBuilder:

C#

```
using System.Globalization;

namespace Middleware.Example;

public class RequestCultureMiddleware
{
```

```
    private readonly RequestDelegate _next;

    public RequestCultureMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task InvokeAsync(HttpContext context)
    {
        var cultureQuery = context.Request.Query["culture"];
        if (!string.IsNullOrWhiteSpace(cultureQuery))
        {
            var culture = new CultureInfo(cultureQuery);

            CultureInfo.CurrentCulture = culture;
            CultureInfo.CurrentUICulture = culture;
        }

        // Call the next delegate/middleware in the pipeline.
        await _next(context);
    }
}

public static class RequestCultureMiddlewareExtensions
{
    public static IApplicationBuilder UseRequestCulture(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<RequestCultureMiddleware>();
    }
}
```

The following code calls the middleware from `Program.cs`:

C#

```
using Middleware.Example;
using System.Globalization;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.UseHttpsRedirection();

app.UseRequestCulture();

app.Run(async (context) =>
{
    await context.Response.WriteAsync(
        $"CurrentCulture.DisplayName:
{CultureInfo.CurrentCulture.DisplayName}");
});
```

```
app.Run();
```

Middleware dependencies

Middleware should follow the Explicit Dependencies Principle by exposing its dependencies in its constructor. Middleware is constructed once per *application lifetime*.

Middleware components can resolve their dependencies from dependency injection (DI) through constructor parameters. UseMiddleware can also accept additional parameters directly.

Per-request middleware dependencies

Middleware is constructed at app startup and therefore has application life time. Scoped lifetime services used by middleware constructors aren't shared with other dependency-injected types during each request. To share a *scoped* service between middleware and other types, add these services to the `InvokeAsync` method's signature. The `InvokeAsync` method can accept additional parameters that are populated by DI:

C#

```
namespace Middleware.Example;

public class MyCustomMiddleware
{
    private readonly RequestDelegate _next;

    public MyCustomMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    // IMessageWriter is injected into InvokeAsync
    public async Task InvokeAsync(HttpContext httpContext, IMessageWriter
svc)
    {
        svc.Write(DateTime.Now.Ticks.ToString());
        await _next(httpContext);
    }
}

public static class MyCustomMiddlewareExtensions
{
    public static IApplicationBuilder UseMyCustomMiddleware(
        this IApplicationBuilder builder)
    {
```

```
        return builder.UseMiddleware<MyCustomMiddleware>();
    }
}
```

Lifetime and registration options contains a complete sample of middleware with *scoped* lifetime services.

The following code is used to test the preceding middleware:

C#

```
using Middleware.Example;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddScoped<IMessageWriter, LoggingMessageWriter>();

var app = builder.Build();

app.UseHttpsRedirection();

app.UseMyCustomMiddleware();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The `IMessageWriter` interface and implementation:

C#

```
namespace Middleware.Example;

public interface IMessageWriter
{
    void Write(string message);
}

public class LoggingMessageWriter : IMessageWriter
{

    private readonly ILogger<LoggingMessageWriter> _logger;

    public LoggingMessageWriter(ILogger<LoggingMessageWriter> logger) =>
        _logger = logger;

    public void Write(string message) =>
        _logger.LogInformation(message);
}
```

Request and response operations in ASP.NET Core

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Justin Kotalik

This article explains how to read from the request body and write to the response body. Code for these operations might be required when writing middleware. Outside of writing middleware, custom code isn't generally required because the operations are handled by MVC and Razor Pages.

There are two abstractions for the request and response bodies: Stream and Pipe. For request reading, HttpRequest.Body is a Stream, and `HttpRequest.BodyReader` is a PipeReader. For response writing, HttpResponse.Body is a Stream, and `HttpResponse.BodyWriter` is a PipeWriter.

Pipelines are recommended over streams. Streams can be easier to use for some simple operations, but pipelines have a performance advantage and are easier to use in most scenarios. ASP.NET Core is starting to use pipelines instead of streams internally. Examples include:

- `FormReader`
- `TextReader`
- `TextWriter`
- `HttpResponse.WriteAsync`

Streams aren't being removed from the framework. Streams continue to be used throughout .NET, and many stream types don't have pipe equivalents, such as `FileStreams` and `ResponseCompression`.

Stream examples

Suppose the goal is to create a middleware that reads the entire request body as a list of strings, splitting on new lines. A simple stream implementation might look like the following example:

> **⚠ Warning**
>
> The following code:
>
> - Is used to demonstrate the problems with not using a pipe to read the request body.
> - Is not intended to be used in production apps.

C#

```
private async Task<List<string>> GetListOfStringsFromStream(Stream
requestBody)
{
    // Build up the request body in a string builder.
    StringBuilder builder = new StringBuilder();

    // Rent a shared buffer to write the request body into.
    byte[] buffer = ArrayPool<byte>.Shared.Rent(4096);

    while (true)
    {
        var bytesRemaining = await requestBody.ReadAsync(buffer, offset: 0,
buffer.Length);
        if (bytesRemaining == 0)
        {
            break;
        }

        // Append the encoded string into the string builder.
        var encodedString = Encoding.UTF8.GetString(buffer, 0,
bytesRemaining);
        builder.Append(encodedString);
    }

    ArrayPool<byte>.Shared.Return(buffer);

    var entireRequestBody = builder.ToString();

    // Split on \n in the string.
    return new List<string>(entireRequestBody.Split("\n"));
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

This code works, but there are some issues:

- Before appending to the `StringBuilder`, the example creates another string (`encodedString`) that is thrown away immediately. This process occurs for all bytes in the stream, so the result is extra memory allocation the size of the entire request body.
- The example reads the entire string before splitting on new lines. It's more efficient to check for new lines in the byte array.

Here's an example that fixes some of the preceding issues:

> **⚠ Warning**
>
> The following code:
>
> - Is used to demonstrate the solutions to some problems in the preceding code while not solving all the problems.
> - Is not intended to be used in production apps.

C#

```
private async Task<List<string>>
GetListOfStringsFromStreamMoreEfficient(Stream requestBody)
{
    StringBuilder builder = new StringBuilder();
    byte[] buffer = ArrayPool<byte>.Shared.Rent(4096);
    List<string> results = new List<string>();

    while (true)
    {
        var bytesRemaining = await requestBody.ReadAsync(buffer, offset: 0,
buffer.Length);

        if (bytesRemaining == 0)
        {
            results.Add(builder.ToString());
            break;
        }

        // Instead of adding the entire buffer into the StringBuilder
        // only add the remainder after the last \n in the array.
        var prevIndex = 0;
        int index;
        while (true)
        {
            index = Array.IndexOf(buffer, (byte)'\n', prevIndex);
            if (index == -1)
            {
```

```
                break;
            }

            var encodedString = Encoding.UTF8.GetString(buffer, prevIndex,
index - prevIndex);

            if (builder.Length > 0)
            {
                // If there was a remainder in the string buffer, include it
in the next string.
                results.Add(builder.Append(encodedString).ToString());
                builder.Clear();
            }
            else
            {
                results.Add(encodedString);
            }

            // Skip past last \n
            prevIndex = index + 1;
        }

        var remainingString = Encoding.UTF8.GetString(buffer, prevIndex,
bytesRemaining - prevIndex);
        builder.Append(remainingString);
    }

    ArrayPool<byte>.Shared.Return(buffer);

    return results;
}
```

This preceding example:

- Doesn't buffer the entire request body in a `StringBuilder` unless there aren't any newline characters.
- Doesn't call `Split` on the string.

However, there are still a few issues:

- If newline characters are sparse, much of the request body is buffered in the string.
- The code continues to create strings (`remainingString`) and adds them to the string buffer, which results in an extra allocation.

These issues are fixable, but the code is becoming progressively more complicated with little improvement. Pipelines provide a way to solve these problems with minimal code complexity.

Pipelines

The following example shows how the same scenario can be handled using a PipeReader:

C#

```
private async Task<List<string>> GetListOfStringFromPipe(PipeReader reader)
{
    List<string> results = new List<string>();

    while (true)
    {
        ReadResult readResult = await reader.ReadAsync();
        var buffer = readResult.Buffer;

        SequencePosition? position = null;

        do
        {
            // Look for a EOL in the buffer
            position = buffer.PositionOf((byte)'\n');

            if (position != null)
            {
                var readOnlySequence = buffer.Slice(0, position.Value);
                AddStringToList(results, in readOnlySequence);

                // Skip the line + the \n character (basically position)
                buffer = buffer.Slice(buffer.GetPosition(1,
position.Value));
            }
        }
        while (position != null);

        if (readResult.IsCompleted && buffer.Length > 0)
        {
            AddStringToList(results, in buffer);
        }

        reader.AdvanceTo(buffer.Start, buffer.End);

        // At this point, buffer will be updated to point one byte after the
last
        // \n character.
        if (readResult.IsCompleted)
        {
            break;
        }
    }

    return results;
}

private static void AddStringToList(List<string> results, in
```

```
ReadOnlySequence<byte> readOnlySequence)
{
    // Separate method because Span/ReadOnlySpan cannot be used in async
methods
    ReadOnlySpan<byte> span = readOnlySequence.IsSingleSegment ?
readOnlySequence.First.Span : readOnlySequence.ToArray().AsSpan();
    results.Add(Encoding.UTF8.GetString(span));
}
```

This example fixes many issues that the streams implementations had:

- There's no need for a string buffer because the `PipeReader` handles bytes that haven't been used.
- Encoded strings are directly added to the list of returned strings.
- Other than the `ToArray` call, and the memory used by the string, string creation is allocation free.

Adapters

The `Body`, `BodyReader`, and `BodyWriter` properties are available for `HttpRequest` and `HttpResponse`. When you set `Body` to a different stream, a new set of adapters automatically adapt each type to the other. If you set `HttpRequest.Body` to a new stream, `HttpRequest.BodyReader` is automatically set to a new `PipeReader` that wraps `HttpRequest.Body`.

StartAsync

`HttpResponse.StartAsync` is used to indicate that headers are unmodifiable and to run `OnStarting` callbacks. When using Kestrel as a server, calling `StartAsync` before using the `PipeReader` guarantees that memory returned by `GetMemory` belongs to Kestrel's internal Pipe rather than an external buffer.

Request decompression in ASP.NET Core

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By David Acker

Request decompression middleware:

- Enables API endpoints to accept requests with compressed content.
- Uses the Content-Encoding HTTP header to automatically identify and decompress requests which contain compressed content.
- Eliminates the need to write code to handle compressed requests.

When the `Content-Encoding` header value on a request matches one of the available decompression providers, the middleware:

- Uses the matching provider to wrap the HttpRequest.Body in an appropriate decompression stream.
- Removes the `Content-Encoding` header, indicating that the request body is no longer compressed.

Requests that don't include a `Content-Encoding` header are ignored by the request decompression middleware.

Decompression:

- Occurs when the body of the request is read. That is, decompression occurs at the endpoint on model binding. The request body isn't decompressed eagerly.
- When attempting to read the decompressed request body with invalid compressed data for the specified `Content-Encoding`, an exception is thrown. Brotli can throw System.InvalidOperationException: Decoder ran into invalid data. Deflate and GZip can throw System.IO.InvalidDataException: The archive entry was compressed using an unsupported compression method.

If the middleware encounters a request with compressed content but is unable to decompress it, the request is passed to the next delegate in the pipeline. For example, a request with an unsupported `Content-Encoding` header value or multiple `Content-Encoding` header values is passed to the next delegate in the pipeline.

Configuration

The following code uses AddRequestDecompression(IServiceCollection) and UseRequestDecompression to enable request decompression for the default `Content-Encoding` types:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRequestDecompression();

var app = builder.Build();

app.UseRequestDecompression();

app.MapPost("/", (HttpRequest request) => Results.Stream(request.Body));

app.Run();
```

Default decompression providers

The `Content-Encoding` header values that the request decompression middleware supports by default are listed in the following table:

Expand table

Content-Encoding header values	Description
`br`	Brotli compressed data format
`deflate`	DEFLATE compressed data format
`gzip`	Gzip file format

Custom decompression providers

Support for custom encodings can be added by creating custom decompression provider classes that implement IDecompressionProvider:

```
C#

public class CustomDecompressionProvider : IDecompressionProvider
{
    public Stream GetDecompressionStream(Stream stream)
    {
        // Perform custom decompression logic here
        return stream;
    }
}
```

Custom decompression providers are registered with RequestDecompressionOptions along with their corresponding `Content-Encoding` header values:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRequestDecompression(options =>
{
    options.DecompressionProviders.Add("custom", new
CustomDecompressionProvider());
});

var app = builder.Build();

app.UseRequestDecompression();

app.MapPost("/", (HttpRequest request) => Results.Stream(request.Body));

app.Run();
```

Request size limits

In order to protect against zip bombs or decompression bombs:

- The maximum size of the decompressed request body is limited to the request body size limit enforced by the endpoint or server.
- If the number of bytes read from the decompressed request body stream exceeds the limit, an InvalidOperationException is thrown to prevent additional bytes from being read from the stream.

In order of precedence, the maximum request size for an endpoint is set by:

1. IRequestSizeLimitMetadata.MaxRequestBodySize, such as RequestSizeLimitAttribute or DisableRequestSizeLimitAttribute for MVC endpoints.
2. The global server size limit IHttpMaxRequestBodySizeFeature.MaxRequestBodySize. `MaxRequestBodySize` can be overridden per request with IHttpMaxRequestBodySizeFeature.MaxRequestBodySize, but defaults to the limit configured for the web server implementation.

Expand table

Web server implementation	`MaxRequestBodySize` configuration
HTTP.sys	HttpSysOptions.MaxRequestBodySize
IIS	IISServerOptions.MaxRequestBodySize
Kestrel	KestrelServerLimits.MaxRequestBodySize

> ⚠ **Warning**
>
> Disabling the request body size limit poses a security risk in regards to uncontrolled resource consumption, particularly if the request body is being buffered. Ensure that safeguards are in place to mitigate the risk of denial-of-service (DoS) attacks.

URL Rewriting Middleware in ASP.NET Core

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

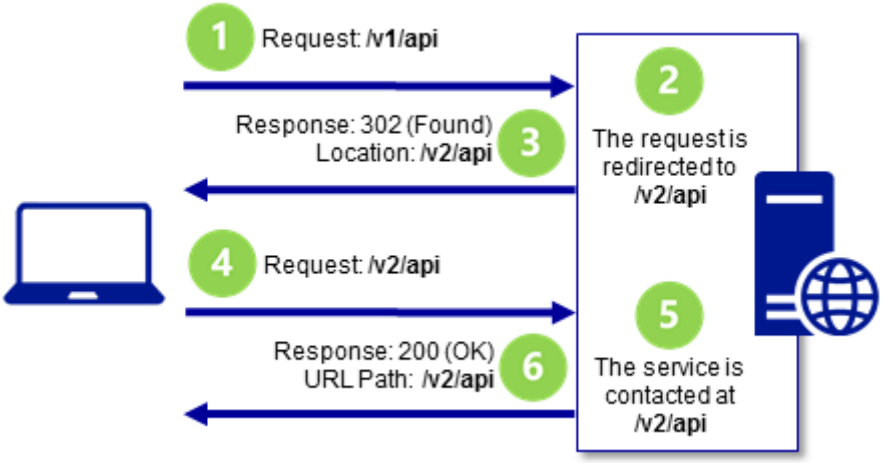
By Kirk Larkin and Rick Anderson

This article introduces URL rewriting with instructions on how to use URL Rewriting Middleware in ASP.NET Core apps.

URL rewriting is the act of modifying request URLs based on one or more predefined rules. URL rewriting creates an abstraction between resource locations and their addresses so that the locations and addresses aren't tightly linked. URL rewriting is valuable in several scenarios to:

- Move or replace server resources temporarily or permanently and maintain stable locators for those resources.
- Split request processing across different apps or across areas of one app.
- Remove, add, or reorganize URL segments on incoming requests.
- Optimize public URLs for Search Engine Optimization (SEO).
- Permit the use of friendly public URLs to help visitors predict the content returned by requesting a resource.
- Redirect insecure requests to secure endpoints.
- Prevent hotlinking, where an external site uses a hosted static asset on another site by linking the asset into its own content.

URL rewriting can reduce the performance of an app. Limit the number and complexity of rules.



URL redirect and URL rewrite

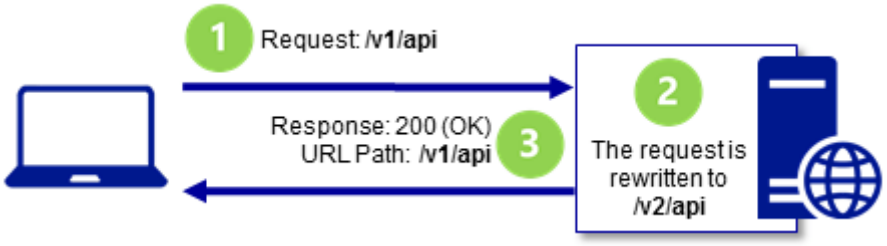
The difference in wording between *URL redirect* and *URL rewrite* is subtle but has important implications for providing resources to clients. ASP.NET Core's URL Rewriting

Middleware is capable of meeting the need for both.

A *URL redirect* involves a client-side operation, where the client is instructed to access a resource at a different address than the client originally requested. This requires a round trip to the server. The redirect URL returned to the client appears in the browser's address bar when the client makes a new request for the resource.

If `/resource` is *redirected* to `/different-resource`, the server responds that the client should obtain the resource at `/different-resource` with a status code indicating that the redirect is either temporary or permanent.

When redirecting requests to a different URL, indicate whether the redirect is permanent or temporary by specifying the status code with the response:



- The 301 - Moved Permanently status code is used where the resource has a new, permanent URL and that all future requests for the resource should use the new URL. *The client may cache and reuse the response when a 301 status code is received.*
- The 302 - Found status code is used where the redirection is temporary or generally subject to change. The 302 status code indicates to the client not to store the URL and use it in the future.

For more information on status codes, see RFC 9110: Status Code Definitions.

A *URL rewrite* is a server-side operation that provides a resource from a different resource address than the client requested. Rewriting a URL doesn't require a round trip to the server. The rewritten URL isn't returned to the client and doesn't appear in the browser's address bar.

If `/resource` is *rewritten* to `/different-resource`, the server *internally* fetches and returns the resource at `/different-resource`.

Although the client might be able to retrieve the resource at the rewritten URL, the client isn't informed that the resource exists at the rewritten URL when it makes its request and receives the response.

URL rewriting sample app

Explore the features of the URL Rewriting Middleware with the sample app. The app applies redirect and rewrite rules and shows the redirected or rewritten URL for several scenarios.

When to use URL rewriting middleware

Use URL Rewriting Middleware when the following approaches aren't satisfactory:

- URL Rewrite module with IIS on Windows Server
- Apache mod_rewrite module on Apache Server
- URL rewriting on Nginx

Use the URL rewriting middleware when the app is hosted on HTTP.sys server.

The main reasons to use the server-based URL rewriting technologies in IIS, Apache, and Nginx are:

- The middleware doesn't support the full features of these modules.

  Some of the features of the server modules don't work with ASP.NET Core projects, such as the `IsFile` and `IsDirectory` constraints of the IIS Rewrite module. In these scenarios, use the middleware instead.

- The performance of the middleware probably doesn't match that of the modules.

  Benchmarking is the only way to know with certainty which approach degrades performance the most or if degraded performance is negligible.

Extension and options

Establish URL rewrite and redirect rules by creating an instance of the RewriteOptions class with extension methods for each of the rewrite rules. Chain multiple rules ***in the order that they should be processed***. The `RewriteOptions` are passed into the URL Rewriting Middleware as it's added to the request pipeline with UseRewriter:

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

In the preceding code, MethodRules is a user defined class. See RewriteRules.cs in this article for more information.

Redirect non-www to www

Three options permit the app to redirect non-`www` requests to `www`:

- AddRedirectToWwwPermanent: Permanently redirect the request to the `www` subdomain if the request is non-`www`. Redirects with a Status308PermanentRedirect status code.
- AddRedirectToWww: Redirect the request to the `www` subdomain if the incoming request is non-`www`. Redirects with a Status307TemporaryRedirect status code. An overload permits providing the status code for the response. Use a field of the StatusCodes class for a status code assignment.

URL redirect

Use AddRedirect to redirect requests. The first parameter contains the .NET regular expression (Regex) for matching on the path of the incoming URL. The second parameter is the replacement string. The third parameter, if present, specifies the status code. If the status code isn't specified, the status code defaults to 302 - Found, which indicates that the resource is temporarily moved or replaced.

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
```

```
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

In a browser with developer tools enabled, make a request to the sample app with the path `/redirect-rule/1234/5678`. The regular expression matches the request path on `redirect-rule/(.*)`, and the path is replaced with `/redirected/1234/5678`. The redirect URL is sent back to the client with a *302 - Found* status code. The browser makes a new request at the redirect URL, which appears in the browser's address bar. Since no rules in the sample app match on the redirect URL:

- The second request receives a *200 - OK* response from the app.
- The body of the response shows the redirect URL.

A round trip is made to the server when a URL is *redirected*.

> ⚠ **Warning**
>
> Be cautious when establishing redirect rules. Redirect rules are evaluated on every request to the app, including after a redirect. It's easy to accidentally create a loop of ***infinite*** redirects.

The part of the expression contained within parentheses is called a capture group. The dot (`.`) of the expression means *match any character*. The asterisk (`*`) indicates *match the preceding character zero or more times*. Therefore, the last two path segments of the URL, `1234/5678`, are captured by capture group `(.*)`. Any value provided in the request URL after `redirect-rule/` is captured by this single capture group.

In the replacement string, captured groups are injected into the string with the dollar sign (`$`) followed by the sequence number of the capture. The first capture group value is obtained with `$1`, the second with `$2`, and they continue in sequence for the capture groups in the regular expression. There's only one captured group in the redirect rule regular expression in `redirect-rule/(.*)`, so there's only one injected group in the replacement string, which is `$1`. When the rule is applied, the URL becomes `/redirected/1234/5678`.

Try `/redirect-rule/1234/5678` with the browser tools on the network tab.

URL redirect to a secure endpoint

Use AddRedirectToHttps to redirect HTTP requests to the same host and path using the HTTPS protocol. If the status code isn't supplied, the middleware defaults to *302 - Found*. If the port isn't supplied:

- The middleware defaults to `null`.
- The scheme changes to `https` (HTTPS protocol), and the client accesses the resource on port 443.

The following example shows how to set the status code to `301 - Moved Permanently` and change the port to the HTTPS port used by Kestrel on localhost. In production, the HTTPS port is set to null:

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

int? localhostHTTPSport = null;
if (app.Environment.IsDevelopment())
{
    localhostHTTPSport = Int32.Parse(Environment.GetEnvironmentVariable(
                    "ASPNETCORE_URLS")!.Split(new Char[] { ':', ';' })[2]);
}

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        // localhostHTTPport not needed for production, used only with
localhost.
        .AddRedirectToHttps(301, localhostHTTPSport)
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
}

app.UseStaticFiles();
```

```
app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

Use AddRedirectToHttpsPermanent to redirect insecure requests to the same host and path with secure HTTPS protocol on port 443. The middleware sets the status code to `301 - Moved Permanently`.

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

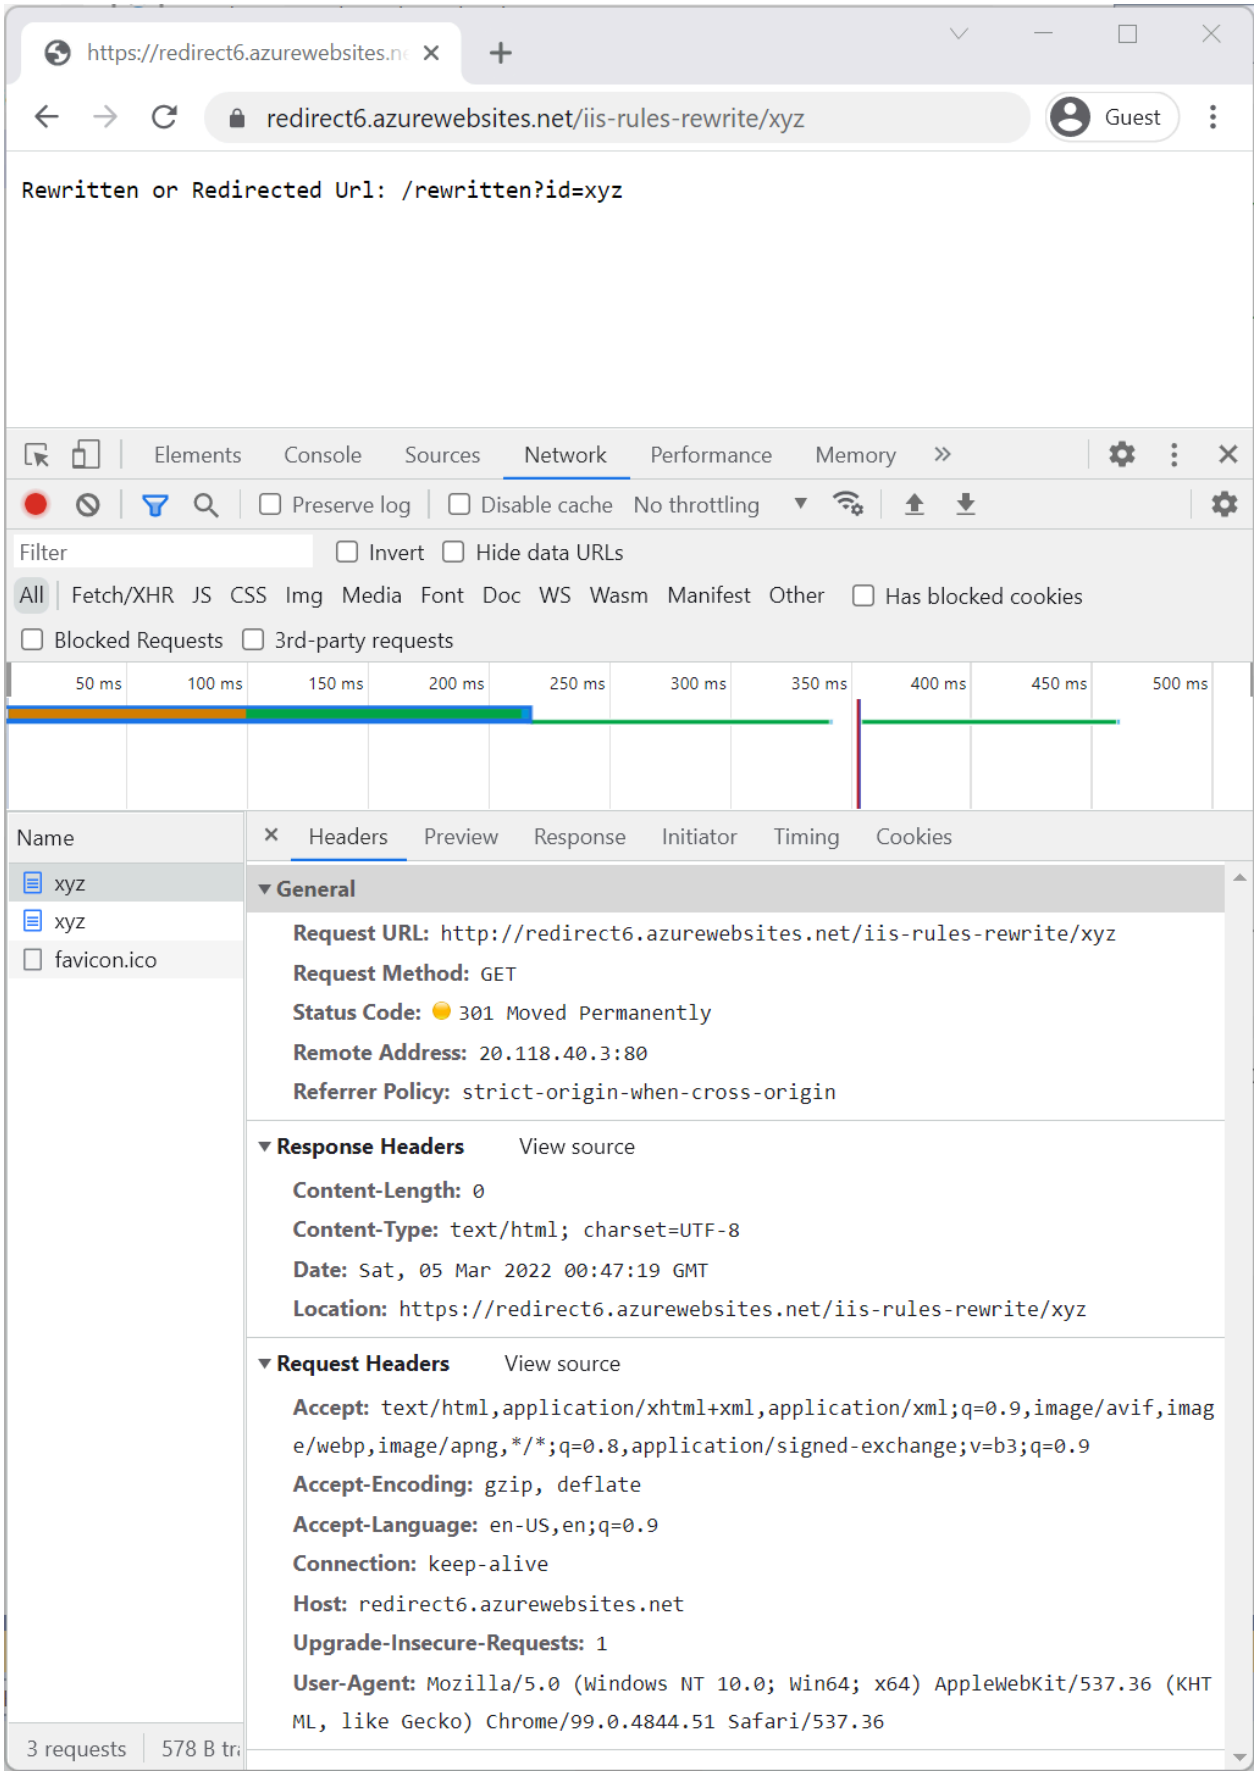
using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```



> ⓘ Note

> When redirecting to a secure endpoint without the requirement for additional redirect rules, we recommend using HTTPS Redirection Middleware. For more information, see **Enforce HTTPS**.

The sample app demonstrates how to use `AddRedirectToHttps` or `AddRedirectToHttpsPermanent`. Make an insecure HTTP request to the app at `http://redirect6.azurewebsites.net/iis-rules-rewrite/xyz`. When testing HTTP to HTTPS redirection with localhost:

- Use the HTTP URL, which has a different port than the HTTPS URL. The HTTP URL is in the `Properties/launchSettings.json` file.
- Removing the `s` from `https://localhost/{port}` fails because localhost doesn't respond on HTTP to the HTTPS port.

The following image shows the F12 browser tools image of a request to `http://redirect6.azurewebsites.net/iis-rules-rewrite/xyz` using the preceding code:

URL rewrite

Use AddRewrite to create a rule for rewriting URLs. The first parameter contains the regular expression for matching on the incoming URL path. The second parameter is the replacement string. The third parameter, `skipRemainingRules: {true|false}`, indicates to

the middleware whether or not to skip additional rewrite rules if the current rule is applied.

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

Try the request to `https://redirect6.azurewebsites.net/rewrite-rule/1234/5678`

The caret (`^`) at the beginning of the expression means that matching starts at the beginning of the URL path.

In the earlier example with the redirect rule, `redirect-rule/(.*)`, there's no caret (`^`) at the start of the regular expression. Therefore, any characters may precede `redirect-rule/` in the path for a successful match.

Expand table

Path	Match
`/redirect-rule/1234/5678`	Yes
`/my-cool-redirect-rule/1234/5678`	Yes
`/anotherredirect-rule/1234/5678`	Yes

The rewrite rule, `^rewrite-rule/(\d+)/(\d+)`, only matches paths if they start with `rewrite-rule/`. In the following table, note the difference in matching.

Expand table

Path	Match
`/rewrite-rule/1234/5678`	Yes
`/my-cool-rewrite-rule/1234/5678`	No
`/anotherrewrite-rule/1234/5678`	No

Following the `^rewrite-rule/` portion of the expression, there are two capture groups, `(\d+)/(\d+)`. The `\d` signifies *match a digit (number)*. The plus sign (`+`) means *match one or more of the preceding character*. Therefore, the URL must contain a number followed by a forward-slash followed by another number. These capture groups are injected into the rewritten URL as `$1` and `$2`. The rewrite rule replacement string places the captured groups into the query string. The requested path `/rewrite-rule/1234/5678` is rewritten to return the resource at `/rewritten?var1=1234&var2=5678`. If a query string is present on the original request, it's preserved when the URL is rewritten.

There's no round trip to the server to return the resource. If the resource exists, it's fetched and returned to the client with a *200 - OK* status code. Because the client isn't redirected, the URL in the browser's address bar doesn't change. Clients can't detect that a URL rewrite operation occurred on the server.

Performance tips for URL rewrite and redirect

For the fastest response:

- Order rewrite rules from the most frequently matched rule to the least frequently matched rule.

- Use `skipRemainingRules: true` whenever possible because matching rules is computationally expensive and increases app response time. Skip the processing of the remaining rules when a match occurs and no additional rule processing is required.

> ⚠ **Warning**
>
> A malicious user can provide expensive to process input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout. For example, the RedirectRule and RewriteRule classes both pass in a one second timeout.

Apache mod_rewrite

Apply Apache mod_rewrite rules with AddApacheModRewrite. Make sure that the rules file is deployed with the app. For more information and examples of mod_rewrite rules, see Apache mod_rewrite.

A StreamReader is used to read the rules from the *ApacheModRewrite.txt* rules file:

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
```

```
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

The sample app redirects requests from `/apache-mod-rules-redirect/(.\*)` to `/redirected?id=$1`. The response status code is *302 - Found*.

```

# Rewrite path with additional sub directory
RewriteRule ^/apache-mod-rules-redirect/(.*) /redirected?id=$1 [L,R=302]
```

Try the request to `https://redirect6.azurewebsites.net/apache-mod-rules-redirect/1234`

The Apache middleware supports the following Apache mod_rewrite server variables:

- CONN_REMOTE_ADDR
- HTTP_ACCEPT
- HTTP_CONNECTION
- HTTP_COOKIE
- HTTP_FORWARDED
- HTTP_HOST
- HTTP_REFERER
- HTTP_USER_AGENT
- HTTPS
- IPV6
- QUERY_STRING
- REMOTE_ADDR
- REMOTE_PORT
- REQUEST_FILENAME
- REQUEST_METHOD
- REQUEST_SCHEME
- REQUEST_URI
- SCRIPT_FILENAME
- SERVER_ADDR
- SERVER_PORT
- SERVER_PROTOCOL

- TIME
- TIME_DAY
- TIME_HOUR
- TIME_MIN
- TIME_MON
- TIME_SEC
- TIME_WDAY
- TIME_YEAR

IIS URL Rewrite Module rules

To use the same rule set that applies to the IIS URL Rewrite Module, use AddIISUrlRewrite. Make sure that the rules file is deployed with the app. Don't direct the middleware to use the app's *web.config* file when running on Windows Server IIS. With IIS, these rules should be stored outside of the app's *web.config* file in order to avoid conflicts with the IIS Rewrite module. For more information and examples of IIS URL Rewrite Module rules, see Using Url Rewrite Module 2.0 and URL Rewrite Module Configuration Reference.

A StreamReader is used to read the rules from the `IISUrlRewrite.xml` rules file:

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
```

```
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

The sample app rewrites requests from `/iis-rules-rewrite/(.*)` to `/rewritten?id=$1`. The response is sent to the client with a *200 - OK* status code.

XML

```
<rewrite>
  <rules>
    <rule name="Rewrite segment to id querystring" stopProcessing="true">
      <match url="^iis-rules-rewrite/(.*)$" />
      <action type="Rewrite" url="rewritten?id={R:1}"
appendQueryString="false"/>
    </rule>
  </rules>
</rewrite>
```

Try the request to `https://redirect6.azurewebsites.net/iis-rules-rewrite/xyz`

Apps that have an active IIS Rewrite Module with server-level rules configured that impacts the app in undesirable ways:

- Consider disabling the IIS Rewrite Module for the app.
- For more information, see Disabling IIS modules.

Unsupported features

The middleware doesn't support the following IIS URL Rewrite Module features:

- Outbound Rules
- Custom Server Variables
- Wildcards
- LogRewrittenUrl

Supported server variables

The middleware supports the following IIS URL Rewrite Module server variables:

- CONTENT_LENGTH
- CONTENT_TYPE
- HTTP_ACCEPT
- HTTP_CONNECTION
- HTTP_COOKIE
- HTTP_HOST
- HTTP_REFERER
- HTTP_URL
- HTTP_USER_AGENT
- HTTPS
- LOCAL_ADDR
- QUERY_STRING
- REMOTE_ADDR
- REMOTE_PORT
- REQUEST_FILENAME
- REQUEST_URI

IFileProvider can be obtained via a PhysicalFileProvider. This approach may provide greater flexibility for the location of rewrite rules files. Make sure that the rewrite rules files are deployed to the server at the path provided.

```
C#

var fileProvider = new
PhysicalFileProvider(Directory.GetCurrentDirectory());
```

Method-based rule

Use Add to implement custom rule logic in a method. `Add` exposes the RewriteContext, which makes available the HttpContext for use in redirect methods. The RewriteContext.Result property determines how additional pipeline processing is handled. Set the value to one of the RuleResult fields described in the following table.

Expand table

Rewrite context result	Action
`RuleResult.ContinueRules` (default)	Continue applying rules.
`RuleResult.EndResponse`	Stop applying rules and send the response.

Rewrite context result	Action
`RuleResult.SkipRemainingRules`	Stop applying rules and send the context to the next middleware.

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

The sample app demonstrates a method that redirects requests for paths that end with `.xml`. When a request is made for `/file.xml`:

- The request is redirected to `/xmlfiles/file.xml`
- The status code is set to `301 - Moved Permanently`. When the browser makes a new request for `/xmlfiles/file.xml`, Static File Middleware serves the file to the client from the *wwwroot/xmlfiles* folder. For a redirect, explicitly set the status code of

the response. Otherwise, a *200 - OK* status code is returned, and the redirect doesn't occur on the client.

`RewriteRules.cs`:

```
C#

public static void RedirectXmlFileRequests(RewriteContext context)
{
    var request = context.HttpContext.Request;

    // Because the client is redirecting back to the same app, stop
    // processing if the request has already been redirected.
    if (request.Path.StartsWithSegments(new PathString("/xmlfiles")) ||
        request.Path.Value==null)
    {
        return;
    }

    if (request.Path.Value.EndsWith(".xml",
StringComparison.OrdinalIgnoreCase))
    {
        var response = context.HttpContext.Response;
        response.StatusCode = (int) HttpStatusCode.MovedPermanently;
        context.Result = RuleResult.EndResponse;
        response.Headers[HeaderNames.Location] =
            "/xmlfiles" + request.Path + request.QueryString;
    }
}
```

This approach can also rewrite requests. The sample app demonstrates rewriting the path for any text file request to serve the *file.txt* text file from the *wwwroot* folder. Static File Middleware serves the file based on the updated request path:

```
C#

using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
```

```
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

`RewriteRules.cs`:

C#

```
public static void RewriteTextFileRequests(RewriteContext context)
{
    var request = context.HttpContext.Request;

    if (request.Path.Value != null &&
        request.Path.Value.EndsWith(".txt",
StringComparison.OrdinalIgnoreCase))
    {
        context.Result = RuleResult.SkipRemainingRules;
        request.Path = "/file.txt";
    }
}
```

IRule-based rule

Use Add to use rule logic in a class that implements the IRule interface. `IRule` provides greater flexibility over using the method-based rule approach. The implementation class may include a constructor that allows passing in parameters for the ApplyRule method.

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
```

```
var app = builder.Build();

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

The values of the parameters in the sample app for the `extension` and the `newPath` are checked to meet several conditions. The `extension` must contain a value, and the value must be `.png`, `.jpg`, or `.gif`. If the `newPath` isn't valid, an ArgumentException is thrown. If a request is made for `image.png`, the request is redirected to `/png-images/image.png`. If a request is made for `image.jpg`, the request is redirected to `/jpg-images/image.jpg`. The status code is set to `301 - Moved Permanently`, and the `context.Result` is set to stop processing rules and send the response.

C#

```
public class RedirectImageRequests : IRule
{
    private readonly string _extension;
    private readonly PathString _newPath;

    public RedirectImageRequests(string extension, string newPath)
    {
        if (string.IsNullOrEmpty(extension))
        {
            throw new ArgumentException(nameof(extension));
```

```
        }

        if (!Regex.IsMatch(extension, @"^\.(png|jpg|gif)$"))
        {
            throw new ArgumentException("Invalid extension",
nameof(extension));
        }

        if (!Regex.IsMatch(newPath, @"(/[A-Za-z0-9]+)+?"))
        {
            throw new ArgumentException("Invalid path", nameof(newPath));
        }

        _extension = extension;
        _newPath = new PathString(newPath);
    }

    public void ApplyRule(RewriteContext context)
    {
        var request = context.HttpContext.Request;

        // Because we're redirecting back to the same app, stop
        // processing if the request has already been redirected
        if (request.Path.StartsWithSegments(new PathString(_newPath)) ||
            request.Path.Value == null)
        {
            return;
        }

        if (request.Path.Value.EndsWith(_extension,
StringComparison.OrdinalIgnoreCase))
        {
            var response = context.HttpContext.Response;
            response.StatusCode = (int) HttpStatusCode.MovedPermanently;
            context.Result = RuleResult.EndResponse;
            response.Headers[HeaderNames.Location] =
                _newPath + request.Path + request.QueryString;
        }
    }
}
```

Try:

- PNG request: `https://redirect6.azurewebsites.net/image.png`
- JPG request: `https://redirect6.azurewebsites.net/image.jpg`

Regex examples

Expand table

Goal	Regex String & Match Example	Replacement String & Output Example
Rewrite path into querystring	`^path/(.*)/(.*)` `/path/abc/123`	`path?var1=$1&var2=$2` `/path?var1=abc&var2=123`
Strip trailing slash	`^path2/(.*)/$` `/path2/xyz/`	`$1` `/path2/xyz`
Enforce trailing slash	`^path3/(.*[^/])$` `/path3/xyz`	`$1/` `/path3/xyz/`
Avoid rewriting specific requests	`^(.*)(?<!\.axd)$` or `^(?!.*\.axd$)(.*)$` Yes: `/path4/resource.htm` No: `/path4/resource.axd`	`rewritten/$1` `/rewritten/resource.htm` `/resource.axd`
Rearrange URL segments	`path5/(.*)/(.*)/(.*)` `path5/1/2/3`	`path5/$3/$2/$1` `path5/3/2/1`
Replace a URL segment	`^path6/(.*)/segment2/(.*)` `^path6/segment1/segment2/segment3`	`path6/$1/replaced/$2` `/path6/segment1/replaced/segment3`

The links in the preceding table use the following code deployed to Azure:

C#

```
using Microsoft.AspNetCore.Rewrite;
using RewriteRules;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

using (StreamReader apacheModRewriteStreamReader =
    File.OpenText("ApacheModRewrite.txt"))
using (StreamReader iisUrlRewriteStreamReader =
    File.OpenText("IISUrlRewrite.xml"))
{
    var options = new RewriteOptions()
        .AddRedirectToHttpsPermanent()
        .AddRedirect("redirect-rule/(.*)", "redirected/$1")
        .AddRewrite(@"^rewrite-rule/(\d+)/(\d+)", "rewritten?
var1=$1&var2=$2",
            skipRemainingRules: true)
```

```
        // Rewrite path to QS.
        .AddRewrite(@"^path/(.*)/(.*)", "path?var1=$1&var2=$2",
            skipRemainingRules: true)
        // Skip trailing slash.
        .AddRewrite(@"^path2/(.*)/$", "path2/$1",
            skipRemainingRules: true)
         // Enforce trailing slash.
         .AddRewrite(@"^path3/(.*[^/])$", "path3/$1/",
            skipRemainingRules: true)
         // Avoid rewriting specific requests.
         .AddRewrite(@"^path4/(.*)(?<!\.axd)$", "rewritten/$1",
            skipRemainingRules: true)
         // Rearrange URL segments
         .AddRewrite(@"^path5/(.*)/(.*)/(.*)", "path5/$3/$2/$1",
            skipRemainingRules: true)
          // Replace a URL segment
          .AddRewrite(@"^path6/(.*)/segment2/(.*)", "path6/$1/replaced/$2",
            skipRemainingRules: true)
```

```
        .AddApacheModRewrite(apacheModRewriteStreamReader)
        .AddIISUrlRewrite(iisUrlRewriteStreamReader)
        .Add(MethodRules.RedirectXmlFileRequests)
        .Add(MethodRules.RewriteTextFileRequests)
        .Add(new RedirectImageRequests(".png", "/png-images"))
        .Add(new RedirectImageRequests(".jpg", "/jpg-images"));

    app.UseRewriter(options);
}

app.UseStaticFiles();

app.Run(context => context.Response.WriteAsync(
    $"Rewritten or Redirected Url: " +
    $"{context.Request.Path + context.Request.QueryString}"));

app.Run();
```

In most of the preceding regular expression samples, the literal `path` is used to make unique testable rewrite rules for the deployed sample. Typically the regular expression wouldn't include `path`. For example, see these regular expression examples table.

File Providers in ASP.NET Core

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Steve Smith

ASP.NET Core abstracts file system access through the use of File Providers. File Providers are used throughout the ASP.NET Core framework. For example:

- IWebHostEnvironment exposes the app's content root and web root as `IFileProvider` types.
- Static File Middleware uses File Providers to locate static files.
- Razor uses File Providers to locate pages and views.
- .NET Core tooling uses File Providers and glob patterns to specify which files should be published.

View or download sample code (how to download)

File Provider interfaces

The primary interface is IFileProvider. `IFileProvider` exposes methods to:

- Obtain file information (IFileInfo).
- Obtain directory information (IDirectoryContents).
- Set up change notifications (using an IChangeToken).

`IFileInfo` provides methods and properties for working with files:

- Exists
- IsDirectory
- Name
- Length (in bytes)
- LastModified date

You can read from the file using the IFileInfo.CreateReadStream method.

The `FileProviderSample` sample app demonstrates how to configure a File Provider in `Startup.ConfigureServices` for use throughout the app via dependency injection.

File Provider implementations

The following table lists implementations of `IFileProvider`.

Expand table

Implementation	Description
Composite File Provider	Used to provide combined access to files and directories from one or more other providers.
Manifest Embedded File Provider	Used to access files embedded in assemblies.
Physical File Provider	Used to access the system's physical files.

Physical File Provider

The PhysicalFileProvider provides access to the physical file system. `PhysicalFileProvider` uses the System.IO.File type (for the physical provider) and scopes all paths to a directory and its children. This scoping prevents access to the file system outside of the specified directory and its children. The most common scenario for creating and using a `PhysicalFileProvider` is to request an `IFileProvider` in a constructor through dependency injection.

When instantiating this provider directly, an absolute directory path is required and serves as the base path for all requests made using the provider. Glob patterns aren't supported in the directory path.

The following code shows how to use `PhysicalFileProvider` to obtain directory contents and file information:

C#

```
var provider = new PhysicalFileProvider(applicationRoot);
var contents = provider.GetDirectoryContents(string.Empty);
var filePath = Path.Combine("wwwroot", "js", "site.js");
var fileInfo = provider.GetFileInfo(filePath);
```

Types in the preceding example:

- `provider` is an `IFileProvider`.
- `contents` is an `IDirectoryContents`.
- `fileInfo` is an `IFileInfo`.

The File Provider can be used to iterate through the directory specified by `applicationRoot` or call `GetFileInfo` to obtain a file's information. Glob patterns can't be passed to the `GetFileInfo` method. The File Provider has no access outside of the `applicationRoot` directory.

The `FileProviderSample` sample app creates the provider in the `Startup.ConfigureServices` method using IHostEnvironment.ContentRootFileProvider:

C#

```
var physicalProvider = _env.ContentRootFileProvider;
```

Manifest Embedded File Provider

The ManifestEmbeddedFileProvider is used to access files embedded within assemblies. The `ManifestEmbeddedFileProvider` uses a manifest compiled into the assembly to reconstruct the original paths of the embedded files.

To generate a manifest of the embedded files:

1. Add the Microsoft.Extensions.FileProviders.Embedded NuGet package to your project.
2. Set the `<GenerateEmbeddedFilesManifest>` property to `true`. Specify the files to embed with <EmbeddedResource>:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.1</TargetFramework>
    <GenerateEmbeddedFilesManifest>true</GenerateEmbeddedFilesManifest>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference
Include="Microsoft.Extensions.FileProviders.Embedded" Version="3.1.0"
/>
```

```
  </ItemGroup>

  <ItemGroup>
    <EmbeddedResource Include="Resource.txt" />
  </ItemGroup>

</Project>
```

Use glob patterns to specify one or more files to embed into the assembly.

The `FileProviderSample` sample app creates an `ManifestEmbeddedFileProvider` and passes the currently executing assembly to its constructor.

`Startup.cs`:

```
C#

var manifestEmbeddedProvider =
    new ManifestEmbeddedFileProvider(typeof(Program).Assembly);
```

Additional overloads allow you to:

- Specify a relative file path.
- Scope files to a last modified date.
- Name the embedded resource containing the embedded file manifest.

Expand table

Overload	Description
`ManifestEmbeddedFileProvider(Assembly, String)`	Accepts an optional `root` relative path parameter. Specify the `root` to scope calls to GetDirectoryContents to those resources under the provided path.
`ManifestEmbeddedFileProvider(Assembly, String, DateTimeOffset)`	Accepts an optional `root` relative path parameter and a `lastModified` date (DateTimeOffset) parameter. The `lastModified` date scopes the last modification date for the IFileInfo instances returned by the IFileProvider.
`ManifestEmbeddedFileProvider(Assembly, String, String, DateTimeOffset)`	Accepts an optional `root` relative path, `lastModified` date, and `manifestName` parameters. The `manifestName` represents the name of the embedded resource containing the manifest.

Composite File Provider

The CompositeFileProvider combines `IFileProvider` instances, exposing a single interface for working with files from multiple providers. When creating the `CompositeFileProvider`, pass one or more `IFileProvider` instances to its constructor.

In the `FileProviderSample` sample app, a `PhysicalFileProvider` and a `ManifestEmbeddedFileProvider` provide files to a `CompositeFileProvider` registered in the app's service container. The following code is found in the project's `Startup.ConfigureServices` method:

```
C#

var physicalProvider = _env.ContentRootFileProvider;
var manifestEmbeddedProvider =
    new ManifestEmbeddedFileProvider(typeof(Program).Assembly);
var compositeProvider =
    new CompositeFileProvider(physicalProvider, manifestEmbeddedProvider);

services.AddSingleton<IFileProvider>(compositeProvider);
```

Watch for changes

The IFileProvider.Watch method provides a scenario to watch one or more files or directories for changes. The `Watch` method:

- Accepts a file path string, which can use glob patterns to specify multiple files.
- Returns an IChangeToken.

The resulting change token exposes:

- HasChanged: A property that can be inspected to determine if a change has occurred.
- RegisterChangeCallback: Called when changes are detected to the specified path string. Each change token only calls its associated callback in response to a single change. To enable constant monitoring, use a TaskCompletionSource<TResult> (shown below) or recreate `IChangeToken` instances in response to changes.

The `WatchConsole` sample app writes a message whenever a `.txt` file in the `TextFiles` directory is modified:

```
C#
```

```
private static readonly string _fileFilter = Path.Combine("TextFiles",
"*.txt");

public static void Main(string[] args)
{
    Console.WriteLine($"Monitoring for changes with filter '{_fileFilter}'
(Ctrl + C to quit)...");

    while (true)
    {
        MainAsync().GetAwaiter().GetResult();
    }
}

private static async Task MainAsync()
{
    var fileProvider = new
PhysicalFileProvider(Directory.GetCurrentDirectory());
    IChangeToken token = fileProvider.Watch(_fileFilter);
    var tcs = new TaskCompletionSource<object>();

    token.RegisterChangeCallback(state =>
        ((TaskCompletionSource<object>)state).TrySetResult(null), tcs);

    await tcs.Task.ConfigureAwait(false);

    Console.WriteLine("file changed");
}
```

Some file systems, such as Docker containers and network shares, may not reliably send change notifications. Set the `DOTNET_USE_POLLING_FILE_WATCHER` environment variable to `1` or `true` to poll the file system for changes every four seconds (not configurable).

Glob patterns

File system paths use wildcard patterns called *glob (or globbing) patterns*. Specify groups of files with these patterns. The two wildcard characters are `*` and `**`:

`*`

Matches anything at the current folder level, any filename, or any file extension. Matches are terminated by `/` and `.` characters in the file path.

`**`

Matches anything across multiple directory levels. Can be used to recursively match many files within a directory hierarchy.

The following table provides common examples of glob patterns.

Expand table

Pattern	Description
`directory/file.txt`	Matches a specific file in a specific directory.
`directory/*.txt`	Matches all files with `.txt` extension in a specific directory.
`directory/*/appsettings.json`	Matches all `appsettings.json` files in directories exactly one level below the `directory` folder.
`directory/**/*.txt`	Matches all files with a `.txt` extension found anywhere under the `directory` folder.

Request Features in ASP.NET Core

Article • 09/17/2024

By Steve Smith

The `HttpContext` API that applications and middleware use to process requests has an abstraction layer underneath it called *feature interfaces*. Each feature interface provides a granular subset of the functionality exposed by `HttpContext`. These interfaces can be added, modified, wrapped, replaced, or even removed by the server or middleware as the request is processed without having to re-implement the entire `HttpContext`. They can also be used to mock functionality when testing.

Feature collections

The Features property of `HttpContext` provides access to the collection of feature interfaces for the current request. Since the feature collection is mutable even within the context of a request, middleware can be used to modify the collection and add support for additional features. Some advanced features are only available by accessing the associated interface through the feature collection.

Feature interfaces

ASP.NET Core defines a number of common HTTP feature interfaces in Microsoft.AspNetCore.Http.Features, which are shared by various servers and middleware to identify the features that they support. Servers and middleware may also provide their own interfaces with additional functionality.

Most feature interfaces provide optional, light-up functionality, and their associated `HttpContext` APIs provide defaults if the feature isn't present. A few interfaces are indicated in the following content as required because they provide core request and response functionality and must be implemented in order to process the request.

The following feature interfaces are from Microsoft.AspNetCore.Http.Features:

IHttpRequestFeature: Defines the structure of an HTTP request, including the protocol, path, query string, headers, and body. This feature is required in order to process requests.

IHttpResponseFeature: Defines the structure of an HTTP response, including the status code, headers, and body of the response. This feature is required in order to process

requests.

IHttpResponseBodyFeature: Defines different ways of writing out the response body, using either a `Stream`, a `PipeWriter`, or a file. This feature is required in order to process requests. This replaces `IHttpResponseFeature.Body` and `IHttpSendFileFeature`.

IHttpAuthenticationFeature: Holds the ClaimsPrincipal currently associated with the request.

IFormFeature: Used to parse and cache incoming HTTP and multipart form submissions.

IHttpBodyControlFeature: Used to control if synchronous IO operations are allowed for the request or response bodies.

`IHttpActivityFeature`: Used to add `Activity` information for diagnostic listeners.

IHttpConnectionFeature: Defines properties for the connection id and local and remote addresses and ports.

IHttpMaxRequestBodySizeFeature: Controls the maximum allowed request body size for the current request.

`IHttpRequestBodyDetectionFeature`: Indicates if the request can have a body.

IHttpRequestIdentifierFeature: Adds a property that can be implemented to uniquely identify requests.

IHttpRequestLifetimeFeature: Defines support for aborting connections or detecting if a request has been terminated prematurely, such as by a client disconnect.

IHttpRequestTrailersFeature: Provides access to the request trailer headers, if any.

IHttpResetFeature: Used to send reset messages for protocols that support them such as HTTP/2 or HTTP/3.

IHttpResponseTrailersFeature: Enables the application to provide response trailer headers if supported.

IHttpUpgradeFeature: Defines support for HTTP Upgrades, which allow the client to specify which additional protocols it would like to use if the server wishes to switch protocols.

IHttpWebSocketFeature: Defines an API for supporting WebSockets.

IHttpsCompressionFeature: Controls if response compression should be used over HTTPS connections.

IItemsFeature: Stores the Items collection for per request application state.

IQueryFeature: Parses and caches the query string.

IRequestBodyPipeFeature: Represents the request body as a PipeReader.

IRequestCookiesFeature: Parses and caches the request `Cookie` header values.

IResponseCookiesFeature: Controls how response cookies are applied to the `Set-Cookie` header.

IServerVariablesFeature: This feature provides access to request server variables such as those provided by IIS.

IServiceProvidersFeature: Provides access to an IServiceProvider with scoped request services.

ISessionFeature: Defines `ISessionFactory` and ISession abstractions for supporting user sessions. `ISessionFeature` is implemented by the SessionMiddleware (see Session in ASP.NET Core).

ITlsConnectionFeature: Defines an API for retrieving client certificates.

ITlsTokenBindingFeature: Defines methods for working with TLS token binding parameters.

ITrackingConsentFeature: Used to query, grant, and withdraw user consent regarding the storage of user information related to site activity and functionality.

Access `HttpContext` in ASP.NET Core

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

HttpContext encapsulates all information about an individual HTTP request and response. An `HttpContext` instance is initialized when an HTTP request is received. The `HttpContext` instance is accessible by middleware and app frameworks such as Web API controllers, Razor Pages, SignalR, gRPC, and more.

For information about using `HttpContext` with a HTTP request and response, see Use HttpContext in ASP.NET Core.

Access `HttpContext` from Razor Pages

The Razor Pages PageModel exposes the PageModel.HttpContext property:

C#

```
public class IndexModel : PageModel
{
    public void OnGet()
    {
        var message = HttpContext.Request.PathBase;

        // ...
    }
}
```

The same property can be used in the corresponding Razor Page View:

CSHTML

```
@page
@model IndexModel

@{
```

```
    var message = HttpContext.Request.PathBase;

    // ...
}
```

Access `HttpContext` from a Razor view in MVC

Razor views in the MVC pattern expose the `HttpContext` via the RazorPage.Context property on the view. The following example retrieves the current username in an intranet app using Windows Authentication:

CSHTML

```
@{
    var username = Context.User.Identity.Name;

    // ...
}
```

Access `HttpContext` from a controller

Controllers expose the ControllerBase.HttpContext property:

C#

```
public class HomeController : Controller
{
    public IActionResult About()
    {
        var pathBase = HttpContext.Request.PathBase;

        // ...

        return View();
    }
}
```

Access `HttpContext` from minimal APIs

To use `HttpContext` from minimal APIs, add a `HttpContext` parameter:

C#

```
app.MapGet("/", (HttpContext context) => context.Response.WriteAsync("Hello
World"));
```

Access `HttpContext` from middleware

To use `HttpContext` from custom middleware components, use the `HttpContext` parameter passed into the `Invoke` or `InvokeAsync` method:

C#

```
public class MyCustomMiddleware
{
    // ...

    public async Task InvokeAsync(HttpContext context)
    {
        // ...
    }
}
```

Access `HttpContext` from SignalR

To use `HttpContext` from SignalR, call the GetHttpContext method on Hub.Context:

C#

```
public class MyHub : Hub
{
    public async Task SendMessage()
    {
        var httpContext = Context.GetHttpContext();

        // ...
    }
}
```

Access `HttpContext` from gRPC methods

To use `HttpContext` from gRPC methods, see Resolve HttpContext in gRPC methods.

Access `HttpContext` from custom components

For other framework and custom components that require access to `HttpContext`, the recommended approach is to register a dependency using the built-in Dependency Injection (DI) container. The DI container supplies the `IHttpContextAccessor` to any classes that declare it as a dependency in their constructors:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();
builder.Services.AddHttpContextAccessor();
builder.Services.AddTransient<IUserRepository, UserRepository>();
```

In the following example:

- `UserRepository` declares its dependency on `IHttpContextAccessor`.
- The dependency is supplied when DI resolves the dependency chain and creates an instance of `UserRepository`.

C#

```
public class UserRepository : IUserRepository
{
    private readonly IHttpContextAccessor _httpContextAccessor;

    public UserRepository(IHttpContextAccessor httpContextAccessor) =>
        _httpContextAccessor = httpContextAccessor;

    public void LogCurrentUser()
    {
        var username = _httpContextAccessor.HttpContext.User.Identity.Name;

        // ...
    }
}
```

`HttpContext` access from a background thread

`HttpContext` isn't thread-safe. Reading or writing properties of the `HttpContext` outside of processing a request can result in a NullReferenceException.

> ⓘ Note
>
> If your app generates sporadic `NullReferenceException` errors, review parts of the code that start background processing or that continue processing after a request

completes. Look for mistakes, such as defining a controller method as `async void`.

To safely do background work with `HttpContext` data:

- Copy the required data during request processing.
- Pass the copied data to a background task.
- Do ***not*** reference `HttpContext` data in parallel tasks. Extract the data needed from the context before starting the parallel tasks.

To avoid unsafe code, never pass `HttpContext` into a method that does background work. Pass the required data instead. In the following example, `SendEmail` calls `SendEmailCoreAsync` to start sending an email. The value of the `X-Correlation-Id` header is passed to `SendEmailCoreAsync` instead of the `HttpContext`. Code execution doesn't wait for `SendEmailCoreAsync` to complete:

C#

```
public class EmailController : Controller
{
    public IActionResult SendEmail(string email)
    {
        var correlationId = HttpContext.Request.Headers["X-Correlation-
Id"].ToString();

        _ = SendEmailCoreAsync(correlationId);

        return View();
    }

    private async Task SendEmailCoreAsync(string correlationId)
    {
        // ...
    }
}
```

`IHttpContextAccessor` / `HttpContext` in Razor components (Blazor)

IHttpContextAccessor must be avoided with interactive rendering because there isn't a valid `HttpContext` available.

IHttpContextAccessor can be used for components that are statically rendered on the server. **However, we recommend avoiding it if possible.**

HttpContext can be used as a cascading parameter only in *statically-rendered root components* for general tasks, such as inspecting and modifying headers or other properties in the `App` component (`Components/App.razor`). The value is always `null` for interactive rendering.

C#

```
[CascadingParameter]
public HttpContext? HttpContext { get; set; }
```

For scenarios where the HttpContext is required in interactive components, we recommend flowing the data via persistent component state from the server. For more information, see Server-side ASP.NET Core Blazor additional security scenarios.

Detect changes with change tokens in ASP.NET Core

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

A *change token* is a general-purpose, low-level building block used to track state changes.

View or download sample code (how to download)

IChangeToken interface

IChangeToken propagates notifications that a change has occurred. `IChangeToken` resides in the Microsoft.Extensions.Primitives namespace. The Microsoft.Extensions.Primitives NuGet package is implicitly provided to the ASP.NET Core apps.

`IChangeToken` has two properties:

- ActiveChangeCallbacks indicate if the token proactively raises callbacks. If `ActiveChangedCallbacks` is set to `false`, a callback is never called, and the app must poll `HasChanged` for changes. It's also possible for a token to never be cancelled if no changes occur or the underlying change listener is disposed or disabled.
- HasChanged receives a value that indicates if a change has occurred.

The `IChangeToken` interface includes the RegisterChangeCallback(Action<Object>, Object) method, which registers a callback that's invoked when the token has changed. `HasChanged` must be set before the callback is invoked.

ChangeToken class

ChangeToken is a static class used to propagate notifications that a change has occurred. `ChangeToken` resides in the Microsoft.Extensions.Primitives namespace. The Microsoft.Extensions.Primitives NuGet package is implicitly provided to the ASP.NET Core apps.

The ChangeToken.OnChange(Func<IChangeToken>, Action) method registers an `Action` to call whenever the token changes:

- `Func<IChangeToken>` produces the token.
- `Action` is called when the token changes.

The ChangeToken.OnChange<TState>(Func<IChangeToken>, Action<TState>, TState) overload takes an additional `TState` parameter that's passed into the token consumer `Action`.

`OnChange` returns an IDisposable. Calling Dispose stops the token from listening for further changes and releases the token's resources.

Example uses of change tokens in ASP.NET Core

Change tokens are used in prominent areas of ASP.NET Core to monitor for changes to objects:

- For monitoring changes to files, IFileProvider's Watch method creates an `IChangeToken` for the specified files or folder to watch.
- `IChangeToken` tokens can be added to cache entries to trigger cache evictions on change.
- For `TOptions` changes, the default OptionsMonitor<TOptions> implementation of IOptionsMonitor<TOptions> has an overload that accepts one or more IOptionsChangeTokenSource<TOptions> instances. Each instance returns an `IChangeToken` to register a change notification callback for tracking options changes.

Monitor for configuration changes

By default, ASP.NET Core templates use JSON configuration files (`appsettings.json`, `appsettings.Development.json`, and `appsettings.Production.json`) to load app configuration settings.

These files are configured using the AddJsonFile(IConfigurationBuilder, String, Boolean, Boolean) extension method on ConfigurationBuilder that accepts a `reloadOnChange`

parameter. `reloadOnChange` indicates if configuration should be reloaded on file changes. This setting appears in the Host convenience method CreateDefaultBuilder:

```
C#

config.AddJsonFile("appsettings.json", optional: true, reloadOnChange: true)
      .AddJsonFile($"appsettings.{env.EnvironmentName}.json", optional:
true,
          reloadOnChange: true);
```

File-based configuration is represented by FileConfigurationSource. `FileConfigurationSource` uses IFileProvider to monitor files.

By default, the `IFileMonitor` is provided by a PhysicalFileProvider, which uses FileSystemWatcher to monitor for configuration file changes.

The sample app demonstrates two implementations for monitoring configuration changes. If any of the `appsettings` files change, both of the file monitoring implementations execute custom code—the sample app writes a message to the console.

A configuration file's `FileSystemWatcher` can trigger multiple token callbacks for a single configuration file change. To ensure that the custom code is only run once when multiple token callbacks are triggered, the sample's implementation checks file hashes. The sample uses SHA1 file hashing. A retry is implemented with an exponential back-off.

`Utilities/Utilities.cs`:

```
C#

public static byte[] ComputeHash(string filePath)
{
    var runCount = 1;

    while(runCount < 4)
    {
        try
        {
            if (File.Exists(filePath))
            {
                using (var fs = File.OpenRead(filePath))
                {
                    return System.Security.Cryptography.SHA1
                        .Create().ComputeHash(fs);
                }
            }
            else
            {
```

```
                throw new FileNotFoundException();
            }
        }
        catch (IOException ex)
        {
            if (runCount == 3)
            {
                throw;
            }

            Thread.Sleep(TimeSpan.FromSeconds(Math.Pow(2, runCount)));
            runCount++;
        }
    }

    return new byte[20];
}
```

Simple startup change token

Register a token consumer `Action` callback for change notifications to the configuration reload token.

In `Startup.Configure`:

C#

```
ChangeToken.OnChange(
    () => config.GetReloadToken(),
    (state) => InvokeChanged(state),
    env);
```

`config.GetReloadToken()` provides the token. The callback is the `InvokeChanged` method:

C#

```
private void InvokeChanged(IWebHostEnvironment env)
{
    byte[] appsettingsHash = ComputeHash("appSettings.json");
    byte[] appsettingsEnvHash =
        ComputeHash($"appSettings.{env.EnvironmentName}.json");

    if (!_appsettingsHash.SequenceEqual(appsettingsHash) ||
        !_appsettingsEnvHash.SequenceEqual(appsettingsEnvHash))
    {
        _appsettingsHash = appsettingsHash;
        _appsettingsEnvHash = appsettingsEnvHash;

        WriteConsole("Configuration changed (Simple Startup Change Token)");
```

```
    }
}
```

The `state` of the callback is used to pass in the `IWebHostEnvironment`, which is useful for specifying the correct `appsettings` configuration file to monitor (for example, `appsettings.Development.json` when in the Development environment). File hashes are used to prevent the `WriteConsole` statement from running multiple times due to multiple token callbacks when the configuration file has only changed once.

This system runs as long as the app is running and can't be disabled by the user.

Monitor configuration changes as a service

The sample implements:

- Basic startup token monitoring.
- Monitoring as a service.
- A mechanism to enable and disable monitoring.

The sample establishes an `IConfigurationMonitor` interface.

`Extensions/ConfigurationMonitor.cs`:

C#

```
public interface IConfigurationMonitor
{
    bool MonitoringEnabled { get; set; }
    string CurrentState { get; set; }
}
```

The constructor of the implemented class, `ConfigurationMonitor`, registers a callback for change notifications:

C#

```
public ConfigurationMonitor(IConfiguration config, IWebHostEnvironment env)
{
    _env = env;

    ChangeToken.OnChange<IConfigurationMonitor>(
        () => config.GetReloadToken(),
        InvokeChanged,
        this);
}
```

```
public bool MonitoringEnabled { get; set; } = false;
public string CurrentState { get; set; } = "Not monitoring";
```

`config.GetReloadToken()` supplies the token. `InvokeChanged` is the callback method. The `state` in this instance is a reference to the `IConfigurationMonitor` instance that's used to access the monitoring state. Two properties are used:

- `MonitoringEnabled`: Indicates if the callback should run its custom code.
- `CurrentState`: Describes the current monitoring state for use in the UI.

The `InvokeChanged` method is similar to the earlier approach, except that it:

- Doesn't run its code unless `MonitoringEnabled` is `true`.
- Outputs the current `state` in its `WriteConsole` output.

C#

```
private void InvokeChanged(IConfigurationMonitor state)
{
    if (MonitoringEnabled)
    {
        byte[] appsettingsHash = ComputeHash("appSettings.json");
        byte[] appsettingsEnvHash =
            ComputeHash($"appSettings.{_env.EnvironmentName}.json");

        if (!_appsettingsHash.SequenceEqual(appsettingsHash) ||
            !_appsettingsEnvHash.SequenceEqual(appsettingsEnvHash))
        {
            string message = $"State updated at {DateTime.Now}";

            _appsettingsHash = appsettingsHash;
            _appsettingsEnvHash = appsettingsEnvHash;

            WriteConsole("Configuration changed (ConfigurationMonitor Class)
" +
                $"{message}, state:{state.CurrentState}");
        }
    }
}
```

An instance `ConfigurationMonitor` is registered as a service in `Startup.ConfigureServices`:

C#

```
services.AddSingleton<IConfigurationMonitor, ConfigurationMonitor>();
```

The Index page offers the user control over configuration monitoring. The instance of `IConfigurationMonitor` is injected into the `IndexModel`.

`Pages/Index.cshtml.cs`:

C#

```
public IndexModel(
    IConfiguration config,
    IConfigurationMonitor monitor,
    FileService fileService)
{
    _config = config;
    _monitor = monitor;
    _fileService = fileService;
}
```

The configuration monitor (`_monitor`) is used to enable or disable monitoring and set the current state for UI feedback:

C#

```
public IActionResult OnPostStartMonitoring()
{
    _monitor.MonitoringEnabled = true;
    _monitor.CurrentState = "Monitoring!";

    return RedirectToPage();
}

public IActionResult OnPostStopMonitoring()
{
    _monitor.MonitoringEnabled = false;
    _monitor.CurrentState = "Not monitoring";

    return RedirectToPage();
}
```

When `OnPostStartMonitoring` is triggered, monitoring is enabled, and the current state is cleared. When `OnPostStopMonitoring` is triggered, monitoring is disabled, and the state is set to reflect that monitoring isn't occurring.

Buttons in the UI enable and disable monitoring.

`Pages/Index.cshtml`:

CSHTML

```
<button class="btn btn-success" asp-page-handler="StartMonitoring">
    Start Monitoring
</button>

<button class="btn btn-danger" asp-page-handler="StopMonitoring">

</button>
```

Monitor cached file changes

File content can be cached in-memory using IMemoryCache. In-memory caching is described in the Cache in-memory topic. Without taking additional steps, such as the implementation described below, *stale* (outdated) data is returned from a cache if the source data changes.

For example, not taking into account the status of a cached source file when renewing a sliding expiration period leads to stale cached file data. Each request for the data renews the sliding expiration period, but the file is never reloaded into the cache. Any app features that use the file's cached content are subject to possibly receiving stale content.

Using change tokens in a file caching scenario prevents the presence of stale file content in the cache. The sample app demonstrates an implementation of the approach.

The sample uses `GetFileContent` to:

- Return file content.
- Implement a retry algorithm with exponential back-off to cover cases where a file access problem temporarily delays reading the file's content.

`Utilities/Utilities.cs`:

C#

```
public async static Task<string> GetFileContent(string filePath)
{
    var runCount = 1;

    while(runCount < 4)
    {
        try
        {
            if (File.Exists(filePath))
            {
                using (var fileStreamReader = File.OpenText(filePath))
                {
                    return await fileStreamReader.ReadToEndAsync();
```

```
                }
            }
            else
            {
                throw new FileNotFoundException();
            }
        }
        catch (IOException ex)
        {
            if (runCount == 3)
            {
                throw;
            }

            Thread.Sleep(TimeSpan.FromSeconds(Math.Pow(2, runCount)));
            runCount++;
        }
    }

    return null;
}
```

A `FileService` is created to handle cached file lookups. The `GetFileContent` method call of the service attempts to obtain file content from the in-memory cache and return it to the caller (`Services/FileService.cs`).

If cached content isn't found using the cache key, the following actions are taken:

1. The file content is obtained using `GetFileContent`.
2. A change token is obtained from the file provider with IFileProviders.Watch. The token's callback is triggered when the file is modified.
3. The file content is cached with a sliding expiration period. The change token is attached with MemoryCacheEntryExtensions.AddExpirationToken to evict the cache entry if the file changes while it's cached.

In the following example, files are stored in the app's content root. `IWebHostEnvironment.ContentRootFileProvider` is used to obtain an IFileProvider pointing at the app's `IWebHostEnvironment.ContentRootPath`. The `filePath` is obtained with IFileInfo.PhysicalPath.

C#

```
public class FileService
{
    private readonly IMemoryCache _cache;
    private readonly IFileProvider _fileProvider;
    private List<string> _tokens = new List<string>();

    public FileService(IMemoryCache cache, IWebHostEnvironment env)
```

```
    {
        _cache = cache;
        _fileProvider = env.ContentRootFileProvider;
    }

    public async Task<string> GetFileContents(string fileName)
    {
        var filePath = _fileProvider.GetFileInfo(fileName).PhysicalPath;
        string fileContent;

        // Try to obtain the file contents from the cache.
        if (_cache.TryGetValue(filePath, out fileContent))
        {
            return fileContent;
        }

        // The cache doesn't have the entry, so obtain the file
        // contents from the file itself.
        fileContent = await GetFileContent(filePath);

        if (fileContent != null)
        {
            // Obtain a change token from the file provider whose
            // callback is triggered when the file is modified.
            var changeToken = _fileProvider.Watch(fileName);

            // Configure the cache entry options for a five minute
            // sliding expiration and use the change token to
            // expire the file in the cache if the file is
            // modified.
            var cacheEntryOptions = new MemoryCacheEntryOptions()
                .SetSlidingExpiration(TimeSpan.FromMinutes(5))
                .AddExpirationToken(changeToken);

            // Put the file contents into the cache.
            _cache.Set(filePath, fileContent, cacheEntryOptions);

            return fileContent;
        }

        return string.Empty;
    }
}
```

The `FileService` is registered in the service container along with the memory caching service.

In `Startup.ConfigureServices`:

```
C#
```

```
services.AddMemoryCache();
services.AddSingleton<FileService>();
```

The page model loads the file's content using the service.

In the Index page's `OnGet` method (`Pages/Index.cshtml.cs`):

C#

```
var fileContent = await _fileService.GetFileContents("poem.txt");
```

CompositeChangeToken class

For representing one or more `IChangeToken` instances in a single object, use the CompositeChangeToken class.

C#

```
var firstCancellationTokenSource = new CancellationTokenSource();
var secondCancellationTokenSource = new CancellationTokenSource();

var firstCancellationToken = firstCancellationTokenSource.Token;
var secondCancellationToken = secondCancellationTokenSource.Token;

var firstCancellationChangeToken = new
CancellationChangeToken(firstCancellationToken);
var secondCancellationChangeToken = new
CancellationChangeToken(secondCancellationToken);

var compositeChangeToken =
    new CompositeChangeToken(
        new List<IChangeToken>
        {
            firstCancellationChangeToken,
            secondCancellationChangeToken
        });
```

`HasChanged` on the composite token reports `true` if any represented token `HasChanged` is `true`. `ActiveChangeCallbacks` on the composite token reports `true` if any represented token `ActiveChangeCallbacks` is `true`. If multiple concurrent change events occur, the composite change callback is invoked one time.

Open Web Interface for .NET (OWIN) with ASP.NET Core

Article • 09/17/2024

By Steve Smith and Rick Anderson

ASP.NET Core:

- Supports the Open Web Interface for .NET (OWIN).
- Has .NET Core compatible replacements for the `Microsoft.Owin.*` (Katana) libraries.

OWIN allows web apps to be decoupled from web servers. It defines a standard way for middleware to be used in a pipeline to handle requests and associated responses. ASP.NET Core applications and middleware can interoperate with OWIN-based applications, servers, and middleware.

OWIN provides a decoupling layer that allows two frameworks with disparate object models to be used together. The `Microsoft.AspNetCore.Owin` package provides two adapter implementations:

- ASP.NET Core to OWIN
- OWIN to ASP.NET Core

This allows ASP.NET Core to be hosted on top of an OWIN compatible server/host or for other OWIN compatible components to be run on top of ASP.NET Core.

> **Note**
>
> Using these adapters comes with a performance cost. Apps using only ASP.NET Core components shouldn't use the `Microsoft.AspNetCore.Owin` package or adapters.

View or download sample code (how to download)

Running OWIN middleware in the ASP.NET Core pipeline

ASP.NET Core's OWIN support is deployed as part of the `Microsoft.AspNetCore.Owin` package. You can import OWIN support into your project by installing this package.

OWIN middleware conforms to the OWIN specification, which requires a `Func<IDictionary<string, object>, Task>` interface, and specific keys be set (such as `owin.ResponseBody`). The following simple OWIN middleware displays "Hello World":

C#

```
public Task OwinHello(IDictionary<string, object> environment)
{
    string responseText = "Hello World via OWIN";
    byte[] responseBytes = Encoding.UTF8.GetBytes(responseText);

    // OWIN Environment Keys: https://owin.org/spec/spec/owin-1.0.0.html
    var responseStream = (Stream)environment["owin.ResponseBody"];
    var responseHeaders = (IDictionary<string,
string[]>)environment["owin.ResponseHeaders"];

    responseHeaders["Content-Length"] = new string[] {
responseBytes.Length.ToString(CultureInfo.InvariantCulture) };
    responseHeaders["Content-Type"] = new string[] { "text/plain" };

    return responseStream.WriteAsync(responseBytes, 0,
responseBytes.Length);
}
```

The sample signature returns a `Task` and accepts an `IDictionary<string, object>` as required by OWIN.

The following code shows how to add the `OwinHello` middleware (shown above) to the ASP.NET Core pipeline with the `UseOwin` extension method.

C#

```
public void Configure(IApplicationBuilder app)
{
    app.UseOwin(pipeline =>
    {
        pipeline(next => OwinHello);
    });
}
```

You can configure other actions to take place within the OWIN pipeline.

> **Note**
>
> Response headers should only be modified prior to the first write to the response stream.

> **Note**
>
> Multiple calls to `UseOwin` is discouraged for performance reasons. OWIN components will operate best if grouped together.

C#

```
app.UseOwin(pipeline =>
{
    pipeline(next =>
    {
        return async environment =>
        {
            // Do something before.
            await next(environment);
            // Do something after.
        };
    });
});
```

Run ASP.NET Core on an OWIN-based server and use its WebSockets support

Another example of how OWIN-based servers' features can be leveraged by ASP.NET Core is access to features like WebSockets. The .NET OWIN web server used in the previous example has support for WebSockets built in, which can be leveraged by an ASP.NET Core application. The example below shows a simple web app that supports WebSockets and echoes back everything sent to the server through WebSockets.

C#

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.Use(async (context, next) =>
        {
            if (context.WebSockets.IsWebSocketRequest)
            {
                WebSocket webSocket = await
context.WebSockets.AcceptWebSocketAsync();
                await EchoWebSocket(webSocket);
            }
            else
            {
                await next();
```

```
            }
        });

        app.Run(context =>
        {
            return context.Response.WriteAsync("Hello World");
        });
    }

    private async Task EchoWebSocket(WebSocket webSocket)
    {
        byte[] buffer = new byte[1024];
        WebSocketReceiveResult received = await webSocket.ReceiveAsync(
            new ArraySegment<byte>(buffer), CancellationToken.None);

        while (!webSocket.CloseStatus.HasValue)
        {
            // Echo anything we receive
            await webSocket.SendAsync(new ArraySegment<byte>(buffer, 0,
received.Count),
                received.MessageType, received.EndOfMessage,
CancellationToken.None);

            received = await webSocket.ReceiveAsync(new ArraySegment<byte>
(buffer),
                CancellationToken.None);
        }

        await webSocket.CloseAsync(webSocket.CloseStatus.Value,
            webSocket.CloseStatusDescription, CancellationToken.None);
    }
}
```

OWIN environment

You can construct an OWIN environment using the `HttpContext`.

C#

```
var environment = new OwinEnvironment(HttpContext);
var features = new OwinFeatureCollection(environment);
```

OWIN keys

OWIN depends on an `IDictionary<string,object>` object to communicate information throughout an HTTP Request/Response exchange. ASP.NET Core implements the keys

listed below. See the primary specification, extensions, and OWIN Key Guidelines and Common Keys.

Request data (OWIN v1.0.0)

Expand table

Key	Value (type)	Description
owin.RequestScheme	`String`	
owin.RequestMethod	`String`	
owin.RequestPathBase	`String`	
owin.RequestPath	`String`	
owin.RequestQueryString	`String`	
owin.RequestProtocol	`String`	
owin.RequestHeaders	`IDictionary<string,string[]>`	
owin.RequestBody	`Stream`	

Request data (OWIN v1.1.0)

Expand table

Key	Value (type)	Description
owin.RequestId	`String`	Optional

Response data (OWIN v1.0.0)

Expand table

Key	Value (type)	Description
owin.ResponseStatusCode	`int`	Optional
owin.ResponseReasonPhrase	`String`	Optional
owin.ResponseHeaders	`IDictionary<string,string[]>`	
owin.ResponseBody	`Stream`	

Other data (OWIN v1.0.0)

Expand table

Key	Value (type)	Description
owin.CallCancelled	`CancellationToken`	
owin.Version	`String`	

Common keys

Expand table

Key	Value (type)	Description
ssl.ClientCertificate	`X509Certificate`	
ssl.LoadClientCertAsync	`Func<Task>`	
server.RemoteIpAddress	`String`	
server.RemotePort	`String`	
server.LocalIpAddress	`String`	
server.LocalPort	`String`	
server.OnSendingHeaders	`Action<Action<object>,object>`	

SendFiles v0.3.0

Expand table

Key	Value (type)	Description
sendfile.SendAsync	See delegate signature	Per Request

Opaque v0.3.0

Expand table

Key	Value (type)	Description
opaque.Version	`String`	

Key	Value (type)	Description
opaque.Upgrade	`OpaqueUpgrade`	See delegate signature
opaque.Stream	`Stream`	
opaque.CallCancelled	`CancellationToken`	

WebSocket v0.3.0

Expand table

Key	Value (type)	Description
websocket.Version	`String`	
websocket.Accept	`WebSocketAccept`	See delegate signature
websocket.AcceptAlt		Non-spec
websocket.SubProtocol	`String`	See RFC6455 Section 4.2.2 Step 5.5
websocket.SendAsync	`WebSocketSendAsync`	See delegate signature
websocket.ReceiveAsync	`WebSocketReceiveAsync`	See delegate signature
websocket.CloseAsync	`WebSocketCloseAsync`	See delegate signature
websocket.CallCancelled	`CancellationToken`	
websocket.ClientCloseStatus	`int`	Optional
websocket.ClientCloseDescription	`String`	Optional

Background tasks with hosted services in ASP.NET Core

Article • 05/31/2024

By Jeow Li Huan

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

In ASP.NET Core, background tasks can be implemented as *hosted services*. A hosted service is a class with background task logic that implements the IHostedService interface. This article provides three hosted service examples:

- Background task that runs on a timer.
- Hosted service that activates a scoped service. The scoped service can use dependency injection (DI).
- Queued background tasks that run sequentially.

Worker Service template

The ASP.NET Core Worker Service template provides a starting point for writing long running service apps. An app created from the Worker Service template specifies the Worker SDK in its project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Worker">
```

To use the template as a basis for a hosted services app:

Visual Studio

1. Create a new project.
2. Select **Worker Service**. Select **Next**.

3. Provide a project name in the **Project name** field or accept the default project name. Select **Next**.
4. In the **Additional information** dialog, Choose a **Framework**. Select **Create**.

Package

An app based on the Worker Service template uses the `Microsoft.NET.Sdk.Worker` SDK and has an explicit package reference to the Microsoft.Extensions.Hosting package. For example, see the sample app's project file (`BackgroundTasksSample.csproj`).

For web apps that use the `Microsoft.NET.Sdk.Web` SDK, the Microsoft.Extensions.Hosting package is referenced implicitly from the shared framework. An explicit package reference in the app's project file isn't required.

IHostedService interface

The IHostedService interface defines two methods for objects that are managed by the host:

- StartAsync(CancellationToken)
- StopAsync(CancellationToken)

`StartAsync`

StartAsync(CancellationToken) contains the logic to start the background task. `StartAsync` is called *before*:

- The app's request processing pipeline is configured.
- The server is started and IApplicationLifetime.ApplicationStarted is triggered.

`StartAsync` should be limited to short running tasks because hosted services are run sequentially, and no further services are started until `StartAsync` runs to completion.

`StopAsync`

- StopAsync(CancellationToken) is triggered when the host is performing a graceful shutdown. `StopAsync` contains the logic to end the background task. Implement IDisposable and finalizers (destructors) to dispose of any unmanaged resources.

The cancellation token has a default 30 second timeout to indicate that the shutdown process should no longer be graceful. When cancellation is requested on the token:

- Any remaining background operations that the app is performing should be aborted.
- Any methods called in `StopAsync` should return promptly.

However, tasks aren't abandoned after cancellation is requested—the caller awaits all tasks to complete.

If the app shuts down unexpectedly (for example, the app's process fails), `StopAsync` might not be called. Therefore, any methods called or operations conducted in `StopAsync` might not occur.

To extend the default 30 second shutdown timeout, set:

- ShutdownTimeout when using Generic Host. For more information, see .NET Generic Host in ASP.NET Core.
- Shutdown timeout host configuration setting when using Web Host. For more information, see ASP.NET Core Web Host.

The hosted service is activated once at app startup and gracefully shut down at app shutdown. If an error is thrown during background task execution, `Dispose` should be called even if `StopAsync` isn't called.

BackgroundService base class

BackgroundService is a base class for implementing a long running IHostedService.

ExecuteAsync(CancellationToken) is called to run the background service. The implementation returns a Task that represents the entire lifetime of the background service. No further services are started until ExecuteAsync becomes asynchronous, such as by calling `await`. Avoid performing long, blocking initialization work in `ExecuteAsync`. The host blocks in StopAsync(CancellationToken) waiting for `ExecuteAsync` to complete.

The cancellation token is triggered when IHostedService.StopAsync is called. Your implementation of `ExecuteAsync` should finish promptly when the cancellation token is fired in order to gracefully shut down the service. Otherwise, the service ungracefully shuts down at the shutdown timeout. For more information, see the IHostedService interface section.

For more information, see the BackgroundService source code.

Timed background tasks

A timed background task makes use of the System.Threading.Timer class. The timer triggers the task's `DoWork` method. The timer is disabled on `StopAsync` and disposed when the service container is disposed on `Dispose`:

C#

```
public class TimedHostedService : IHostedService, IDisposable
{
    private int executionCount = 0;
    private readonly ILogger<TimedHostedService> _logger;
    private Timer? _timer = null;

    public TimedHostedService(ILogger<TimedHostedService> logger)
    {
        _logger = logger;
    }

    public Task StartAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation("Timed Hosted Service running.");

        _timer = new Timer(DoWork, null, TimeSpan.Zero,
            TimeSpan.FromSeconds(5));

        return Task.CompletedTask;
    }

    private void DoWork(object? state)
    {
        var count = Interlocked.Increment(ref executionCount);

        _logger.LogInformation(
            "Timed Hosted Service is working. Count: {Count}", count);
    }

    public Task StopAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation("Timed Hosted Service is stopping.");

        _timer?.Change(Timeout.Infinite, 0);

        return Task.CompletedTask;
    }

    public void Dispose()
    {
        _timer?.Dispose();
    }
}
```

The Timer doesn't wait for previous executions of `DoWork` to finish, so the approach shown might not be suitable for every scenario. Interlocked.Increment is used to increment the execution counter as an atomic operation, which ensures that multiple threads don't update `executionCount` concurrently.

The service is registered in `IHostBuilder.ConfigureServices` (`Program.cs`) with the `AddHostedService` extension method:

C#

```
services.AddHostedService<TimedHostedService>();
```

Consuming a scoped service in a background task

To use scoped services within a BackgroundService, create a scope. No scope is created for a hosted service by default.

The scoped background task service contains the background task's logic. In the following example:

- The service is asynchronous. The `DoWork` method returns a `Task`. For demonstration purposes, a delay of ten seconds is awaited in the `DoWork` method.
- An ILogger is injected into the service.

C#

```
internal interface IScopedProcessingService
{
    Task DoWork(CancellationToken stoppingToken);
}

internal class ScopedProcessingService : IScopedProcessingService
{
    private int executionCount = 0;
    private readonly ILogger _logger;

    public ScopedProcessingService(ILogger<ScopedProcessingService> logger)
    {
        _logger = logger;
    }

    public async Task DoWork(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
```

```
            executionCount++;

            _logger.LogInformation(
                "Scoped Processing Service is working. Count: {Count}",
executionCount);

            await Task.Delay(10000, stoppingToken);
        }
    }
}
```

The hosted service creates a scope to resolve the scoped background task service to call its `DoWork` method. `DoWork` returns a `Task`, which is awaited in `ExecuteAsync`:

C#

```
public class ConsumeScopedServiceHostedService : BackgroundService
{
    private readonly ILogger<ConsumeScopedServiceHostedService> _logger;

    public ConsumeScopedServiceHostedService(IServiceProvider services,
        ILogger<ConsumeScopedServiceHostedService> logger)
    {
        Services = services;
        _logger = logger;
    }

    public IServiceProvider Services { get; }

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        _logger.LogInformation(
            "Consume Scoped Service Hosted Service running.");

        await DoWork(stoppingToken);
    }

    private async Task DoWork(CancellationToken stoppingToken)
    {
        _logger.LogInformation(
            "Consume Scoped Service Hosted Service is working.");

        using (var scope = Services.CreateScope())
        {
            var scopedProcessingService =
                scope.ServiceProvider
                    .GetRequiredService<IScopedProcessingService>();

            await scopedProcessingService.DoWork(stoppingToken);
        }
    }
```

```
    public override async Task StopAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation(
            "Consume Scoped Service Hosted Service is stopping.");

        await base.StopAsync(stoppingToken);
    }
}
```

The services are registered in `IHostBuilder.ConfigureServices` (`Program.cs`). The hosted service is registered with the `AddHostedService` extension method:

C#

```
services.AddHostedService<ConsumeScopedServiceHostedService>();
services.AddScoped<IScopedProcessingService, ScopedProcessingService>();
```

Queued background tasks

A background task queue is based on the .NET 4.x QueueBackgroundWorkItem:

C#

```
public interface IBackgroundTaskQueue
{
    ValueTask QueueBackgroundWorkItemAsync(Func<CancellationToken,
ValueTask> workItem);

    ValueTask<Func<CancellationToken, ValueTask>> DequeueAsync(
        CancellationToken cancellationToken);
}

public class BackgroundTaskQueue : IBackgroundTaskQueue
{
    private readonly Channel<Func<CancellationToken, ValueTask>> _queue;

    public BackgroundTaskQueue(int capacity)
    {
        // Capacity should be set based on the expected application load and
        // number of concurrent threads accessing the queue.
        // BoundedChannelFullMode.Wait will cause calls to WriteAsync() to
return a task,
        // which completes only when space became available. This leads to
backpressure,
        // in case too many publishers/calls start accumulating.
        var options = new BoundedChannelOptions(capacity)
        {
            FullMode = BoundedChannelFullMode.Wait
        };
```

```
        _queue = Channel.CreateBounded<Func<CancellationToken, ValueTask>>
(options);
    }

    public async ValueTask QueueBackgroundWorkItemAsync(
        Func<CancellationToken, ValueTask> workItem)
    {
        if (workItem == null)
        {
            throw new ArgumentNullException(nameof(workItem));
        }

        await _queue.Writer.WriteAsync(workItem);
    }

    public async ValueTask<Func<CancellationToken, ValueTask>> DequeueAsync(
        CancellationToken cancellationToken)
    {
        var workItem = await _queue.Reader.ReadAsync(cancellationToken);

        return workItem;
    }
}
```

In the following `QueueHostedService` example:

- The `BackgroundProcessing` method returns a `Task`, which is awaited in `ExecuteAsync`.
- Background tasks in the queue are dequeued and executed in `BackgroundProcessing`.
- Work items are awaited before the service stops in `StopAsync`.

C#

```
public class QueuedHostedService : BackgroundService
{
    private readonly ILogger<QueuedHostedService> _logger;

    public QueuedHostedService(IBackgroundTaskQueue taskQueue,
        ILogger<QueuedHostedService> logger)
    {
        TaskQueue = taskQueue;
        _logger = logger;
    }

    public IBackgroundTaskQueue TaskQueue { get; }

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        _logger.LogInformation(
```

```
            $"Queued Hosted Service is running.{Environment.NewLine}" +
            $"{Environment.NewLine}Tap W to add a work item to the " +
            $"background queue.{Environment.NewLine}");

        await BackgroundProcessing(stoppingToken);
    }

    private async Task BackgroundProcessing(CancellationToken stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            var workItem =
                await TaskQueue.DequeueAsync(stoppingToken);

            try
            {
                await workItem(stoppingToken);
            }
            catch (Exception ex)
            {
                _logger.LogError(ex,
                    "Error occurred executing {WorkItem}.",
nameof(workItem));
            }
        }
    }

    public override async Task StopAsync(CancellationToken stoppingToken)
    {
        _logger.LogInformation("Queued Hosted Service is stopping.");

        await base.StopAsync(stoppingToken);
    }
}
```

A `MonitorLoop` service handles enqueuing tasks for the hosted service whenever the `w` key is selected on an input device:

- The `IBackgroundTaskQueue` is injected into the `MonitorLoop` service.
- `IBackgroundTaskQueue.QueueBackgroundWorkItem` is called to enqueue a work item.
- The work item simulates a long-running background task:
  - Three 5-second delays are executed (`Task.Delay`).
  - A `try-catch` statement traps OperationCanceledException if the task is cancelled.

C#

```
public class MonitorLoop
{
    private readonly IBackgroundTaskQueue _taskQueue;
```

```
    private readonly ILogger _logger;
    private readonly CancellationToken _cancellationToken;

    public MonitorLoop(IBackgroundTaskQueue taskQueue,
        ILogger<MonitorLoop> logger,
        IHostApplicationLifetime applicationLifetime)
    {
        _taskQueue = taskQueue;
        _logger = logger;
        _cancellationToken = applicationLifetime.ApplicationStopping;
    }

    public void StartMonitorLoop()
    {
        _logger.LogInformation("MonitorAsync Loop is starting.");

        // Run a console user input loop in a background thread
        Task.Run(async () => await MonitorAsync());
    }

    private async ValueTask MonitorAsync()
    {
        while (!_cancellationToken.IsCancellationRequested)
        {
            var keyStroke = Console.ReadKey();

            if (keyStroke.Key == ConsoleKey.W)
            {
                // Enqueue a background work item
                await
_taskQueue.QueueBackgroundWorkItemAsync(BuildWorkItem);
            }
        }
    }

    private async ValueTask BuildWorkItem(CancellationToken token)
    {
        // Simulate three 5-second tasks to complete
        // for each enqueued work item

        int delayLoop = 0;
        var guid = Guid.NewGuid().ToString();

        _logger.LogInformation("Queued Background Task {Guid} is starting.",
guid);

        while (!token.IsCancellationRequested && delayLoop < 3)
        {
            try
            {
                await Task.Delay(TimeSpan.FromSeconds(5), token);
            }
            catch (OperationCanceledException)
            {
                // Prevent throwing if the Delay is cancelled
```

```
            }

            delayLoop++;

            _logger.LogInformation("Queued Background Task {Guid} is
running. "
                                   + "{DelayLoop}/3", guid, delayLoop);
        }

        if (delayLoop == 3)
        {
            _logger.LogInformation("Queued Background Task {Guid} is
complete.", guid);
        }
        else
        {
            _logger.LogInformation("Queued Background Task {Guid} was
cancelled.", guid);
        }
    }
}
```

The services are registered in `IHostBuilder.ConfigureServices` (`Program.cs`). The hosted service is registered with the `AddHostedService` extension method:

C#

```
services.AddSingleton<MonitorLoop>();
services.AddHostedService<QueuedHostedService>();
services.AddSingleton<IBackgroundTaskQueue>(ctx =>
{
    if (!int.TryParse(hostContext.Configuration["QueueCapacity"], out var
queueCapacity))
        queueCapacity = 100;
    return new BackgroundTaskQueue(queueCapacity);
});
```

`MonitorLoop` is started in `Program.cs`:

C#

```
var monitorLoop = host.Services.GetRequiredService<MonitorLoop>();
monitorLoop.StartMonitorLoop();
```

Asynchronous timed background task

The following code creates an asynchronous timed background task:

C#

```
namespace TimedBackgroundTasks;

public class TimedHostedService : BackgroundService
{
    private readonly ILogger<TimedHostedService> _logger;
    private int _executionCount;

    public TimedHostedService(ILogger<TimedHostedService> logger)
    {
        _logger = logger;
    }

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        _logger.LogInformation("Timed Hosted Service running.");

        // When the timer should have no due-time, then do the work once
now.
        DoWork();

        using PeriodicTimer timer = new(TimeSpan.FromSeconds(1));

        try
        {
            while (await timer.WaitForNextTickAsync(stoppingToken))
            {
                DoWork();
            }
        }
        catch (OperationCanceledException)
        {
            _logger.LogInformation("Timed Hosted Service is stopping.");
        }
    }

    // Could also be a async method, that can be awaited in ExecuteAsync
above
    private void DoWork()
    {
        int count = Interlocked.Increment(ref _executionCount);

        _logger.LogInformation("Timed Hosted Service is working. Count:
{Count}", count);
    }
}
```

Native AOT

The Worker Service templates support .NET native ahead-of-time (AOT) with the `--aot` flag:

Visual Studio

1. Create a new project.
2. Select **Worker Service**. Select **Next**.
3. Provide a project name in the **Project name** field or accept the default project name. Select **Next**.
4. In the **Additional information** dialog:
5. Choose a **Framework**.
6. Check the **Enable Native AOT publish** checkbox.
7. Select **Create**.

The AOT option adds `<PublishAot>true</PublishAot>` to the project file:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Worker">

  <PropertyGroup>
    <TargetFramework>net8.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
    <InvariantGlobalization>true</InvariantGlobalization>
+   <PublishAot>true</PublishAot>
    <UserSecretsId>dotnet-WorkerWithAot-e94b2</UserSecretsId>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.Extensions.Hosting" Version="8.0.0-
preview.4.23259.5" />
  </ItemGroup>
</Project>
```

Use hosting startup assemblies in ASP.NET Core

Article • 07/26/2024

By Pavel Krymets

An IHostingStartup (hosting startup) implementation adds enhancements to an app at startup from an external assembly. For example, an external library can use a hosting startup implementation to provide additional configuration providers or services to an app.

View or download sample code (how to download)

HostingStartup attribute

A HostingStartup attribute indicates the presence of a hosting startup assembly to activate at runtime.

The entry assembly or the assembly containing the `Startup` class is automatically scanned for the `HostingStartup` attribute. The list of assemblies to search for `HostingStartup` attributes is loaded at runtime from configuration in the WebHostDefaults.HostingStartupAssembliesKey. The list of assemblies to exclude from discovery is loaded from the WebHostDefaults.HostingStartupExcludeAssembliesKey.

In the following example, the namespace of the hosting startup assembly is `StartupEnhancement`. The class containing the hosting startup code is `StartupEnhancementHostingStartup`:

C#

```
[assembly: HostingStartup(typeof(StartupEnhancement.StartupEnhancementHostingStartup))]
```

The `HostingStartup` attribute is typically located in the hosting startup assembly's `IHostingStartup` implementation class file.

Discover loaded hosting startup assemblies

To discover loaded hosting startup assemblies, enable logging and check the app's logs. Errors that occur when loading assemblies are logged. Loaded hosting startup assemblies are logged at the Debug level, and all errors are logged.

Disable automatic loading of hosting startup assemblies

To disable automatic loading of hosting startup assemblies, use one of the following approaches:

- To prevent all hosting startup assemblies from loading, set one of the following to `true` or `1`:
  - Prevent Hosting Startup host configuration setting:

    C#

    ```
    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseSetting(
                        WebHostDefaults.PreventHostingStartupKey, "true")
                    .UseStartup<Startup>();
            });
    ```

  - `ASPNETCORE_PREVENTHOSTINGSTARTUP` environment variable.
- To prevent specific hosting startup assemblies from loading, set one of the following to a semicolon-delimited string of hosting startup assemblies to exclude at startup:
  - Hosting Startup Exclude Assemblies host configuration setting:

    C#

    ```
    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseSetting(
                        WebHostDefaults.HostingStartupExcludeAssembliesKey,
                        "{ASSEMBLY1;ASSEMBLY2; ...}")
                    .UseStartup<Startup>();
            });
    ```

    The `{ASSEMBLY1;ASSEMBLY2; ...}` placeholder represents the semicolon-separated list of assemblies.

  - `ASPNETCORE_HOSTINGSTARTUPEXCLUDEASSEMBLIES` environment variable.

If both the host configuration setting and the environment variable are set, the host setting controls the behavior.

Disabling hosting startup assemblies using the host setting or environment variable disables the assembly globally and may disable several characteristics of an app.

Project

Create a hosting startup with either of the following project types:

- Class library
- Console app without an entry point

Class library

A hosting startup enhancement can be provided in a class library. The library contains a `HostingStartup` attribute.

The sample code includes a Razor Pages app, *HostingStartupApp*, and a class library, *HostingStartupLibrary*. The class library:

- Contains a hosting startup class, `ServiceKeyInjection`, which implements `IHostingStartup`. `ServiceKeyInjection` adds a pair of service strings to the app's configuration using the in-memory configuration provider (AddInMemoryCollection).
- Includes a `HostingStartup` attribute that identifies the hosting startup's namespace and class.

The `ServiceKeyInjection` class's Configure method uses an IWebHostBuilder to add enhancements to an app.

`HostingStartupLibrary/ServiceKeyInjection.cs`:

C#

```
[assembly: HostingStartup(typeof(HostingStartupLibrary.ServiceKeyInjection))]

namespace HostingStartupLibrary
{
    public class ServiceKeyInjection : IHostingStartup
    {
        public void Configure(IWebHostBuilder builder)
        {
            builder.ConfigureAppConfiguration(config =>
            {
                var dict = new Dictionary<string, string>
                {
                    {"DevAccount_FromLibrary", "DEV_1111111-1111"},
                    {"ProdAccount_FromLibrary", "PROD_2222222-2222"}
                };

                config.AddInMemoryCollection(dict);
            });
        }
    }
}
```

The app's Index page reads and renders the configuration values for the two keys set by the class library's hosting startup assembly:

`HostingStartupApp/Pages/Index.cshtml.cs`:

C#

```
public class IndexModel : PageModel
{
    public IndexModel(IConfiguration config)
    {
        ServiceKey_Development_Library = config["DevAccount_FromLibrary"];
        ServiceKey_Production_Library = config["ProdAccount_FromLibrary"];
        ServiceKey_Development_Package = config["DevAccount_FromPackage"];
        ServiceKey_Production_Package = config["ProdAccount_FromPackage"];
    }

    public string ServiceKey_Development_Library { get; private set; }
    public string ServiceKey_Production_Library { get; private set; }
    public string ServiceKey_Development_Package { get; private set; }
    public string ServiceKey_Production_Package { get; private set; }

    public void OnGet()
    {
    }
}
```

The sample code also includes a NuGet package project that provides a separate hosting startup, *HostingStartupPackage*. The package has the same characteristics of the class library described earlier. The package:

- Contains a hosting startup class, `ServiceKeyInjection`, which implements `IHostingStartup`. `ServiceKeyInjection` adds a pair of service strings to the app's configuration.
- Includes a `HostingStartup` attribute.

`HostingStartupPackage/ServiceKeyInjection.cs`:

C#

```
[assembly: HostingStartup(typeof(HostingStartupPackage.ServiceKeyInjection))]

namespace HostingStartupPackage
{
    public class ServiceKeyInjection : IHostingStartup
    {
        public void Configure(IWebHostBuilder builder)
        {
            builder.ConfigureAppConfiguration(config =>
            {
                var dict = new Dictionary<string, string>
                {
                    {"DevAccount_FromPackage", "DEV_3333333-3333"},
                    {"ProdAccount_FromPackage", "PROD_4444444-4444"}
                };

                config.AddInMemoryCollection(dict);
```

```
            });
        }
    }
}
```

The app's Index page reads and renders the configuration values for the two keys set by the package's hosting startup assembly:

`HostingStartupApp/Pages/Index.cshtml.cs`:

C#

```
public class IndexModel : PageModel
{
    public IndexModel(IConfiguration config)
    {
        ServiceKey_Development_Library = config["DevAccount_FromLibrary"];
        ServiceKey_Production_Library = config["ProdAccount_FromLibrary"];
        ServiceKey_Development_Package = config["DevAccount_FromPackage"];
        ServiceKey_Production_Package = config["ProdAccount_FromPackage"];
    }

    public string ServiceKey_Development_Library { get; private set; }
    public string ServiceKey_Production_Library { get; private set; }
    public string ServiceKey_Development_Package { get; private set; }
    public string ServiceKey_Production_Package { get; private set; }

    public void OnGet()
    {
    }
}
```

Console app without an entry point

This approach is only available for .NET Core apps, not .NET Framework.

A dynamic hosting startup enhancement that doesn't require a compile-time reference for activation can be provided in a console app without an entry point that contains a `HostingStartup` attribute. Publishing the console app produces a hosting startup assembly that can be consumed from the runtime store.

A console app without an entry point is used in this process because:

- A dependencies file is required to consume the hosting startup in the hosting startup assembly. A dependencies file is a runnable app asset that's produced by publishing an app, not a library.
- A library can't be added directly to the runtime package store, which requires a runnable project that targets the shared runtime.

In the creation of a dynamic hosting startup:

- A hosting startup assembly is created from the console app without an entry point that:
  - Includes a class that contains the `IHostingStartup` implementation.

    - Includes a HostingStartup attribute to identify the `IHostingStartup` implementation class.
- The console app is published to obtain the hosting startup's dependencies. A consequence of publishing the console app is that unused dependencies are trimmed from the dependencies file.
- The dependencies file is modified to set the runtime location of the hosting startup assembly.
- The hosting startup assembly and its dependencies file is placed into the runtime package store. To discover the hosting startup assembly and its dependencies file, they're listed in a pair of environment variables.

The console app references the Microsoft.AspNetCore.Hosting.Abstractions package:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Hosting.Abstractions"
                      Version="3.0.0" />
  </ItemGroup>

</Project>
```

A HostingStartup attribute identifies a class as an implementation of `IHostingStartup` for loading and execution when building the IWebHost. In the following example, the namespace is `StartupEnhancement`, and the class is `StartupEnhancementHostingStartup`:

C#

```
[assembly: HostingStartup(typeof(StartupEnhancement.StartupEnhancementHostingStartup))]
```

A class implements `IHostingStartup`. The class's Configure method uses an IWebHostBuilder to add enhancements to an app. `IHostingStartup.Configure` in the hosting startup assembly is called by the runtime before `Startup.Configure` in user code, which allows user code to overwrite any configuration provided by the hosting startup assembly.

C#

```
namespace StartupEnhancement
{
    public class StartupEnhancementHostingStartup : IHostingStartup
    {
        public void Configure(IWebHostBuilder builder)
        {
            // Use the IWebHostBuilder to add app enhancements.
        }
    }
}
```

When building an `IHostingStartup` project, the dependencies file (`.deps.json`) sets the `runtime` location of the assembly to the *bin* folder:

JSON

```
"targets": {
  ".NETCoreApp,Version=v3.0": {
    "StartupEnhancement/1.0.0": {
      "dependencies": {
        "Microsoft.AspNetCore.Hosting.Abstractions": "3.0.0"
      },
      "runtime": {
        "StartupEnhancement.dll": {}
      }
    }
  }
}
```

Only part of the file is shown. The assembly name in the example is `StartupEnhancement`.

Configuration provided by the hosting startup

There are two approaches to handling configuration depending on whether you want the hosting startup's configuration to take precedence or the app's configuration to take precedence:

1. Provide configuration to the app using ConfigureAppConfiguration to load the configuration after the app's ConfigureAppConfiguration delegates execute. Hosting startup configuration takes priority over the app's configuration using this approach.
2. Provide configuration to the app using UseConfiguration to load the configuration before the app's ConfigureAppConfiguration delegates execute. The app's configuration values take priority over those provided by the hosting startup using this approach.

C#

```
public class ConfigurationInjection : IHostingStartup
{
    public void Configure(IWebHostBuilder builder)
    {
        Dictionary<string, string> dict;

        builder.ConfigureAppConfiguration(config =>
        {
            dict = new Dictionary<string, string>
            {
                {"ConfigurationKey1",
                    "From IHostingStartup: Higher priority " +
                    "than the app's configuration."},
            };

            config.AddInMemoryCollection(dict);
        });

        dict = new Dictionary<string, string>
        {
```

```
            {"ConfigurationKey2",
                "From IHostingStartup: Lower priority " +
                "than the app's configuration."},
        };

        var builtConfig = new ConfigurationBuilder()
            .AddInMemoryCollection(dict)
            .Build();

        builder.UseConfiguration(builtConfig);
    }
}
```

Specify the hosting startup assembly

For either a class library- or console app-supplied hosting startup, specify the hosting startup assembly's name in the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable. The environment variable is a semicolon-delimited list of assemblies.

Only hosting startup assemblies are scanned for the `HostingStartup` attribute. For the sample app, *HostingStartupApp*, to discover the hosting startups described earlier, the environment variable is set to the following value:

```
HostingStartupLibrary;HostingStartupPackage;StartupDiagnostics
```

A hosting startup assembly can also be set using the Hosting Startup Assemblies host configuration setting:

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseSetting(
                    WebHostDefaults.HostingStartupAssembliesKey,
                    "{ASSEMBLY1;ASSEMBLY2; ...}")
                .UseStartup<Startup>();
        });
```

The `{ASSEMBLY1;ASSEMBLY2; ...}` placeholder represents the semicolon-separated list of assemblies.

When multiple hosting startup assembles are present, their Configure methods are executed in the order that the assemblies are listed.

Activation

Options for hosting startup activation are:

- Runtime store: Activation doesn't require a compile-time reference for activation. The sample app places the hosting startup assembly and dependencies files into a folder, *deployment*, to facilitate deployment of the hosting startup in a multimachine environment. The *deployment* folder also includes a PowerShell script that creates or modifies environment variables on the deployment system to enable the hosting startup.
- Compile-time reference required for activation
  - NuGet package
  - Project bin folder

Runtime store

The hosting startup implementation is placed in the runtime store. A compile-time reference to the assembly isn't required by the enhanced app.

After the hosting startup is built, a runtime store is generated using the manifest project file and the dotnet store command.

.NET CLI

```
dotnet store --manifest {MANIFEST FILE} --runtime {RUNTIME IDENTIFIER} --output {OUTPUT
LOCATION} --skip-optimization
```

In the sample app (*RuntimeStore* project) the following command is used:

.NET CLI

```
dotnet store --manifest store.manifest.csproj --runtime win7-x64 --output
./deployment/store --skip-optimization
```

For the runtime to discover the runtime store, the runtime store's location is added to the `DOTNET_SHARED_STORE` environment variable.

Modify and place the hosting startup's dependencies file

To activate the enhancement without a package reference to the enhancement, specify additional dependencies to the runtime with `additionalDeps`. `additionalDeps` allows you to:

- Extend the app's library graph by providing a set of additional `.deps.json` files to merge with the app's own `.deps.json` file on startup.
- Make the hosting startup assembly discoverable and loadable.

The recommended approach for generating the additional dependencies file is to:

1. Execute `dotnet publish` on the runtime store manifest file referenced in the previous section.
2. Remove the manifest reference from libraries and the `runtime` section of the resulting `.deps.json` file.

In the example project, the `store.manifest/1.0.0` property is removed from the `targets` and `libraries` section:

JSON

```
{
  "runtimeTarget": {
    "name": ".NETCoreApp,Version=v3.0",
    "signature": ""
  },
  "compilationOptions": {},
  "targets": {
    ".NETCoreApp,Version=v3.0": {
      "store.manifest/1.0.0": {
        "dependencies": {
          "StartupDiagnostics": "1.0.0"
        },
        "runtime": {
          "store.manifest.dll": {}
        }
      },
      "StartupDiagnostics/1.0.0": {
        "runtime": {
          "lib/netcoreapp3.0/StartupDiagnostics.dll": {
            "assemblyVersion": "1.0.0.0",
            "fileVersion": "1.0.0.0"
          }
        }
      }
    }
  },
  "libraries": {
    "store.manifest/1.0.0": {
      "type": "project",
      "serviceable": false,
      "sha512": ""
    },
    "StartupDiagnostics/1.0.0": {
      "type": "package",
      "serviceable": true,
      "sha512": "sha512-
xrhzuNSyM5/f4ZswhooJ9dmIYLP64wMnqUJSyTKVDKDVj5T+qtzypl8JmM/aFJLLpYrf0FYpVWvGujd7/FfMEw=
=",
      "path": "startupdiagnostics/1.0.0",
      "hashPath": "startupdiagnostics.1.0.0.nupkg.sha512"
    }
  }
}
```

Place the `.deps.json` file into the following location:

```
{ADDITIONAL DEPENDENCIES PATH}/shared/{SHARED FRAMEWORK NAME}/{SHARED FRAMEWORK
VERSION}/{ENHANCEMENT ASSEMBLY NAME}.deps.json
```

- `{ADDITIONAL DEPENDENCIES PATH}`: Location added to the `DOTNET_ADDITIONAL_DEPS` environment variable.
- `{SHARED FRAMEWORK NAME}`: Shared framework required for this additional dependencies file.
- `{SHARED FRAMEWORK VERSION}`: Minimum shared framework version.
- `{ENHANCEMENT ASSEMBLY NAME}`: The enhancement's assembly name.

In the sample app (*RuntimeStore* project), the additional dependencies file is placed into the following location:

```
deployment/additionalDeps/shared/Microsoft.AspNetCore.App/3.0.0/StartupDiagnostics.deps
.json
```

For runtime to discover the runtime store location, the additional dependencies file location is added to the `DOTNET_ADDITIONAL_DEPS` environment variable.

In the sample app (*RuntimeStore* project), building the runtime store and generating the additional dependencies file is accomplished using a PowerShell script.

For examples of how to set environment variables for various operating systems, see Use multiple environments.

Deployment

To facilitate the deployment of a hosting startup in a multimachine environment, the sample app creates a *deployment* folder in published output that contains:

- The hosting startup runtime store.
- The hosting startup dependencies file.
- A PowerShell script that creates or modifies the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES`, `DOTNET_SHARED_STORE`, and `DOTNET_ADDITIONAL_DEPS` to support the activation of the hosting startup. Run the script from an administrative PowerShell command prompt on the deployment system.

NuGet package

A hosting startup enhancement can be provided in a NuGet package. The package has a `HostingStartup` attribute. The hosting startup types provided by the package are made available to the app using either of the following approaches:

- The enhanced app's project file makes a package reference for the hosting startup in the app's project file (a compile-time reference). With the compile-time reference in place, the hosting startup assembly and all of its dependencies are incorporated into the app's dependency file (`.deps.json`). This approach applies to a hosting startup assembly package published to nuget.org.
- The hosting startup's dependencies file is made available to the enhanced app as described in the Runtime store section (without a compile-time reference).

For more information on NuGet packages and the runtime store, see the following topics:

- How to Create a NuGet Package with Cross Platform Tools
- Publishing packages
- Runtime package store

Project bin folder

A hosting startup enhancement can be provided by a *bin*-deployed assembly in the enhanced app. The hosting startup types provided by the assembly are made available to the app using one of the following approaches:

- The enhanced app's project file makes an assembly reference to the hosting startup (a compile-time reference). With the compile-time reference in place, the hosting startup assembly and all of its dependencies are incorporated into the app's dependency file (`.deps.json`). This approach applies when the deployment scenario calls for making a compile-time reference to the hosting startup's assembly (*.dll* file) and moving the assembly to either:
  - The consuming project.
  - A location accessible by the consuming project.
- The hosting startup's dependencies file is made available to the enhanced app as described in the Runtime store section (without a compile-time reference).
- When targeting the .NET Framework, the assembly is loadable in the default load context, which on .NET Framework means that the assembly is located at either of the following locations:
  - Application base path: The *bin* folder where the app's executable (*.exe*) is located.
  - Global Assembly Cache (GAC): The GAC stores assemblies that several .NET Framework apps share. For more information, see How to: Install an assembly into the global assembly cache in the .NET Framework documentation.

Sample code

The sample code (how to download) demonstrates hosting startup implementation scenarios:

- Two hosting startup assemblies (class libraries) set a pair of in-memory configuration key-value pairs each:
  - NuGet package (*HostingStartupPackage*)
  - Class library (*HostingStartupLibrary*)
- A hosting startup is activated from a runtime store-deployed assembly (*StartupDiagnostics*). The assembly adds two middlewares to the app at startup that provide diagnostic information on:
  - Registered services
  - Address (scheme, host, path base, path, query string)
  - Connection (remote IP, remote port, local IP, local port, client certificate)
  - Request headers
  - Environment variables

To run the sample:

Activation from a NuGet package

1. Compile the *HostingStartupPackage* package with the dotnet pack command.
2. Add the package's assembly name of the *HostingStartupPackage* to the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable.
3. Compile and run the app. A package reference is present in the enhanced app (a compile-time reference). A `<PropertyGroup>` in the app's project file specifies the package project's output (*../HostingStartupPackage/bin/Debug*) as a package source. This allows the app to use the package without uploading the package to nuget.org. For more information, see the notes in the HostingStartupApp's project file.

   XML

   ```
   <PropertyGroup>

   <RestoreSources>$(RestoreSources);https://api.nuget.org/v3/index.json;../HostingSt
   artupPackage/bin/Debug</RestoreSources>
   </PropertyGroup>
   ```

4. Observe that the service configuration key values rendered by the Index page match the values set by the package's `ServiceKeyInjection.Configure` method.

If you make changes to the *HostingStartupPackage* project and recompile it, clear the local NuGet package caches to ensure that the *HostingStartupApp* receives the updated package and not a stale package from the local cache. To clear the local NuGet caches, execute the following dotnet nuget locals command:

.NET CLI

```
dotnet nuget locals all --clear
```

Activation from a class library

1. Compile the *HostingStartupLibrary* class library with the dotnet build command.
2. Add the class library's assembly name of *HostingStartupLibrary* to the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable.
3. *bin*-deploy the class library's assembly to the app by copying the *HostingStartupLibrary.dll* file from the class library's compiled output to the app's *bin/Debug* folder.
4. Compile and run the app. An `<ItemGroup>` in the app's project file references the class library's assembly (*.\bin\Debug\netcoreapp3.0\HostingStartupLibrary.dll*) (a compile-time reference). For more information, see the notes in the HostingStartupApp's project file.

   XML

```
<ItemGroup>
  <Reference Include=".\\bin\\Debug\\netcoreapp3.0\\HostingStartupLibrary.dll">
    <HintPath>.\bin\Debug\netcoreapp3.0\HostingStartupLibrary.dll</HintPath>
    <SpecificVersion>False</SpecificVersion>
  </Reference>
</ItemGroup>
```

5. Observe that the service configuration key values rendered by the Index page match the values set by the class library's `ServiceKeyInjection.Configure` method.

Activation from a runtime store-deployed assembly

1. The *StartupDiagnostics* project uses PowerShell to modify its `StartupDiagnostics.deps.json` file. PowerShell is installed by default on Windows starting with Windows 7 SP1 and Windows Server 2008 R2 SP1. To obtain PowerShell on other platforms, see Installing various versions of PowerShell.
2. Execute the *build.ps1* script in the *RuntimeStore* folder. The script:
   - Generates the `StartupDiagnostics` package in the *obj\packages* folder.
   - Generates the runtime store for `StartupDiagnostics` in the *store* folder. The `dotnet store` command in the script uses the `win7-x64` runtime identifier (RID) for a hosting startup deployed to Windows. When providing the hosting startup for a different runtime, substitute the correct RID on line 37 of the script. The runtime store for `StartupDiagnostics` would later be moved to the user's or system's runtime store on the machine where the assembly will be consumed. The user runtime store install location for the `StartupDiagnostics` assembly is *.dotnet/store/x64/netcoreapp3.0/startupdiagnostics/1.0.0/lib/netcoreapp3.0/StartupDiagnostics.dll*.
   - Generates the `additionalDeps` for `StartupDiagnostics` in the *additionalDeps* folder. The additional dependencies would later be moved to the user's or system's additional dependencies. The user `StartupDiagnostics` additional dependencies install location is `.dotnet/x64/additionalDeps/StartupDiagnostics/shared/Microsoft.NETCore.App/3.0.0/StartupDiagnostics.deps.json`.
   - Places the *deploy.ps1* file in the *deployment* folder.
3. Run the *deploy.ps1* script in the *deployment* folder. The script appends:
   - `StartupDiagnostics` to the `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` environment variable.
   - The hosting startup dependencies path (in the RuntimeStore project's *deployment* folder) to the `DOTNET_ADDITIONAL_DEPS` environment variable.
   - The runtime store path (in the RuntimeStore project's *deployment* folder) to the `DOTNET_SHARED_STORE` environment variable.
4. Run the sample app.
5. Request the `/services` endpoint to see the app's registered services. Request the `/diag` endpoint to see the diagnostic information.

Use ASP.NET Core APIs in a class library

Article • 06/18/2024

By Scott Addie

This document provides guidance for using ASP.NET Core APIs in a class library. For all other library guidance, see Open-source library guidance.

Determine which ASP.NET Core versions to support

ASP.NET Core adheres to the .NET Core support policy. Consult the support policy when determining which ASP.NET Core versions to support in a library. A library should:

- Make an effort to support all ASP.NET Core versions classified as *Long-Term Support* (LTS).
- Not feel obligated to support ASP.NET Core versions classified as *End of Life* (EOL).

As preview releases of ASP.NET Core are made available, breaking changes are posted in the aspnet/Announcements GitHub repository. Compatibility testing of libraries can be conducted as framework features are being developed.

Use the ASP.NET Core shared framework

With the release of .NET Core 3.0, many ASP.NET Core assemblies are no longer published to NuGet as packages. Instead, the assemblies are included in the `Microsoft.AspNetCore.App` shared framework, which is installed with the .NET Core SDK and runtime installers. For a list of packages no longer being published, see Remove obsolete package references.

As of .NET Core 3.0, projects using the `Microsoft.NET.Sdk.Web` MSBuild SDK implicitly reference the shared framework. Projects using the `Microsoft.NET.Sdk` or `Microsoft.NET.Sdk.Razor` SDK must reference ASP.NET Core to use ASP.NET Core APIs in the shared framework.

To reference ASP.NET Core, add the following `<FrameworkReference>` element to your project file:

```
XML
```

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.1</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

Include Blazor extensibility

Blazor supports creating Razor components class libraries for server-side and client-side apps. To support Razor components in a class library, the class library must use the Microsoft.NET.Sdk.Razor SDK.

Support server-side and client-side apps

To support Razor component consumption by server-side and client-side apps from a single library, use the following instructions for your editor.

Visual Studio

Use the **Razor Class Library** project template.

> ⓘ Note
>
> Do ***not*** select the **Support pages and views** checkbox. Selecting the checkbox results in a class library that only supports server-side apps.

The library generated from the project template:

- Targets the current .NET framework based on the installed SDK.
- Enables browser compatibility checks for platform dependencies by including `browser` as a supported platform with the `SupportedPlatform` MSBuild item.
- Adds a NuGet package reference for Microsoft.AspNetCore.Components.Web.

RazorClassLibrary-CSharp.csproj (reference source)

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Support multiple framework versions

If the library must support features added to Blazor in the current release while also supporting one or more earlier releases, multi-target the library. Provide a semicolon-separated list of Target Framework Monikers (TFMs) in the `TargetFrameworks` MSBuild property:

XML

```xml
<TargetFrameworks>{TARGET FRAMEWORKS}</TargetFrameworks>
```

In the preceding example, the `{TARGET FRAMEWORKS}` placeholder represents the semicolon-separated TFMs list. For example, `netcoreapp3.1;net5.0`.

Only support server-side consumption

Class libraries are rarely built to only support server-side apps. If the class library only requires server-side-specific features, such as access to CircuitHandler or Microsoft.AspNetCore.Components.Server.ProtectedBrowserStorage, or uses ASP.NET Core-specific features, such as middleware, MVC controllers, or Razor Pages, use **one** of the following approaches:

- Specify that the library supports pages and views when the library is created with the **Support pages and views** checkbox (Visual Studio) or the `-s|--support-pages-and-views` option with the `dotnet new` command:

  .NET CLI

  ```
  dotnet new razorclasslib -s
  ```

- Only provide a framework reference to ASP.NET Core in the library's project file in addition to any other required MSBuild properties:

XML

```xml
<ItemGroup>
  <FrameworkReference Include="Microsoft.AspNetCore.App" />
</ItemGroup>
```

For more information on libraries containing Razor components, see Consume ASP.NET Core Razor components from a Razor class library (RCL).

Include MVC extensibility

This section outlines recommendations for libraries that include:

- Razor views or Razor Pages
- Tag Helpers
- View components

This section doesn't discuss multi-targeting to support multiple versions of MVC. For guidance on supporting multiple ASP.NET Core versions, see Support multiple ASP.NET Core versions.

Razor views or Razor Pages

A project that includes Razor views or Razor Pages must use the Microsoft.NET.Sdk.Razor SDK.

If the project targets .NET Core 3.x, it requires:

- An `AddRazorSupportForMvc` MSBuild property set to `true`.
- A `<FrameworkReference>` element for the shared framework.

The **Razor Class Library** project template satisfies the preceding requirements for projects targeting .NET Core. Use the following instructions for your editor.

Visual Studio

Use the **Razor Class Library** project template. The template's **Support pages and views** checkbox should be selected.

For example:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.1</TargetFramework>
    <AddRazorSupportForMvc>true</AddRazorSupportForMvc>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

If the project targets .NET Standard instead, a Microsoft.AspNetCore.Mvc package reference is required. The `Microsoft.AspNetCore.Mvc` package moved into the shared framework in ASP.NET Core 3.0 and is therefore no longer published. For example:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
    <TargetFramework>netstandard2.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.2.0" />
  </ItemGroup>

</Project>
```

Tag Helpers

A project that includes Tag Helpers should use the `Microsoft.NET.Sdk` SDK. If targeting .NET Core 3.x, add a `<FrameworkReference>` element for the shared framework. For example:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.1</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>
```

```
</Project>
```

If targeting .NET Standard (to support versions earlier than ASP.NET Core 3.x), add a package reference to Microsoft.AspNetCore.Mvc.Razor. The `Microsoft.AspNetCore.Mvc.Razor` package moved into the shared framework and is therefore no longer published. For example:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netstandard2.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.2.0" />
  </ItemGroup>

</Project>
```

View components

A project that includes View components should use the `Microsoft.NET.Sdk` SDK. If targeting .NET Core 3.x, add a `<FrameworkReference>` element for the shared framework. For example:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.1</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

If targeting .NET Standard (to support versions earlier than ASP.NET Core 3.x), add a package reference to Microsoft.AspNetCore.Mvc.ViewFeatures. The `Microsoft.AspNetCore.Mvc.ViewFeatures` package moved into the shared framework and is therefore no longer published. For example:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>netstandard2.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.Mvc.ViewFeatures"
Version="2.2.0" />
  </ItemGroup>

</Project>
```

Support multiple ASP.NET Core versions

Multi-targeting is required to author a library that supports multiple variants of ASP.NET Core. Consider a scenario in which a Tag Helpers library must support the following ASP.NET Core variants:

- ASP.NET Core 2.1 targeting .NET Framework 4.6.1
- ASP.NET Core 2.x targeting .NET Core 2.x
- ASP.NET Core 3.x targeting .NET Core 3.x

The following project file supports these variants via the `TargetFrameworks` property:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFrameworks>netcoreapp2.1;netcoreapp3.1;net461</TargetFrameworks>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Markdig" Version="0.16.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' != 'netcoreapp3.1'">
    <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor"
Version="2.1.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netcoreapp3.1'">
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>
</Project>
```

With the preceding project file:

- The `Markdig` package is added for all consumers.
- A reference to Microsoft.AspNetCore.Mvc.Razor is added for consumers targeting .NET Framework 4.6.1 or later or .NET Core 2.x. Version 2.1.0 of the package works with ASP.NET Core 2.2 because of backwards compatibility.
- The shared framework is referenced for consumers targeting .NET Core 3.x. The `Microsoft.AspNetCore.Mvc.Razor` package is included in the shared framework.

Alternatively, .NET Standard 2.0 could be targeted instead of targeting both .NET Core 2.1 and .NET Framework 4.6.1:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFrameworks>netstandard2.0;netcoreapp3.1</TargetFrameworks>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Markdig" Version="0.16.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' != 'netcoreapp3.1'">
    <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor"
Version="2.1.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netcoreapp3.1'">
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>
</Project>
```

With the preceding project file, the following caveats exist:

- Since the library only contains Tag Helpers, it's more straightforward to target the specific platforms on which ASP.NET Core runs: .NET Core and .NET Framework. Tag Helpers can't be used by other .NET Standard 2.0-compliant target frameworks such as Unity, UWP, and Xamarin.
- Using .NET Standard 2.0 from .NET Framework has some issues that were addressed in .NET Framework 4.7.2. You can improve the experience for consumers using .NET Framework 4.6.1 through 4.7.1 by targeting .NET Framework 4.6.1.

If your library needs to call platform-specific APIs, target specific .NET implementations instead of .NET Standard. For more information, see Multi-targeting.

Use an API that hasn't changed

Imagine a scenario in which you're upgrading a middleware library from .NET Core 2.2 to 3.1. The ASP.NET Core middleware APIs being used in the library haven't changed between ASP.NET Core 2.2 and 3.1. To continue supporting the middleware library in .NET Core 3.1, take the following steps:

- Follow the standard library guidance.
- Add a package reference for each API's NuGet package if the corresponding assembly doesn't exist in the shared framework.

Use an API that changed

Imagine a scenario in which you're upgrading a library from .NET Core 2.2 to .NET Core 3.1. An ASP.NET Core API being used in the library has a breaking change in ASP.NET Core 3.1. Consider whether the library can be rewritten to not use the broken API in all versions.

If you can rewrite the library, do so and continue to target an earlier target framework (for example, .NET Standard 2.0 or .NET Framework 4.6.1) with package references.

If you can't rewrite the library, take the following steps:

- Add a target for .NET Core 3.1.
- Add a `<FrameworkReference>` element for the shared framework.
- Use the #if preprocessor directive with the appropriate target framework symbol to conditionally compile code.

For example, synchronous reads and writes on HTTP request and response streams are disabled by default as of ASP.NET Core 3.1. ASP.NET Core 2.2 supports the synchronous behavior by default. Consider a middleware library in which synchronous reads and writes should be enabled where I/O is occurring. The library should enclose the code to enable synchronous features in the appropriate preprocessor directive. For example:

C#

```
public async Task Invoke(HttpContext httpContext)
{
    if (httpContext.Request.Path.StartsWithSegments(_path,
StringComparison.Ordinal))
    {
        httpContext.Response.StatusCode = (int) HttpStatusCode.OK;
        httpContext.Response.ContentType = "application/json";
        httpContext.Response.ContentLength = _bufferSize;
```

```
#if !NETCOREAPP3_1 && !NETCOREAPP5_0
        var syncIOFeature =
httpContext.Features.Get<IHttpBodyControlFeature>();
        if (syncIOFeature != null)
        {
            syncIOFeature.AllowSynchronousIO = true;
        }

        using (var sw = new StreamWriter(
            httpContext.Response.Body, _encoding, bufferSize: _bufferSize))
        {
            _json.Serialize(sw, new JsonMessage { message = "Hello, World!"
});
        }
#else
        await JsonSerializer.SerializeAsync<JsonMessage>(
            httpContext.Response.Body, new JsonMessage { message = "Hello,
World!" });
#endif
        return;
    }

    await _next(httpContext);
}
```

Use an API introduced in 3.1

Imagine that you want to use an ASP.NET Core API that was introduced in ASP.NET Core 3.1. Consider the following questions:

1. Does the library functionally require the new API?
2. Can the library implement this feature in a different way?

If the library functionally requires the API and there's no way to implement it down-level:

- Target .NET Core 3.x only.
- Add a `<FrameworkReference>` element for the shared framework.

If the library can implement the feature in a different way:

- Add .NET Core 3.x as a target framework.
- Add a `<FrameworkReference>` element for the shared framework.
- Use the #if preprocessor directive with the appropriate target framework symbol to conditionally compile code.

For example, the following Tag Helper uses the IWebHostEnvironment interface introduced in ASP.NET Core 3.1. Consumers targeting .NET Core 3.1 execute the code

path defined by the `NETCOREAPP3_1` target framework symbol. The Tag Helper's constructor parameter type changes to IHostingEnvironment for .NET Core 2.1 and .NET Framework 4.6.1 consumers. This change was necessary because ASP.NET Core 3.1 marked `IHostingEnvironment` as obsolete and recommended `IWebHostEnvironment` as the replacement.

C#

```
[HtmlTargetElement("script", Attributes = "asp-inline")]
public class ScriptInliningTagHelper : TagHelper
{
    private readonly IFileProvider _wwwroot;

#if NETCOREAPP3_1
    public ScriptInliningTagHelper(IWebHostEnvironment env)
#else
    public ScriptInliningTagHelper(IHostingEnvironment env)
#endif
    {
        _wwwroot = env.WebRootFileProvider;
    }

    // code omitted for brevity
}
```

The following multi-targeted project file supports this Tag Helper scenario:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFrameworks>netcoreapp2.1;netcoreapp3.1;net461</TargetFrameworks>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Markdig" Version="0.16.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' != 'netcoreapp3.1'">
    <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor"
Version="2.1.0" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netcoreapp3.1'">
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>
</Project>
```

Use an API removed from the shared framework

To use an ASP.NET Core assembly that was removed from the shared framework, add the appropriate package reference. For a list of packages removed from the shared framework in ASP.NET Core 3.1, see Remove obsolete package references.

For example, to add the web API client:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>net6.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNet.WebApi.Client"
Version="5.2.7" />
  </ItemGroup>

</Project>
```

Microsoft.AspNetCore.App for ASP.NET Core

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

The ASP.NET Core shared framework (`Microsoft.AspNetCore.App`) contains assemblies that are developed and supported by Microsoft. `Microsoft.AspNetCore.App` is installed when the .NET Core 3.0 or later SDK is installed. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and includes a runtime component and a targeting pack. For more information, see The shared framework.

- Projects that target the `Microsoft.NET.Sdk.Web` SDK implicitly reference the `Microsoft.AspNetCore.App` framework.

No additional references are required for these projects:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">
  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>
    ...
</Project>
```

The ASP.NET Core shared framework:

- Doesn't include third-party dependencies.
- Includes all supported packages by the ASP.NET Core team.

Microsoft.AspNetCore.All metapackage for ASP.NET Core 2.0

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

> **Note**
>
> The `Microsoft.AspNetCore.All` metapackage isn't used in ASP.NET Core 3.0 and later. For more information, see this GitHub issue.

> **Note**
>
> We recommend applications targeting ASP.NET Core 2.1 and later use the Microsoft.AspNetCore.App metapackage rather than this package. See Migrating from Microsoft.AspNetCore.All to Microsoft.AspNetCore.App in this article.

This feature requires ASP.NET Core 2.x targeting .NET Core 2.x.

Microsoft.AspNetCore.All is a metapackage that refers to a shared framework. A *shared framework* is a set of assemblies (*.dll* files) that are not in the app's folders. The shared framework must be installed on the machine to run the app. For more information, see The shared framework.

The shared framework that `Microsoft.AspNetCore.All` refers to includes:

- All supported packages by the ASP.NET Core team.
- All supported packages by the Entity Framework Core.
- Internal and 3rd-party dependencies used by ASP.NET Core and Entity Framework Core.

All the features of ASP.NET Core 2.x and Entity Framework Core 2.x are included in the `Microsoft.AspNetCore.All` package. The default project templates targeting ASP.NET

Core 2.0 use this package.

The version number of the `Microsoft.AspNetCore.All` metapackage represents the minimum ASP.NET Core version and Entity Framework Core version.

The following `.csproj` file references the `Microsoft.AspNetCore.All` metapackage for ASP.NET Core:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.All" Version="2.0.9" />
  </ItemGroup>

</Project>
```

Implicit versioning

In ASP.NET Core 2.1 or later, you can specify the `Microsoft.AspNetCore.All` package reference without a version. When the version isn't specified, an implicit version is specified by the SDK (`Microsoft.NET.Sdk.Web`). We recommend relying on the implicit version specified by the SDK and not explicitly setting the version number on the package reference. If you have questions about this approach, leave a GitHub comment at the Discussion for the Microsoft.AspNetCore.App implicit version.

The implicit version is set to `major.minor.0` for portable apps. The shared framework roll-forward mechanism runs the app on the latest compatible version among the installed shared frameworks. To guarantee the same version is used in development, test, and production, ensure the same version of the shared framework is installed in all environments. For self-contained apps, the implicit version number is set to the `major.minor.patch` of the shared framework bundled in the installed SDK.

Specifying a version number on the `Microsoft.AspNetCore.All` package reference does **not** guarantee that version of the shared framework is chosen. For example, suppose version "2.1.1" is specified, but "2.1.3" is installed. In that case, the app will use "2.1.3". Although not recommended, you can disable roll forward (patch and/or minor). For more information regarding dotnet host roll-forward and how to configure its behavior, see dotnet host roll forward.

The project's SDK must be set to `Microsoft.NET.Sdk.Web` in the project file to use the implicit version of `Microsoft.AspNetCore.All`. When the `Microsoft.NET.Sdk` SDK is specified (`<Project Sdk="Microsoft.NET.Sdk">` at the top of the project file), the following warning is generated:

Warning NU1604: Project dependency Microsoft.AspNetCore.All does not contain an inclusive lower bound. Include a lower bound in the dependency version to ensure consistent restore results.

This is a known issue with the .NET Core 2.1 SDK and will be fixed in the .NET Core 2.2 SDK.

Migrating from Microsoft.AspNetCore.All to Microsoft.AspNetCore.App

The following packages are included in `Microsoft.AspNetCore.All` but not the `Microsoft.AspNetCore.App` package.

- `Microsoft.AspNetCore.ApplicationInsights.HostingStartup`
- `Microsoft.AspNetCore.AzureAppServices.HostingStartup`
- `Microsoft.AspNetCore.AzureAppServicesIntegration`
- `Microsoft.AspNetCore.DataProtection.AzureKeyVault`
- `Microsoft.AspNetCore.DataProtection.AzureStorage`
- `Microsoft.AspNetCore.Server.Kestrel.Transport.Libuv`
- `Microsoft.AspNetCore.SignalR.Redis`
- `Microsoft.Data.Sqlite`
- `Microsoft.Data.Sqlite.Core`
- `Microsoft.EntityFrameworkCore.Sqlite`
- `Microsoft.EntityFrameworkCore.Sqlite.Core`
- `Microsoft.Extensions.Caching.Redis`
- `Microsoft.Extensions.Configuration.AzureKeyVault`
- `Microsoft.Extensions.Logging.AzureAppServices`
- `Microsoft.VisualStudio.Web.BrowserLink`

To move from `Microsoft.AspNetCore.All` to `Microsoft.AspNetCore.App`, if your app uses any APIs from the above packages, or packages brought in by those packages, add references to those packages in your project.

Any dependencies of the preceding packages that otherwise aren't dependencies of `Microsoft.AspNetCore.App` are not included implicitly. For example:

- `StackExchange.Redis` as a dependency of `Microsoft.Extensions.Caching.Redis`
- `Microsoft.ApplicationInsights` as a dependency of `Microsoft.AspNetCore.ApplicationInsights.HostingStartup`

Update ASP.NET Core 2.1

We recommend migrating to the `Microsoft.AspNetCore.App` metapackage for 2.1 and later. To keep using the `Microsoft.AspNetCore.All` metapackage and ensure the latest patch version is deployed:

- On development machines and build servers: Install the latest .NET Core SDK.
- On deployment servers: Install the latest .NET Core runtime. Your app will roll forward to the latest installed version on an application restart.

High-performance logging in .NET

Article • 04/11/2024

The LoggerMessage class exposes functionality to create cacheable delegates that require fewer object allocations and reduced computational overhead compared to logger extension methods, such as LogInformation and LogDebug. For high-performance logging scenarios, use the LoggerMessage pattern.

LoggerMessage provides the following performance advantages over logger extension methods:

- Logger extension methods require "boxing" (converting) value types, such as `int`, into `object`. The LoggerMessage pattern avoids boxing by using static Action fields and extension methods with strongly typed parameters.
- Logger extension methods must parse the message template (named format string) every time a log message is written. LoggerMessage only requires parsing a template once when the message is defined.

> **Important**
>
> Instead of using the **LoggerMessage class** to create high-performance logs, you can use the **LoggerMessage attribute** in .NET 6 and later versions. The `LoggerMessageAttribute` provides source-generation logging support designed to deliver a highly usable and highly performant logging solution for modern .NET applications. For more information, see **Compile-time logging source generation (.NET Fundamentals)**.

The sample app demonstrates LoggerMessage features with a priority queue processing worker service. The app processes work items in priority order. As these operations occur, log messages are generated using the LoggerMessage pattern.

> **Tip**
>
> All of the logging example source code is available in the **Samples Browser** for download. For more information, see **Browse code samples: Logging in .NET**.

Define a logger message

Use Define(LogLevel, EventId, String) to create an Action delegate for logging a message. Define overloads permit passing up to six type parameters to a named format string (template).

The string provided to the Define method is a template and not an interpolated string. Placeholders are filled in the order that the types are specified. Placeholder names in the template should be descriptive and consistent across templates. They serve as property names within structured log data. We recommend Pascal casing for placeholder names. For example, `{Item}`, `{DateTime}`.

Each log message is an Action held in a static field created by LoggerMessage.Define. For example, the sample app creates a field to describe a log message for the processing of work items:

C#

```
private static readonly Action<ILogger, Exception>
s_failedToProcessWorkItem;
```

For the Action, specify:

- The log level.
- A unique event identifier (EventId) with the name of the static extension method.
- The message template (named format string).

As work items are dequeued for processing, the worker service app sets the:

- Log level to LogLevel.Critical.
- Event ID to `13` with the name of the `FailedToProcessWorkItem` method.
- Message template (named format string) to a string.

C#

```
s_failedToProcessWorkItem = LoggerMessage.Define(
    LogLevel.Critical,
    new EventId(13, nameof(FailedToProcessWorkItem)),
    "Epic failure processing item!");
```

The LoggerMessage.Define method is used to configure and define an Action delegate, which represents a log message.

Structured logging stores may use the event name when it's supplied with the event ID to enrich logging. For example, Serilog uses the event name.

The Action is invoked through a strongly typed extension method. The `PriorityItemProcessed` method logs a message every time a work item is processed. `FailedToProcessWorkItem` is called if and when an exception occurs:

C#

```
protected override async Task ExecuteAsync(
    CancellationToken stoppingToken)
{
    using (IDisposable? scope = logger.ProcessingWorkScope(DateTime.Now))
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            try
            {
                WorkItem? nextItem =
priorityQueue.ProcessNextHighestPriority();

                if (nextItem is not null)
                {
                    logger.PriorityItemProcessed(nextItem);
                }
            }
            catch (Exception ex)
            {
                logger.FailedToProcessWorkItem(ex);
            }

            await Task.Delay(1_000, stoppingToken);
        }
    }
}
```

Inspect the app's console output:

Console

```
crit: WorkerServiceOptions.Example.Worker[13]
      Epic failure processing item!
      System.Exception: Failed to verify communications.
         at
WorkerServiceOptions.Example.Worker.ExecuteAsync(CancellationToken
stoppingToken) in
         ..\Worker.cs:line 27
```

To pass parameters to a log message, define up to six types when creating the static field. The sample app logs the work item details when processing items by defining a `WorkItem` type for the Action field:

C#

```
private static readonly Action<ILogger, WorkItem, Exception>
s_processingPriorityItem;
```

The delegate's log message template receives its placeholder values from the types provided. The sample app defines a delegate for adding a work item where the item parameter is a `WorkItem`:

C#

```
s_processingPriorityItem = LoggerMessage.Define<WorkItem>(
    LogLevel.Information,
    new EventId(1, nameof(PriorityItemProcessed)),
    "Processing priority item: {Item}");
```

The static extension method for logging that a work item is being processed, `PriorityItemProcessed`, receives the work item argument value and passes it to the Action delegate:

C#

```
public static void PriorityItemProcessed(
    this ILogger logger, WorkItem workItem) =>
    s_processingPriorityItem(logger, workItem, default!);
```

In the worker service's `ExecuteAsync` method, `PriorityItemProcessed` is called to log the message:

C#

```
protected override async Task ExecuteAsync(
    CancellationToken stoppingToken)
{
    using (IDisposable? scope = logger.ProcessingWorkScope(DateTime.Now))
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            try
            {
                WorkItem? nextItem =
priorityQueue.ProcessNextHighestPriority();

                if (nextItem is not null)
                {
                    logger.PriorityItemProcessed(nextItem);
                }
            }
```

```
            catch (Exception ex)
            {
                logger.FailedToProcessWorkItem(ex);
            }

            await Task.Delay(1_000, stoppingToken);
        }
    }
}
```

Inspect the app's console output:

Console

```
info: WorkerServiceOptions.Example.Worker[1]
      Processing priority item: Priority-Extreme (50db062a-9732-4418-936d-
110549ad79e4): 'Verify communications'
```

Define logger message scope

The DefineScope(string) method creates a Func<TResult> delegate for defining a log scope. DefineScope overloads permit passing up to six type parameters to a named format string (template).

As is the case with the Define method, the string provided to the DefineScope method is a template and not an interpolated string. Placeholders are filled in the order that the types are specified. Placeholder names in the template should be descriptive and consistent across templates. They serve as property names within structured log data. We recommend Pascal casing for placeholder names. For example, `{Item}`, `{DateTime}`.

Define a log scope to apply to a series of log messages using the DefineScope method. Enable `IncludeScopes` in the console logger section of *appsettings.json*:

JSON

```
{
    "Logging": {
        "Console": {
            "IncludeScopes": true
        },
        "LogLevel": {
            "Default": "Information",
            "Microsoft": "Warning",
            "Microsoft.Hosting.Lifetime": "Information"
        }
```

```
    }
}
```

To create a log scope, add a field to hold a Func<TResult> delegate for the scope. The sample app creates a field named `s_processingWorkScope` (*Internal/LoggerExtensions.cs*):

C#

```
private static readonly Func<ILogger, DateTime, IDisposable?>
s_processingWorkScope;
```

Use DefineScope to create the delegate. Up to six types can be specified for use as template arguments when the delegate is invoked. The sample app uses a message template that includes the date time in which processing started:

C#

```
s_processingWorkScope =
    LoggerMessage.DefineScope<DateTime>(
        "Processing scope, started at: {DateTime}");
```

Provide a static extension method for the log message. Include any type parameters for named properties that appear in the message template. The sample app takes in a `DateTime` for a custom time stamp to log and returns `_processingWorkScope`:

C#

```
public static IDisposable? ProcessingWorkScope(
    this ILogger logger, DateTime time) =>
    s_processingWorkScope(logger, time);
```

The scope wraps the logging extension calls in a using block:

C#

```
protected override async Task ExecuteAsync(
    CancellationToken stoppingToken)
{
    using (IDisposable? scope = logger.ProcessingWorkScope(DateTime.Now))
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            try
            {
                WorkItem? nextItem =
priorityQueue.ProcessNextHighestPriority();
```

```
                if (nextItem is not null)
                {
                    logger.PriorityItemProcessed(nextItem);
                }
            }
            catch (Exception ex)
            {
                logger.FailedToProcessWorkItem(ex);
            }

            await Task.Delay(1_000, stoppingToken);
        }
    }
}
```

Inspect the log messages in the app's console output. The following result shows priority ordering of log messages with the log scope message included:

Console

```
info: WorkerServiceOptions.Example.Worker[1]
      => Processing scope, started at: 04/11/2024 11:27:52
      Processing priority item: Priority-Extreme (7d153ef9-8894-4282-836a-

03368e60bd6b): 'Set process state'
info: Microsoft.Hosting.Lifetime[0]
      Application is shutting down...
```

Log level guarded optimizations

Another performance optimization can be made by checking the LogLevel, with ILogger.IsEnabled(LogLevel) before an invocation to the corresponding `Log*` method. When logging isn't configured for the given `LogLevel`, the following statements are true:

- ILogger.Log isn't called.
- An allocation of `object[]` representing the parameters is avoided.
- Value type boxing is avoided.

For more information:

- Micro benchmarks in the .NET runtime
- Background and motivation for log level checks

Develop ASP.NET Core apps using a file watcher

Article • 05/31/2024

By Rick Anderson and Victor Hurdugaci

`dotnet watch` is a tool that runs a .NET CLI command when source files change. For example, a file change can trigger compilation, test execution, or deployment.

This tutorial uses an existing web API with two endpoints: one that returns a sum and one that returns a product. The product method has a bug, which is fixed in this tutorial.

Download the sample app. It consists of two projects: *WebApp* (an ASP.NET Core web API) and *WebAppTests* (unit tests for the web API).

In a command shell, navigate to the *WebApp* folder. Run the following command:

.NET CLI

```
dotnet run
```

> **Note**
>
> You can use `dotnet run --project <PROJECT>` to specify a project to run. For example, running `dotnet run --project WebApp` from the root of the sample app will also run the *WebApp* project.

The console output shows messages similar to the following (indicating that the app is running and awaiting requests):

Console

```
$ dotnet run
Hosting environment: Development
Content root path: C:/Docs/aspnetcore/tutorials/dotnet-watch/sample/WebApp
Now listening on: http://localhost:5000
Application started. Press Ctrl+C to shut down.
```

In a web browser, navigate to `http://localhost:<port number>/api/math/sum?a=4&b=5`. You should see the result of `9`.

Navigate to the product API (`http://localhost:<port number>/api/math/product?a=4&b=5`). It returns `9`, not `20` as you'd expect. That problem is fixed later in the tutorial.

Run .NET CLI commands using `dotnet watch`

Any .NET CLI command can be run with `dotnet watch`. For example:

Expand table

Command	Command with watch
dotnet run	dotnet watch run
dotnet run -f netcoreapp3.1	dotnet watch run -f netcoreapp3.1
dotnet run -f netcoreapp3.1 -- --arg1	dotnet watch run -f netcoreapp3.1 -- --arg1
dotnet test	dotnet watch test

Run `dotnet watch run` in the *WebApp* folder. The console output indicates `watch` has started.

Running `dotnet watch run` on a web app launches a browser that navigates to the app's URL once ready. `dotnet watch` does this by reading the app's console output and waiting for the ready message displayed by WebHost.

`dotnet watch` refreshes the browser when it detects changes to watched files. To do this, the watch command injects a middleware to the app that modifies HTML responses created by the app. The middleware adds a JavaScript script block to the page that allows `dotnet watch` to instruct the browser to refresh. Currently, changes to all watched files, including static content such as `.html` and `.css` files cause the app to be rebuilt.

`dotnet watch`:

- Only watches files that impact builds by default.
- Any additionally watched files (via configuration) still results in a build taking place.

For more information on configuration, see dotnet-watch configuration in this document.

> **Note**
>
> You can use `dotnet watch --project <PROJECT>` to specify a project to watch. For example, running `dotnet watch --project WebApp run` from the root of the sample

app will also run and watch the *WebApp* project.

Make changes with `dotnet watch`

Make sure `dotnet watch` is running.

Fix the bug in the `Product` method of `MathController.cs` so it returns the product and not the sum:

```C#
public static int Product(int a, int b)
{
    return a * b;
}
```

Save the file. The console output indicates that `dotnet watch` detected a file change and restarted the app.

Verify `http://localhost:<port number>/api/math/product?a=4&b=5` returns the correct result.

Run tests using `dotnet watch`

1. Change the `Product` method of `MathController.cs` back to returning the sum. Save the file.
2. In a command shell, navigate to the *WebAppTests* folder.
3. Run dotnet restore.
4. Run `dotnet watch test`. Its output indicates that a test failed and that the watcher is awaiting file changes:

   ```Console
   Total tests: 2. Passed: 1. Failed: 1. Skipped: 0.
   Test Run Failed.
   ```

5. Fix the `Product` method code so it returns the product. Save the file.

`dotnet watch` detects the file change and reruns the tests. The console output indicates the tests passed.

Customize files list to watch

By default, `dotnet-watch` tracks all files matching the following glob patterns:

- `**/*.cs`
- `*.csproj`
- `**/*.resx`
- Content files: `wwwroot/**`, `**/*.config`, `**/*.json`

More items can be added to the watch list by editing the `.csproj` file. Items can be specified individually or by using glob patterns.

XML

```
<ItemGroup>
    <!-- extends watching group to include *.js files -->
    <Watch Include="**\*.js"
Exclude="node_modules\**\*;**\*.js.map;obj\**\*;bin\**\*" />
</ItemGroup>
```

Opt-out of files to be watched

`dotnet-watch` can be configured to ignore its default settings. To ignore specific files, add the `Watch="false"` attribute to an item's definition in the `.csproj` file:

XML

```
<ItemGroup>
    <!-- exclude Generated.cs from dotnet-watch -->
    <Compile Include="Generated.cs" Watch="false" />

    <!-- exclude Strings.resx from dotnet-watch -->
    <EmbeddedResource Include="Strings.resx" Watch="false" />

    <!-- exclude changes in this referenced project -->
    <ProjectReference Include="..\ClassLibrary1\ClassLibrary1.csproj"
Watch="false" />
</ItemGroup>
```

XML

```
<ItemGroup>
     <!-- Exclude all Content items from being watched. -->
    <Content Update="@(Content)" Watch="false" />
</ItemGroup>
```

Custom watch projects

`dotnet-watch` isn't restricted to C# projects. Custom watch projects can be created to handle different scenarios. Consider the following project layout:

- **test/**
  - `UnitTests/UnitTests.csproj`
  - `IntegrationTests/IntegrationTests.csproj`

If the goal is to watch both projects, create a custom project file configured to watch both projects:

XML

```xml
<Project>
    <ItemGroup>
        <TestProjects Include="**\*.csproj" />
        <Watch Include="**\*.cs" />
    </ItemGroup>

    <Target Name="Test">
        <MSBuild Targets="VSTest" Projects="@(TestProjects)" />
    </Target>

    <Import Project="$(MSBuildExtensionsPath)\Microsoft.Common.targets" />
</Project>
```

To start file watching on both projects, change to the *test* folder. Execute the following command:

.NET CLI

```dotnetcli
dotnet watch msbuild /t:Test
```

VSTest executes when any file changes in either test project.

dotnet-watch configuration

Some configuration options can be passed to `dotnet watch` through environment variables. The available variables are:

Expand table

Setting	Description
`DOTNET_USE_POLLING_FILE_WATCHER`	If set to "1" or "true", `dotnet watch` uses a polling file watcher instead of CoreFx's `FileSystemWatcher`. Used when watching files on network shares or Docker mounted volumes.
`DOTNET_WATCH_SUPPRESS_MSBUILD_INCREMENTALISM`	By default, `dotnet watch` optimizes the build by avoiding certain operations such as running restore or re-evaluating the set of watched files on every file change. If set to "1" or "true", these optimizations are disabled.
`DOTNET_WATCH_SUPPRESS_LAUNCH_BROWSER`	`dotnet watch run` attempts to launch browsers for web apps with `launchBrowser` configured in `launchSettings.json`. If set to "1" or "true", this behavior is suppressed.
`DOTNET_WATCH_SUPPRESS_BROWSER_REFRESH`	`dotnet watch run` attempts to refresh browsers when it detects file changes. If set to "1" or "true", this behavior is suppressed. This behavior is also suppressed if `DOTNET_WATCH_SUPPRESS_LAUNCH_BROWSER` is set.

Browser refresh

`dotnet watch` injects a script into the app that allows it to refresh the browser when the content changes. In some scenarios, such as when the app enables response compression, `dotnet watch` might ***not*** be able to inject the script. For such cases in development, manually inject the script into the app. For example, to configure the web app to manually inject the script, update the layout file to include `_framework/aspnet-browser-refresh.js`:

razor

```razor
@* _Layout.cshtml *@
<environment names="Development">
    <script src="/_framework/aspnetcore-browser-refresh.js"></script>
</environment>
```

Non-ASCII characters

Visual Studio 17.2 and later includes the .NET SDK 6.0.300 and later. With the .NET SDK and 6.0.300 later, `dotnet-watch` emits non-ASCII characters to the console during a hot

reload session. On certain console hosts, such as the Windows conhost, these characters may appear garbled. To avoid garbled characters, consider one of the following approaches:

- Configure the `DOTNET_WATCH_SUPPRESS_EMOJIS=1` environment variable to suppress emitting these values.
- Switch to a different terminal, such as https://github.com/microsoft/terminal, that supports rendering non-ASCII characters.

Factory-based middleware activation in ASP.NET Core

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

IMiddlewareFactory/IMiddleware is an extensibility point for middleware activation that offers the following benefits:

- Activation per client request (injection of scoped services)
- Strong typing of middleware

UseMiddleware extension methods check if a middleware's registered type implements IMiddleware. If it does, the IMiddlewareFactory instance registered in the container is used to resolve the IMiddleware implementation instead of using the convention-based middleware activation logic. The middleware is registered as a scoped or transient service in the app's service container.

IMiddleware is activated per client request (connection), so scoped services can be injected into the middleware's constructor.

IMiddleware

IMiddleware defines middleware for the app's request pipeline. The InvokeAsync(HttpContext, RequestDelegate) method handles requests and returns a Task that represents the execution of the middleware.

Middleware activated by convention:

C#

```
public class ConventionalMiddleware
{
    private readonly RequestDelegate _next;

    public ConventionalMiddleware(RequestDelegate next)
```

```
        => _next = next;

    public async Task InvokeAsync(HttpContext context, SampleDbContext
dbContext)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            dbContext.Requests.Add(new Request("Conventional", keyValue));

            await dbContext.SaveChangesAsync();
        }

        await _next(context);
    }
}
```

Middleware activated by MiddlewareFactory:

C#

```
public class FactoryActivatedMiddleware : IMiddleware
{
    private readonly SampleDbContext _dbContext;

    public FactoryActivatedMiddleware(SampleDbContext dbContext)
        => _dbContext = dbContext;

    public async Task InvokeAsync(HttpContext context, RequestDelegate next)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            _dbContext.Requests.Add(new Request("Factory", keyValue));

            await _dbContext.SaveChangesAsync();
        }

        await next(context);
    }
}
```

Extensions are created for the middleware:

C#

```
public static class MiddlewareExtensions
{
    public static IApplicationBuilder UseConventionalMiddleware(
        this IApplicationBuilder app)
```

```
        => app.UseMiddleware<ConventionalMiddleware>();

    public static IApplicationBuilder UseFactoryActivatedMiddleware(
        this IApplicationBuilder app)
        => app.UseMiddleware<FactoryActivatedMiddleware>();
}
```

It isn't possible to pass objects to the factory-activated middleware with UseMiddleware:

C#

```
public static IApplicationBuilder UseFactoryActivatedMiddleware(
    this IApplicationBuilder app, bool option)
{
    // Passing 'option' as an argument throws a NotSupportedException at
runtime.
    return app.UseMiddleware<FactoryActivatedMiddleware>(option);
}
```

The factory-activated middleware is added to the built-in container in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddDbContext<SampleDbContext>
    (options => options.UseInMemoryDatabase("SampleDb"));

builder.Services.AddTransient<FactoryActivatedMiddleware>();
```

Both middleware are registered in the request processing pipeline, also in `Program.cs`:

C#

```
var app = builder.Build();

app.UseConventionalMiddleware();
app.UseFactoryActivatedMiddleware();
```

IMiddlewareFactory

IMiddlewareFactory provides methods to create middleware. The middleware factory implementation is registered in the container as a scoped service.

The default IMiddlewareFactory implementation, MiddlewareFactory, is found in the Microsoft.AspNetCore.Http package.

Middleware activation with a third-party container in ASP.NET Core

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article demonstrates how to use IMiddlewareFactory and IMiddleware as an extensibility point for middleware activation with a third-party container. For introductory information on `IMiddlewareFactory` and `IMiddleware`, see Factory-based middleware activation in ASP.NET Core.

View or download sample code (how to download)

The sample app demonstrates middleware activation by an `IMiddlewareFactory` implementation, `SimpleInjectorMiddlewareFactory`. The sample uses the Simple Injector dependency injection (DI) container.

The sample's middleware implementation records the value provided by a query string parameter (`key`). The middleware uses an injected database context (a scoped service) to record the query string value in an in-memory database.

> **Note**
>
> The sample app uses Simple Injector purely for demonstration purposes. Use of Simple Injector isn't an endorsement. Middleware activation approaches described in the Simple Injector documentation and GitHub issues are recommended by the maintainers of Simple Injector. For more information, see the Simple Injector documentation and Simple Injector GitHub repository.

IMiddlewareFactory

IMiddlewareFactory provides methods to create middleware.

In the sample app, a middleware factory is implemented to create a `SimpleInjectorActivatedMiddleware` instance. The middleware factory uses the Simple Injector container to resolve the middleware:

C#

```
public class SimpleInjectorMiddlewareFactory : IMiddlewareFactory
{
    private readonly Container _container;

    public SimpleInjectorMiddlewareFactory(Container container)
    {
        _container = container;
    }

    public IMiddleware Create(Type middlewareType)
    {
        return _container.GetInstance(middlewareType) as IMiddleware;
    }

    public void Release(IMiddleware middleware)
    {
        // The container is responsible for releasing resources.
    }
}
```

IMiddleware

IMiddleware defines middleware for the app's request pipeline.

Middleware activated by an `IMiddlewareFactory` implementation (`Middleware/SimpleInjectorActivatedMiddleware.cs`):

C#

```
public class SimpleInjectorActivatedMiddleware : IMiddleware
{
    private readonly AppDbContext _db;

    public SimpleInjectorActivatedMiddleware(AppDbContext db)
    {
        _db = db;
    }

    public async Task InvokeAsync(HttpContext context, RequestDelegate next)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
```

```
        {
            _db.Add(new Request()
                {
                    DT = DateTime.UtcNow,
                    MiddlewareActivation =
"SimpleInjectorActivatedMiddleware",
                    Value = keyValue
                });

            await _db.SaveChangesAsync();
        }

        await next(context);
    }
}
```

An extension is created for the middleware (`Middleware/MiddlewareExtensions.cs`):

C#

```
public static class MiddlewareExtensions
{
    public static IApplicationBuilder UseSimpleInjectorActivatedMiddleware(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<SimpleInjectorActivatedMiddleware>();
    }
}
```

`Startup.ConfigureServices` must perform several tasks:

- Set up the Simple Injector container.
- Register the factory and middleware.
- Make the app's database context available from the Simple Injector container.

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    // Replace the default middleware factory with the
    // SimpleInjectorMiddlewareFactory.
    services.AddTransient<IMiddlewareFactory>(_ =>
    {
        return new SimpleInjectorMiddlewareFactory(_container);
    });

    // Wrap ASP.NET Core requests in a Simple Injector execution
    // context.
    services.UseSimpleInjectorAspNetRequestScoping(_container);
```

```
    // Provide the database context from the Simple
    // Injector container whenever it's requested from
    // the default service container.
    services.AddScoped<AppDbContext>(provider =>
        _container.GetInstance<AppDbContext>());

    _container.Options.DefaultScopedLifestyle = new AsyncScopedLifestyle();

    _container.Register<AppDbContext>(() =>
    {
        var optionsBuilder = new DbContextOptionsBuilder<DbContext>();
        optionsBuilder.UseInMemoryDatabase("InMemoryDb");
        return new AppDbContext(optionsBuilder.Options);
    }, Lifestyle.Scoped);

    _container.Register<SimpleInjectorActivatedMiddleware>();

    _container.Verify();
}
```

The middleware is registered in the request processing pipeline in `Startup.Configure`:

C#

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseSimpleInjectorActivatedMiddleware();

    app.UseStaticFiles();
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

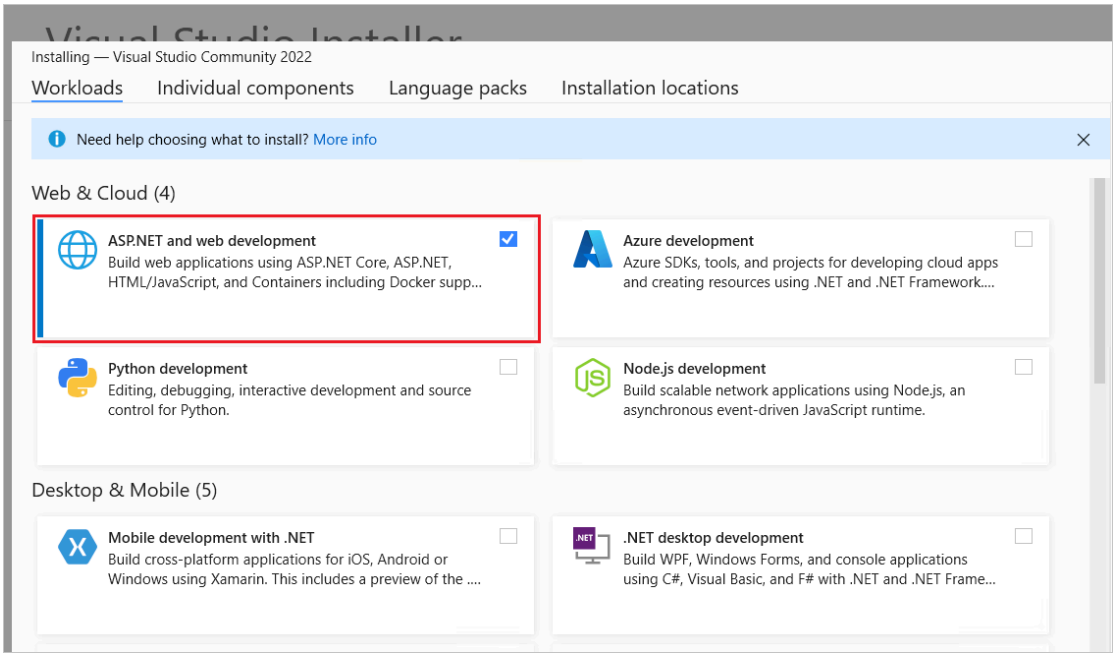
Migrate from ASP.NET Core in .NET 8 to ASP.NET Core in .NET 9



Article • 11/06/2024

This article explains how to update an ASP.NET Core in .NET 8 to ASP.NET Core in .NET 9.

Prerequisites

Visual Studio

- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.

Update the .NET SDK version in `global.json`

If you rely on a global.json file to target a specific .NET Core SDK version, update the `version` property to the .NET 9.0 SDK version that's installed. For example:

diff

```
{
  "sdk": {
-    "version": "8.0.100"
```

```
+    "version": "9.0.100"
  }
}
```

Update the target framework

Update the project file's Target Framework Moniker (TFM) to `net9.0`:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
-    <TargetFramework>net8.0</TargetFramework>
+    <TargetFramework>net9.0</TargetFramework>
  </PropertyGroup>

</Project>
```

Update package references

In the project file, update each Microsoft.AspNetCore.* , Microsoft.EntityFrameworkCore.* , Microsoft.Extensions.* , and System.Net.Http.Json package reference's `Version` attribute to 9.0.0 or later. For example:

diff

```
<ItemGroup>
-   <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="8.0.2" />
-   <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="8.0.2" />
-   <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="8.0.0" />
-   <PackageReference Include="System.Net.Http.Json" Version="8.0.0" />
+   <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="9.0.0" />
+   <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="9.0.0" />
+   <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="9.0.0" />
+   <PackageReference Include="System.Net.Http.Json" Version="9.0.0" />
</ItemGroup>
```

Replace `UseStaticFiles` with `MapStaticAssets`

Optimize the handling of static files in your web apps by replacing UseStaticFiles with MapStaticAssets in the app's `Program` file:

diff

```
- app.UseStaticFiles();
+ app.MapStaticAssets();
```

In MVC & Razor Pages apps you additionally need to chain a call to `.WithStaticAssets` after `MapRazorPages` or `MapControllerRoute` in `Program.cs`. For an example, see the Static files in ASP.NET Core.

ASP.NET Core automatically fingerprints and precompresses your static files at build and publish time, and then MapStaticAssets surfaces the optimized files as endpoints using endpoint routing with appropriate caching headers.

To resolve the fingerprinted file names from your app:

- In Blazor apps, use the ComponentBase.Assets property. Update explicit references to static assets in Razor component files (`.razor`) to use `@Assets["{ASSET PATH}"]`, where the `{ASSET PATH}` placeholder is the path to the asset. Note that this should ***NOT*** be done for the Blazor framework scripts (`blazor.*.js`). In the following example, Bootstrap, the Blazor project template app stylesheet (`app.css`), and the CSS isolation stylesheet (based on an app's namespace of `BlazorSample`) are linked in a root component, typically the `App` component (`Components/App.razor`):

  razor

  ```
  <link rel="stylesheet" href="@Assets["bootstrap/bootstrap.min.css"]" />
  <link rel="stylesheet" href="@Assets["app.css"]" />
  <link rel="stylesheet" href="@Assets["BlazorSample.styles.css"]" />
  ```

- In MVC & Razor Pages apps, the script and link tag helpers will automatically resolve the fingerprinted file names.

To resolve the fingerprinted file names when importing JavaScript modules, add a generated import map:

- In Blazor apps, add the (ImportMap) component to the `<head>` content of the app's root component, typically in the `App` component (`App.razor`):

  razor

```
<ImportMap />
```

- In MVC & Razor pages apps, add `<script type="importmap"></script>` to the head of the main layout file, which is updated by the Import Map Tag Helper.

For more information, see the following resources:

- What's new in ASP.NET Core 9.0
- ASP.NET Core Blazor static files

Blazor

Adopt simplified authentication state serialization for Blazor Web Apps

Blazor Web Apps can optionally adopt simplified authentication state serialization.

In the server project:

- Remove the Persisting Authentication State Provider (`PersistingAuthenticationStateProvider.cs`).

- Remove the service registration from the `Program` file. Instead, chain a call to AddAuthenticationStateSerialization on AddRazorComponents:

diff

```
- builder.Services.AddScoped<AuthenticationStateProvider,
PersistingAuthenticationStateProvider>();

  builder.Services.AddRazorComponents()
      .AddInteractiveServerComponents()
      .AddInteractiveWebAssemblyComponents()
+     .AddAuthenticationStateSerialization();
```

The API only serializes the server-side name and role claims for access in the browser. To include all claims, set SerializeAllClaims to `true`:

C#

```
.AddAuthenticationStateSerialization(options => options.SerializeAllClaims =
true);
```

In the client project (`.Client`):

- Remove the Persistent Authentication State Provider (`PersistentAuthenticationStateProvider.cs`).
- Remove the service registration from the `Program` file. Instead, call AddAuthenticationStateDeserialization on the service collection:

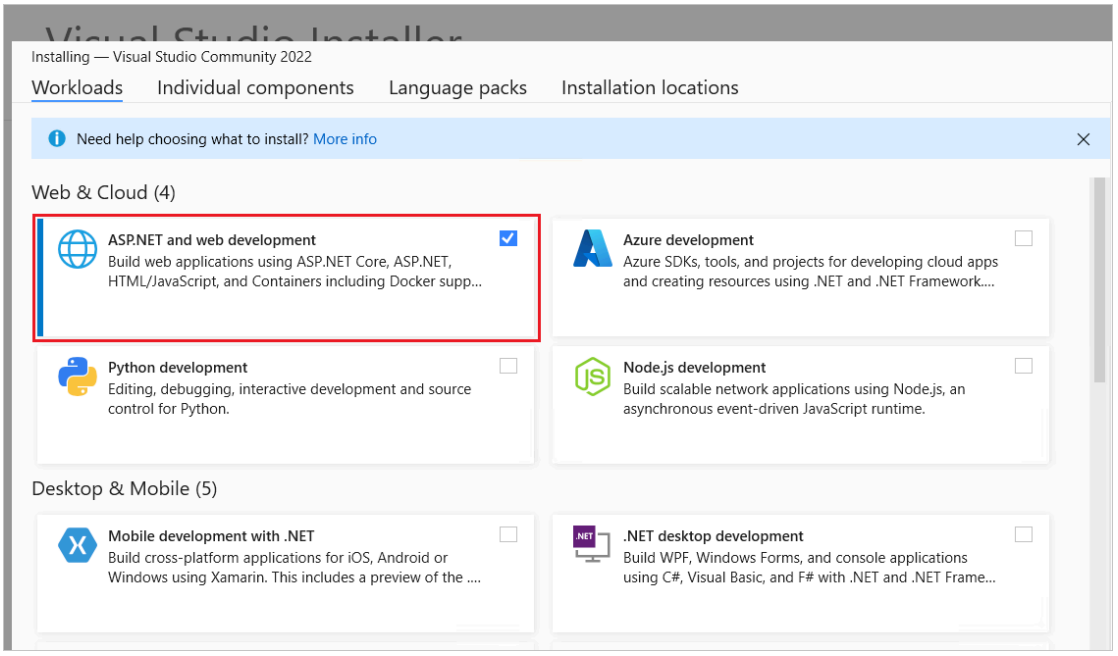
  diff

  ```
  - builder.Services.AddSingleton<AuthenticationStateProvider,
  PersistentAuthenticationStateProvider>();
  + builder.Services.AddAuthenticationStateDeserialization();
  ```

For more information, see What's new in ASP.NET Core 9.0.

Additional resources

Migrate from ASP.NET Core in .NET 7 to .NET 8



Article • 10/25/2024

This article explains how to update an existing ASP.NET Core 7.0 project to ASP.NET Core 8.0.

Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.

Update the .NET SDK version in `global.json`

If you rely on a global.json file to target a specific .NET Core SDK version, update the `version` property to the .NET 8.0 SDK version that's installed. For example:

diff

```
{
  "sdk": {
-    "version": "7.0.100"
+    "version": "8.0.100"
```

```
  }
}
```

Update the target framework

Update the project file's Target Framework Moniker (TFM) to `net8.0`:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
-    <TargetFramework>net7.0</TargetFramework>
+    <TargetFramework>net8.0</TargetFramework>
  </PropertyGroup>

</Project>
```

Update package references

In the project file, update each Microsoft.AspNetCore.* , Microsoft.EntityFrameworkCore.* , Microsoft.Extensions.* , and System.Net.Http.Json package reference's `Version` attribute to 8.00 or later. For example:

diff

```
<ItemGroup>
-   <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="7.0.12" />
-   <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="7.0.12" />
-   <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="7.0.0" />
-   <PackageReference Include="System.Net.Http.Json" Version="7.0.1" />
+   <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="8.0.0" />
+   <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="8.0.0" />
+   <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="8.0.0" />
+   <PackageReference Include="System.Net.Http.Json" Version="8.0.0" />
</ItemGroup>
```

Blazor

The following migration scenarios are covered:

- Update a Blazor Server app
- Adopt all Blazor Web App conventions
- Convert a Blazor Server app into a Blazor Web App
- Update a Blazor WebAssembly app
- Convert a hosted Blazor WebAssembly app into a Blazor Web App
- Update service and endpoint option configuration
- Drop Blazor Server with Yarp routing workaround
- Migrate CascadingValue components in layout components
- Migrate the BlazorEnableCompression MSBuild property
- Migrate the <CascadingAuthenticationState> component to cascading authentication state services
- *New article*: HTTP caching issues during migration
- *New article*: New article on class libraries with static server-side rendering (static SSR)
- Discover components from additional assemblies
- Drop [Parameter] attribute when the parameter is supplied from a query string
- Blazor Server script fallback policy authorization

For guidance on adding Blazor support to an ASP.NET Core app, see Integrate ASP.NET Core Razor components into ASP.NET Core apps.

Update a Blazor Server app

We recommend using Blazor Web Apps in .NET 8, but Blazor Server is supported. To continue using Blazor Server with .NET 8, follow the guidance in the first three sections of this article:

- Update the .NET SDK version in global.json
- Update the target framework
- Update package references

New Blazor features introduced for Blazor Web Apps aren't available to a Blazor Server app updated to run under .NET 8. If you wish to adopt the new .NET 8 Blazor features, follow the guidance in either of the following sections:

- Adopt all Blazor Web App conventions
- Convert a Blazor Server app into a Blazor Web App

Adopt all Blazor Web App conventions

To optionally adopt all of the new Blazor Web App conventions, we recommend the following process:

- Create a new app from the Blazor Web App project template. For more information, see Tooling for ASP.NET Core Blazor.
- Move the your app's components and code to the new Blazor Web App, making modifications to adopt new features.
- Update the layout and styles of the Blazor Web App.

New .NET 8 features are covered in What's new in ASP.NET Core 8.0. When updating an app from .NET 6 or earlier, see the migration and release notes (*What's new* articles) for intervening releases.

Convert a Blazor Server app into a Blazor Web App

Blazor Server apps are supported in .NET 8 without any code changes. Use the following guidance to convert a Blazor Server app into an equivalent .NET 8 Blazor Web App, which makes all of the new .NET 8 features available.

> **ⓘ Important**
>
> This section focuses on the minimal changes required to convert a .NET 7 Blazor Server app into a .NET 8 Blazor Web App. To adopt all of the new Blazor Web App conventions, follow the guidance in the **Adopt all Blazor Web App conventions** section.

1. Follow the guidance in the first three sections of this article:
   - Update the .NET SDK version in global.json
   - Update the target framework
   - Update package references
2. Move the contents of the `App` component (`App.razor`) to a new `Routes` component file (`Routes.razor`) added to the project's root folder. Leave the empty `App.razor` file in the app in the project's root folder.
3. Add an entry to the `_Imports.razor` file to make shorthand render modes available to the app:

   razor

   ```
   @using static Microsoft.AspNetCore.Components.Web.RenderMode
   ```

4. Move the content in the `_Host` page (`Pages/_Host.cshtml`) to the empty `App.razor` file. Proceed to make the following changes to the `App` component.

> **Note**
>
> In the following example, the project's namespace is `BlazorServerApp`. Adjust the namespace to match your project.

Remove the following lines from the top of the file:

```
diff
- @page "/"
- @using Microsoft.AspNetCore.Components.Web
- @namespace BlazorServerApp.Pages
- @addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

Replace the preceding lines with a line that injects an IHostEnvironment instance:

```
razor
@inject IHostEnvironment Env
```

Remove the tilde (`~`) from the `href` of the `<base>` tag and replace with the base path for your app:

```
diff
- <base href="~/" />
+ <base href="/" />
```

Remove the Component Tag Helper for the HeadOutlet component and replace it with the HeadOutlet component.

Remove the following line:

```
diff
- <component type="typeof(HeadOutlet)" render-mode="ServerPrerendered"
/>
```

Replace the preceding line with the following:

```
```

razor

```razor
<HeadOutlet @rendermode="InteractiveServer" />
```

Remove the Component Tag Helper for the `App` component and replace it with the `Routes` component.

Remove the following line:

diff

```diff
- <component type="typeof(App)" render-mode="ServerPrerendered" />
```

Replace the preceding line with the following:

razor

```razor
<Routes @rendermode="InteractiveServer" />
```

> **Note**
>
> The preceding configuration assumes that the app's components adopt interactive server rendering. For more information, including how to adopt static server-side rendering (SSR), see ASP.NET Core Blazor render modes.

Remove the Environment Tag Helpers for error UI and replace them with the following Razor markup.

Remove the following lines:

diff

```diff
- <environment include="Staging,Production">
-     An error has occurred. This application may no longer respond
until reloaded.
- </environment>
- <environment include="Development">
-     An unhandled exception has occurred. See browser dev tools for
details.
- </environment>
```

Replace the preceding lines with the following:

razor

```
@if (Env.IsDevelopment())
{
    <text>
        An unhandled exception has occurred. See browser dev tools for
details.
    </text>
}
else
{
    <text>
        An error has occurred. This app may no longer respond until
reloaded.
    </text>
}
```

Change the Blazor script from `blazor.server.js` to `blazor.web.js`:

diff

```
- <script src="_framework/blazor.server.js"></script>
+ <script src="_framework/blazor.web.js"></script>
```

5. Delete the `Pages/_Host.cshtml` file.

6. Update `Program.cs`:

> **Note**
>
> In the following example, the project's namespace is `BlazorServerApp`. Adjust the namespace to match your project.

Add a `using` statement to the top of the file for the project's namespace:

C#

```
using BlazorServerApp;
```

Replace AddServerSideBlazor with AddRazorComponents and a chained call to AddInteractiveServerComponents.

Remove the following line:

diff

```
- builder.Services.AddServerSideBlazor();
```

Replace the preceding line with Razor component and interactive server component services. Calling AddRazorComponents adds antiforgery services (AddAntiforgery) by default.

C#

```
builder.Services.AddRazorComponents()
    .AddInteractiveServerComponents();
```

Remove the following line:

diff

```
- app.MapBlazorHub();
```

Replace the preceding line with a call to MapRazorComponents, supplying the `App` component as the root component type, and add a chained call to AddInteractiveServerRenderMode:

C#

```
app.MapRazorComponents<App>()
    .AddInteractiveServerRenderMode();
```

Remove the following line:

diff

```
- app.MapFallbackToPage("/_Host");
```

Remove Routing Middleware:

diff

```
- app.UseRouting();
```

Add Antiforgery Middleware to the request processing pipeline after the line that adds HTTPS Redirection Middleware (`app.UseHttpsRedirection`):

C#

```
app.UseAntiforgery();
```

The preceding call to `app.UseAntiforgery` must be placed after calls, if present, to `app.UseAuthentication` and `app.UseAuthorization`. There's no need to explicitly add antiforgery services (`builder.Services.AddAntiforgery`), as they're added automatically by AddRazorComponents, which was covered earlier.

7. If the Blazor Server app was configured to disable prerendering, you can continue to disable prerendering for the updated app. In the `App` component, change the value assigned to the `@rendermode` Razor directive attributes for the HeadOutlet and `Routes` components.

   Change the value of the `@rendermode` directive attribute for both the HeadOutlet and `Routes` components to disable prerendering:

   ```
   diff
   ```

   ```
   - @rendermode="InteractiveServer"
   + @rendermode="new InteractiveServerRenderMode(prerender: false)"
   ```

   For more information, see ASP.NET Core Blazor render modes.

Update a Blazor WebAssembly app

Follow the guidance in the first three sections of this article:

- Update the .NET SDK version in global.json
- Update the target framework
- Update package references

For apps that adopt lazy assembly loading, change the file extension from `.dll` to `.wasm` in the app's implementation to reflect Blazor WebAssembly's adoption of Webcil assembly packaging.

Prior to the release of .NET 8, guidance in Deployment layout for ASP.NET Core hosted Blazor WebAssembly apps addresses environments that block clients from downloading and executing DLLs with a multipart bundling approach. In .NET 8 or later, Blazor uses the Webcil file format to address this problem. Multipart bundling using the experimental NuGet package described by the *WebAssembly deployment layout* article isn't supported for Blazor apps in .NET 8 or later. If you desire to continue using the multipart bundle package in .NET 8 or later apps, you can use the guidance in the article

to create your own multipart bundling NuGet package, but it won't be supported by Microsoft.

Convert a hosted Blazor WebAssembly app into a Blazor Web App

Blazor WebAssembly apps are supported in .NET 8 without any code changes. Use the following guidance to convert an ASP.NET Core hosted Blazor WebAssembly app into an equivalent .NET 8 Blazor Web App, which makes all of the new .NET 8 features available.

> **ⓘ Important**
>
> This section focuses on the minimal changes required to convert a .NET 7 ASP.NET Core hosted Blazor WebAssembly app into a .NET 8 Blazor Web App. To adopt all of the new Blazor Web App conventions, follow the guidance in the **Adopt all Blazor Web App conventions** section.

1. Follow the guidance in the first three sections of this article:

   - Update the .NET SDK version in global.json
   - Update the target framework
   - Update package references

   > **ⓘ Important**
   >
   > Using the preceding guidance, update the `.Client`, `.Server`, and `.Shared` projects of the solution.

2. In the `.Client` project file (`.csproj`), add the following MSBuild properties:

   XML

   ```xml
   <NoDefaultLaunchSettingsFile>true</NoDefaultLaunchSettingsFile>
   <StaticWebAssetProjectMode>Default</StaticWebAssetProjectMode>
   ```

   Also in the `.Client` project file, remove the Microsoft.AspNetCore.Components.WebAssembly.DevServer package reference:

   diff

   ```
   - <PackageReference
   ```

```
Include="Microsoft.AspNetCore.Components.WebAssembly.DevServer"... />
```

3. Move the file content from the `.Client/wwwroot/index.html` file to a new `App` component file (`App.razor`) created at the root of the `.Server` project. After you move the file's contents, delete the `index.html` file.

   Rename `App.razor` in the `.Client` project to `Routes.razor`.

   In `Routes.razor`, update the value of the `AppAssembly` attribute to `typeof(Program).Assembly`.

4. In the `.Client` project, add an entry to the `_Imports.razor` file to make shorthand render modes available to the app:

   ```razor
   @using static Microsoft.AspNetCore.Components.Web.RenderMode
   ```

   Make a copy of the `.Client` project's `_Imports.razor` file and add it to the `.Server` project.

5. Make the following changes to the `App.razor` file:

   Replace the website's default website title (`<title>...</title>`) with a HeadOutlet component. Note the website title for use later and remove the title tags and title:

   ```diff
   - <title>...</title>
   ```

   Where you removed the title, place a HeadOutlet component assigning the Interactive WebAssembly render mode (prerendering disabled):

   ```razor
   <HeadOutlet @rendermode="new
   InteractiveWebAssemblyRenderMode(prerender: false)" />
   ```

   Change the CSS style bundle:

   ```diff
   - <link href="{CLIENT PROJECT ASSEMBLY NAME}.styles.css"
   rel="stylesheet">
   ```

```
+ <link href="{SERVER PROJECT ASSEMBLY NAME}.styles.css"
rel="stylesheet">
```

Placeholders in the preceding code:

- `{CLIENT PROJECT ASSEMBLY NAME}`: Client project assembly name. Example: `BlazorSample.Client`
- `{SERVER PROJECT ASSEMBLY NAME}`: Server project assembly name. Example: `BlazorSample.Server`

Locate following `<div>...</div>` HTML markup:

diff

```
- <div id="app">
-     ...
- </div>
```

Replace the preceding `<div>...</div>` HTML markup with the `Routes` component using the Interactive WebAssembly render mode (prerendering disabled):

razor

```
<Routes @rendermode="new InteractiveWebAssemblyRenderMode(prerender:
false)" />
```

Update the `blazor.webassembly.js` script to `blazor.web.js`:

diff

```
- <script src="_framework/blazor.webassembly.js"></script>
+ <script src="_framework/blazor.web.js"></script>
```

6. Open the `.Client` project's layout file (`.Client/Shared/MainLayout.razor`) and add a PageTitle component with the website's default title (`{TITLE}` placeholder):

razor

```
<PageTitle>{TITLE}</PageTitle>
```

> ⓘ **Note**

> Other layout files should also receive a PageTitle component with the default website title.
>
> For more information, see Control head content in ASP.NET Core Blazor apps.

7. Remove the following lines from `.Client/Program.cs`:

```diff
- builder.RootComponents.Add<App>("#app");
- builder.RootComponents.Add<HeadOutlet>("head::after");
```

8. Update `.Server/Program.cs`:

   Add Razor component and interactive WebAssembly component services to the project. Call AddRazorComponents with a chained call to AddInteractiveWebAssemblyComponents. Calling AddRazorComponents adds antiforgery services (AddAntiforgery) by default.

```C#
builder.Services.AddRazorComponents()
    .AddInteractiveWebAssemblyComponents();
```

   Add Antiforgery Middleware to the request processing pipeline.

   Place the following line after the call to `app.UseHttpsRedirection`. The call to `app.UseAntiforgery` must be placed after calls, if present, to `app.UseAuthentication` and `app.UseAuthorization`. There's no need to explicitly add antiforgery services (`builder.Services.AddAntiforgery`), as they're added automatically by AddRazorComponents, which was covered earlier.

```C#
app.UseAntiforgery();
```

   Remove the following line:

```diff
- app.UseBlazorFrameworkFiles();
```

Remove the following line:

```diff
- app.MapFallbackToFile("index.html");
```

Replace the preceding line with a call to MapRazorComponents, supplying the `App` component as the root component type, and add chained calls to AddInteractiveWebAssemblyRenderMode and AddAdditionalAssemblies:

```C#
app.MapRazorComponents<App>()
    .AddInteractiveWebAssemblyRenderMode()
    .AddAdditionalAssemblies(typeof({CLIENT APP
NAMESPACE}._Imports).Assembly);
```

In the preceding example, the `{CLIENT APP NAMESPACE}` placeholder is the namespace of the `.Client` project (for example, `HostedBlazorApp.Client`).

9. Run the solution from the `.Server` project:

   For Visual Studio, confirm that the `.Server` project is selected in **Solution Explorer** when running the app.

   If using the .NET CLI, run the project from the `.Server` project's folder.

Update service and endpoint option configuration

With the release of Blazor Web Apps in .NET 8, Blazor service and endpoint option configuration is updated with the introduction of new API for interactive component services and component endpoint configuration.

Updated configuration guidance appears in the following locations:

- Setting and reading the app's environment: Contains updated guidance, especially in the section titled *Read the environment client-side in a Blazor Web App*.
- Server-side circuit handler options: Covers new Blazor-SignalR circuit and hub options configuration.
- Render Razor components from JavaScript: Covers dynamic component registration with RegisterForJavaScript.
- Blazor custom elements: Blazor Web App registration: Covers root component custom element registration with `RegisterCustomElement`.

- Prefix for Blazor WebAssembly assets: Covers control of the path string that indicates the prefix for Blazor WebAssembly assets.
- Temporary redirection URL validity duration: Covers control of the lifetime of data protection validity for temporary redirection URLs emitted by Blazor server-side rendering.
- Detailed errors: Covers enabling detailed errors for Razor component server-side rendering.
- Prerendering configuration: Prerendering is enabled by default for Blazor Web Apps. Follow this link for guidance on how to disable prerendering if you have special circumstances that require an app to disable prerendering.
- Form binding options: Covers form binding options configuration.

Drop Blazor Server with Yarp routing workaround

If you previously followed the guidance in Enable ASP.NET Core Blazor Server support with Yarp in incremental migration for migrating a Blazor Server app with Yarp to .NET 6 or .NET 7, you can reverse the workaround steps that you took when following the article's guidance. Routing and deep linking for Blazor Server with Yarp work correctly in .NET 8.

Migrate `CascadingValue` components in layout components

Cascading parameters don't pass data across render mode boundaries, and layouts are statically rendered in otherwise interactive apps. Therefore, apps that seek to use cascading parameters in interactively rendered components won't be able to cascade the values from a layout.

The two approaches for migration are:

- (*Recommended*) Pass the state as a root-level cascading value. For more information, see Root-level cascading values.
- Wrap the router in the `Routes` component with the CascadingValue component and make the `Routes` component interactively rendered. For an example, see CascadingValue component.

For more information, see Cascading values/parameters and render mode boundaries.

Migrate the `BlazorEnableCompression` MSBuild property

For Blazor WebAssembly apps that disable compression and target .NET 7 or earlier but are built with the .NET 8 SDK, the `BlazorEnableCompression` MSBuild property has changed to `CompressionEnabled`:

diff

```
<PropertyGroup>
-   <BlazorEnableCompression>false</BlazorEnableCompression>
+   <CompressionEnabled>false</CompressionEnabled>
</PropertyGroup>
```

When using the .NET CLI publish command, use the new property:

.NET CLI

```
dotnet publish -p:CompressionEnabled=false
```

For more information, see the following resources:

- Static Web Assets Compression Flag Breaking Change (dotnet/announcements #283)
- Host and deploy ASP.NET Core Blazor WebAssembly

Migrate the `<CascadingAuthenticationState>` component to cascading authentication state services

In .NET 7 or earlier, the CascadingAuthenticationState component is wrapped around some part of the UI tree, for example around the Blazor router, to provide cascading authentication state:

razor

```
<CascadingAuthenticationState>
    <Router ...>
        ...
    </Router>
</CascadingAuthenticationState>
```

In .NET 8, don't use the CascadingAuthenticationState component:

diff

```
- <CascadingAuthenticationState>
      <Router ...>
          ...
```

```
      </Router>
- </CascadingAuthenticationState>
```

Instead, add cascading authentication state services to the service collection by calling AddCascadingAuthenticationState in the `Program` file:

```
C#

builder.Services.AddCascadingAuthenticationState();
```

For more information, see the following resources:

- *ASP.NET Core Blazor authentication and authorization* article
  - AuthenticationStateProvider service
  - Expose the authentication state as a cascading parameter
  - Customize unauthorized content with the Router component
- Secure ASP.NET Core server-side Blazor apps

New article on HTTP caching issues

We've added a new article that discusses some of the common HTTP caching issues that can occur when upgrading Blazor apps across major versions and how to address HTTP caching issues.

For more information, see Avoid HTTP caching issues when upgrading ASP.NET Core Blazor apps.

New article on class libraries with static server-side rendering (static SSR)

We've added a new article that discusses component library authorship in Razor class libraries (RCLs) with static server-side rendering (static SSR).

For more information, see ASP.NET Core Razor class libraries (RCLs) with static server-side rendering (static SSR).

Discover components from additional assemblies

When migrating from a Blazor Server app to a Blazor Web App, access the guidance in ASP.NET Core Blazor routing and navigation if the app uses routable components from additional assemblies, such as component class libraries.

Drop `[Parameter]` attribute when the parameter is supplied from a query string

The `[Parameter]` attribute is no longer required when supplying a parameter from the query string:

```diff
- [Parameter]
  [SupplyParameterFromQuery]
```

Blazor Server script fallback policy authorization

In .NET 7, the Blazor Server script (`blazor.server.js`) is served by Static Files Middleware. Placing the call for Static Files Middleware (UseStaticFiles) in the request processing pipeline before the call to Authorization Middleware (UseAuthorization) is sufficient in .NET 7 apps to serve the Blazor script to anonymous users.

In .NET 8, the Blazor Server script is served by its own endpoint, using endpoint routing. This change is introduced by Fixed bug - Passing options to UseStaticFiles breaks Blazor Server (dotnet/aspnetcore #45897).

Consider a multi-tenant scenario where:

- Both the default and fallback policies are set identically.
- The tenant is resolved using the first segment in the request path (for example, `tld.com/tenant-name/...`).
- The requests to tenant endpoints are authenticated by an additional authentication scheme, which adds an additional identity to the request principal.
- The fallback authorization policy has requirements that check claims via the additional identity.

Requests for the Blazor script file (`blazor.server.js`) are served at `/_framework/blazor.server.js`, which is hardcoded in the framework. Requests for the file aren't authenticated by the additional authentication scheme for tenants ***but are still challenged by the fallback policy***, which results in returning an unauthorized result.

This problem is under evaluation for a new framework feature in MapRazorComponents broken with FallbackPolicy RequireAuthenticatedUser (dotnet/aspnetcore 51836), which is currently scheduled for .NET 9's release in November, 2024. Until then, you can work around this problem using any of the following three approaches:

- Don't use a fallback policy. Apply the `[Authorize]` attribute in the `_Imports.razor` file to apply it to all of the components of the app. For non-blazor endpoints, explicitly use `[Authorize]` or `RequireAuthorization`.

- Add `[AllowAnonymous]` to the `/_framework/blazor.server.js` endpoint in the `Program` file:

  C#

  ```
  app.MapBlazorHub().Add(endpointBuilder =>
  {
      if (endpointBuilder is
          RouteEndpointBuilder
          {
              RoutePattern: { RawText: "/_framework/blazor.server.js" }
          })
      {
          endpointBuilder.Metadata.Add(new AllowAnonymousAttribute());
      }
  });
  ```

- Register a custom `AuthorizationHandler` that checks the HttpContext to allow the `/_framework/blazor.server.js` file through.

Docker

Update Docker images

For apps using Docker, update the *Dockerfile* `FROM` statements and scripts. Use a base image that includes the ASP.NET Core 8.0 runtime. Consider the following `docker pull` command difference between ASP.NET Core 7.0 and 8.0:

diff

```
- docker pull mcr.microsoft.com/dotnet/aspnet:7.0
+ docker pull mcr.microsoft.com/dotnet/aspnet:8.0
```

Update Docker port

The default ASP.NET Core port configured in .NET container images has been updated from port 80 to 8080.

The new `ASPNETCORE_HTTP_PORTS` environment variable was added as a simpler alternative to `ASPNETCORE_URLS`.

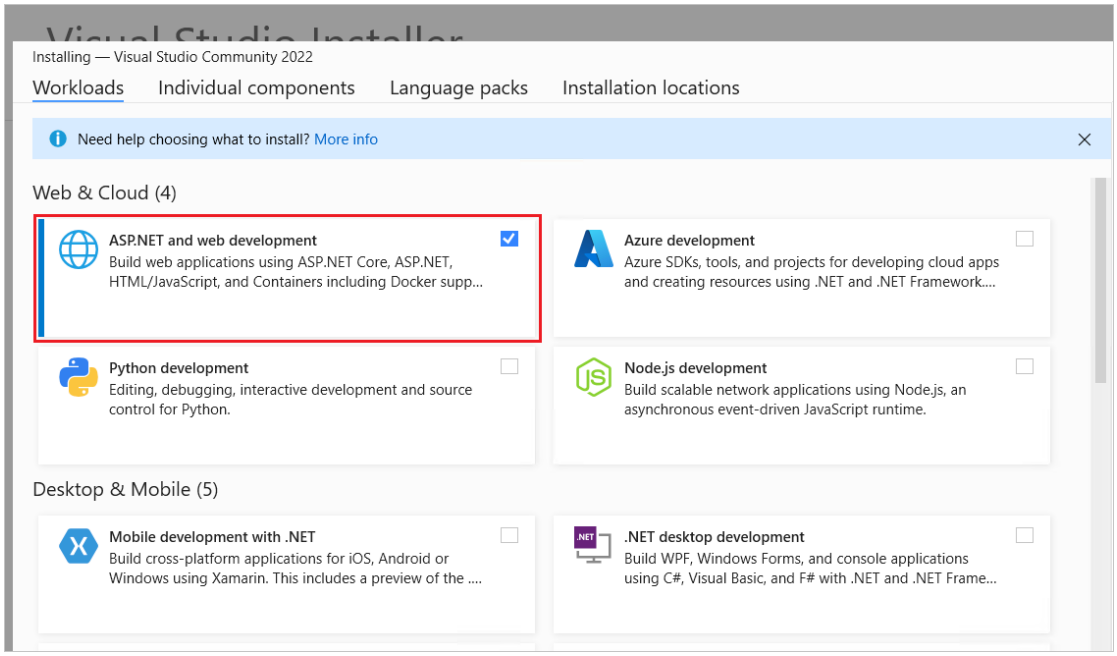
For more information, see:

- Default ASP.NET Core port changed from 80 to 8080.
- Specify ports only with ASPNETCORE_HTTP_PORTS

Review breaking changes

For breaking changes from .NET Core .NET 7.0 to 8.0, see Breaking changes in .NET 8, which includes ASP.NET Core and Entity Framework Core sections.

Migrate from ASP.NET Core 6.0 to 7.0



Article • 06/01/2023

This article explains how to update an existing ASP.NET Core 6.0 project to ASP.NET Core 7.0.

Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.

Update .NET Core SDK version in global.json

If you rely on a global.json file to target a specific .NET Core SDK version, update the `version` property to the .NET 7.0 SDK version that's installed. For example:

diff

```
{
  "sdk": {
-    "version": "6.0.200"
+    "version": "7.0.100"
```

```
  }
}
```

Update the target framework

Update the project file's Target Framework Moniker (TFM) to `net7.0`:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
-    <TargetFramework>net6.0</TargetFramework>
+    <TargetFramework>net7.0</TargetFramework>
  </PropertyGroup>

</Project>
```

Update package references

In the project file, update each Microsoft.AspNetCore.* , Microsoft.EntityFrameworkCore.* , Microsoft.Extensions.* , and System.Net.Http.Json package reference's `Version` attribute to 7.0.0 or later. For example:

diff

```
<ItemGroup>
-    <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="6.0.9" />
-    <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="6.0.9" />
-    <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="6.0.9" />
-    <PackageReference Include="System.Net.Http.Json" Version="6.0.0" />
+    <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="7.0.0" />
+    <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="7.0.0" />
+    <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="7.0.0" />
+    <PackageReference Include="System.Net.Http.Json" Version="7.0.0" />
</ItemGroup>
```

Blazor

Adopt .NET 7 features

After following the guidance earlier in this article to update an app to 7.0, adopt specific features by following the links in What's new in ASP.NET Core 7.0.

To adopt all of the new 7.0 features for Blazor apps, we recommend the following process:

- Create a new 7.0 Blazor project from one of the Blazor project templates. For more information, see Tooling for ASP.NET Core Blazor.
- Move the app's components and code to the 7.0 app making modifications to adopt the new 7.0 features.

Migrate unmarshalled JavaScript interop

Unmarshalled interop using the IJSUnmarshalledRuntime interface is obsolete and should be replaced with JavaScript `[JSImport]`/`[JSExport]` interop.

For more information, see JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.

Blazor WebAssembly authentication uses history state for redirects

The support for authentication in Blazor WebAssembly apps changed to rely on navigation history state instead of query strings in the URL. As a result, passing the return URL through the query string fails to redirect back to the original page after a successful login in .NET 7.

The following example demonstrates **the prior redirection approach for apps that target .NET 6 or earlier**, which is based on a redirect URL (`?returnUrl=`) with NavigateTo:

razor

```
@inject NavigationManager Navigation
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@code {
    protected override void OnInitialized()
    {
        Navigation.NavigateTo(
```

```
            $"authentication/login?returnUrl=
{Uri.EscapeDataString(Navigation.Uri)}");
    }
}
```

The following example demonstrates **the new redirection approach for apps that target .NET 7 or later**, which is based on navigation history state with NavigateToLogin:

razor

```
@inject NavigationManager Navigation
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@using Microsoft.Extensions.Options

@inject
IOptionsSnapshot<RemoteAuthenticationOptions<ApiAuthorizationProviderOptions
>> OptionsSnapshot
@code {
    protected override void OnInitialized()
    {

Navigation.NavigateToLogin(OptionsSnapshot.Get(Options.DefaultName).Authenti
cationPaths.LogInPath);
    }
}
```

As part of this change, SignOutSessionStateManager is obsolete in .NET 7 or later and replaced with NavigateToLogout.

The following example demonstrates **the prior approach** in `Shared/LoginDisplay.razor` of an app generated from the Blazor WebAssembly project template:

razor

```
@inject SignOutSessionStateManager SignOutManager

...

@code{
    private async Task BeginLogout(MouseEventArgs args)
    {
        await SignOutManager.SetSignOutState();
        Navigation.NavigateTo("authentication/logout");
    }
}
```

The following example demonstrates **the new approach** that calls NavigateToLogout. The injection (`@inject`) of the SignOutSessionStateManager is removed from the

component's directives at the top of the file, and the `BeginLogOut` method is updated to the following code:

```razor
@code{
    public void BeginLogOut()
    {
        Navigation.NavigateToLogout("authentication/logout");
    }
}
```

The SignOutSessionStateManager service registration is removed in `Program.cs`:

```diff
- builder.Services.AddScoped<SignOutSessionStateManager>();
```

For more information, see the following resources:

- [Breaking change]: Updates to Authentication in webassembly applications
- ASP.NET Core Blazor routing and navigation
- Secure ASP.NET Core Blazor WebAssembly
- ASP.NET Core Blazor authentication and authorization

.NET WebAssembly build tools for .NET 6 projects

You can now use the .NET WebAssembly build tools with a .NET 6 project when working with the .NET 7 SDK. The new `wasm-tools-net6` workload includes the .NET WebAssembly build tools for .NET 6 projects so that they can be used with the .NET 7 SDK. The existing `wasm-tools` workload installs the .NET WebAssembly build tools for .NET 7 projects. However, the .NET 7 version of the .NET WebAssembly build tools are incompatible with existing projects built with .NET 6. Projects using the .NET WebAssembly build tools that need to support both .NET 6 and .NET 7 must use multi-targeting.

Update Docker images

For apps using Docker, update your *Dockerfile* `FROM` statements and scripts. Use a base image that includes the ASP.NET Core 7.0 runtime. Consider the following `docker pull` command difference between ASP.NET Core 6.0 and 7.0:

```
```

diff

```
- docker pull mcr.microsoft.com/dotnet/aspnet:6.0
+ docker pull mcr.microsoft.com/dotnet/aspnet:7.0
```

Review breaking changes

For breaking changes from .NET Core 6.0 to .NET 7.0, see Breaking changes in .NET 7. ASP.NET Core and Entity Framework Core are included in the list.

Migrate from ASP.NET Core 5.0 to 6.0

Article • 10/18/2024

This article explains how to update an existing ASP.NET Core 5.0 project to ASP.NET Core 6.0. For instructions on how to migrate from ASP.NET Core 3.1 to ASP.NET Core 6.0, see Migrate from ASP.NET Core 3.1 to 6.0.

Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.
- .NET 6.0 SDK

Update .NET SDK version in global.json

If you rely upon a global.json file to target a specific .NET SDK version, update the `version` property to the .NET 6.0 SDK version that's installed. For example:

diff

```
{
  "sdk": {
-    "version": "5.0.100"
+    "version": "6.0.100"
  }
}
```

Update the target framework

Update the project file's Target Framework Moniker (TFM) to `net6.0`:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
-    <TargetFramework>net5.0</TargetFramework>
+    <TargetFramework>net6.0</TargetFramework>
  </PropertyGroup>
```

```
</Project>
```

Update package references

In the project file, update each Microsoft.AspNetCore.* and Microsoft.Extensions.* package reference's `Version` attribute to 6.0.0 or later. For example:

diff

```
<ItemGroup>
-    <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="5.0.3" />
-    <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="5.0.0" />
+    <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="6.0.0" />
+    <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="6.0.0" />
</ItemGroup>
```

New hosting model

The new .NET 6 minimal hosting model for ASP.NET Core apps requires only one file and a few lines of code. **Apps migrating to 6.0 don't need to use the new minimal hosting model.** For more information, see Apps migrating to 6.0 don't need to use the new minimal hosting model in the following section.

The following code from the ASP.NET Core empty template creates an app using the new minimal hosting model:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The minimal hosting model:

- Significantly reduces the number of files and lines of code required to create an app. Only one file is needed with four lines of code.

- Unifies `Startup.cs` and `Program.cs` into a single `Program.cs` file.
- Uses top-level statements to minimize the code required for an app.
- Uses global using directives to eliminate or minimize the number of using statement lines required.

The following code displays the `Startup.cs` and `Program.cs` files from an ASP.NET Core 5 Web App template (Razor Pages) with unused `using` statements removed:

C#

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
// Unused usings removed.

namespace WebAppRPv5
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        // This method gets called by the runtime. Use this method to add
services to the container.
        public void ConfigureServices(IServiceCollection services)
        {
            services.AddRazorPages();
        }

        // This method gets called by the runtime. Use this method to
configure the HTTP request pipeline.
        public void Configure(IApplicationBuilder app, IWebHostEnvironment
env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
                // The default HSTS value is 30 days. You may want to change
this for production scenarios, see https://aka.ms/aspnetcore-hsts.
                app.UseHsts();
            }
```

```
            app.UseHttpsRedirection();
            app.UseStaticFiles();

            app.UseRouting();

            app.UseAuthorization();

            app.UseEndpoints(endpoints =>
            {
                endpoints.MapRazorPages();
            });
        }
    }
}
```

C#

```
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Hosting;
// Unused usings removed.

namespace WebAppRPv5
{
    public class Program
    {
        public static void Main(string[] args)
        {
            CreateHostBuilder(args).Build().Run();
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

In ASP.NET Core 6, the preceding code is replaced by the following:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
```

```
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The preceding ASP.NET Core 6 sample shows how:

- ConfigureServices is replaced with WebApplication.Services.
- `builder.Build()` returns a configured WebApplication to the variable `app`. Configure is replaced with configuration calls to same services using `app`.

Detailed examples of migrating ASP.NET Core 5 `Startup` code to ASP.NET Core 6 using the minimal hosting model are provided later in this document.

There are a few changes to the other files generated for the Web App template:

- `Index.cshtml` and `Privacy.cshtml` have the unused `using` statements removed.
- `RequestId` in `Error.cshtml` is declared as a nullable reference type (NRT):

diff

```
- public string RequestId { get; set; }
+ public string? RequestId { get; set; }
```

- Log level defaults have changed in `appsettings.json` and `appsettings.Development.json`:

diff

```
- "Microsoft": "Warning",
- "Microsoft.Hosting.Lifetime": "Information"
+ "Microsoft.AspNetCore": "Warning"
```

In the preceding ASP.NET Core template code, `"Microsoft": "Warning"` has been changed to `"Microsoft.AspNetCore": "Warning"`. This change results in logging all informational messages from the `Microsoft` namespace ***except*** `Microsoft.AspNetCore`. For example, `Microsoft.EntityFrameworkCore` is now logged at the informational level.

For more details on the new hosting model, see the Frequently asked questions section. For more information on the adoption of NRTs and .NET compiler null-state analysis, see the Nullable reference types (NRTs) and .NET compiler null-state static analysis section.

Apps migrating to or using 6.0 and later don't need to use the new minimal hosting model

Using Startup and the Generic Host used by the ASP.NET Core 3.1 and 5.0 templates is fully supported.

Use Startup with the new minimal hosting model

ASP.NET Core 3.1 and 5.0 apps can use their `Startup` code with the new minimal hosting model. Using `Startup` with the minimal hosting model has the following advantages:

- No hidden reflection is used to call the `Startup` class.
- Asynchronous code can be written because the developer controls the call to `Startup`.
- Code can be written that interleaves `ConfigureServices` and `Configure`.

One minor limitation in using `Startup` code with the new minimal hosting model is that to inject a dependency into `Configure`, the service in `Program.cs` must be manually resolved.

Consider the following code generated by the ASP.NET Core 3.1 or 5.0 Razor Pages template:

C#

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
```

```
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

C#

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseRouting();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

The preceding code migrated to the new minimal hosting model:

C#

```
using Microsoft.AspNetCore.Builder;

var builder = WebApplication.CreateBuilder(args);
```

```
var startup = new Startup(builder.Configuration);

startup.ConfigureServices(builder.Services);

var app = builder.Build();

startup.Configure(app, app.Environment);

app.Run();
```

C#

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (!env.IsDevelopment())
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseRouting();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

In the preceding code, the `if (env.IsDevelopment())` block is removed because in development mode, the developer exception page middleware is enabled by default. For more information, see Differences between the ASP.NET Core 5 and 6 hosting models in the next section.

When using a custom dependency injection (DI) container, add the following highlighted code:

C#

```
using Autofac;
using Autofac.Extensions.DependencyInjection;
using Microsoft.AspNetCore.Builder;
using Microsoft.Extensions.Hosting;

var builder = WebApplication.CreateBuilder(args);

var startup = new Startup(builder.Configuration);

startup.ConfigureServices(builder.Services);

// Using a custom DI container.
builder.Host.UseServiceProviderFactory(new AutofacServiceProviderFactory());
builder.Host.ConfigureContainer<ContainerBuilder>
(startup.ConfigureContainer);

var app = builder.Build();

startup.Configure(app, app.Environment);

app.Run();
```

C#

```
using Autofac;
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    //  Using a custom DI container
    public void ConfigureContainer(ContainerBuilder builder)
    {
        // Configure custom container.
    }
    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (!env.IsDevelopment())
```

```
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseRouting();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

When using the minimal hosting model, the endpoint routing middleware wraps the entire middleware pipeline, therefore there's no need to have explicit calls to `UseRouting` or `UseEndpoints` to register routes. `UseRouting` can still be used to specify where route matching happens, but `UseRouting` doesn't need to be explicitly called if routes should be matched at the beginning of the middleware pipeline.

In the following code, the calls to `UseRouting` and `UseEndpoints` are removed from `Startup`. `MapRazorPages` is called in `Program.cs`:

C#

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (!env.IsDevelopment())
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
```

```
        //app.UseRouting();

        //app.UseEndpoints(endpoints =>
        //{
        //    endpoints.MapRazorPages();
        //});
    }
}
```

C#

```
using Microsoft.AspNetCore.Builder;

var builder = WebApplication.CreateBuilder(args);

var startup = new Startup(builder.Configuration);

startup.ConfigureServices(builder.Services);

var app = builder.Build();

startup.Configure(app, app.Environment);

app.MapRazorPages();

app.Run();
```

When using `Startup` with the new minimal hosting model, keep in mind the following difference:

- `Program.cs` controls the instantiation and lifetime of the `Startup` class.
- Any additional services injected into the `Configure` method need to be manually resolved by the `Program` class.

Differences between the ASP.NET Core 5 and 6 hosting models

- In development mode, the developer exception page middleware is enabled by default.
- The app name defaults to the entry point assembly's name: `Assembly.GetEntryAssembly().GetName().FullName`. When using the WebApplicationBuilder in a library, explicitly change the app name to the library's assembly to allow MVC's application part discovery to work. See Change the content root, app name, and environment in this document for detailed instructions.

- The endpoint routing middleware wraps the entire middleware pipeline, therefore there's no need to have explicit calls to `UseRouting` or `UseEndpoints` to register routes. `UseRouting` can still be used to specify where route matching happens, but `UseRouting` doesn't need to be explicitly called if routes should be matched at the beginning of the middleware pipeline.
- The pipeline is created before any IStartupFilter runs, therefore exceptions caused while building the pipeline aren't visible to the `IStartupFilter` call chain.
- Some tools, such as EF migrations, use Program.CreateHostBuilder to access the app's `IServiceProvider` to execute custom logic in the context of the app. These tools have been updated to use a new technique to execute custom logic in the context of the app. Entity Framework Migrations is an example of a tool that uses `Program.CreateHostBuilder` in this way. We're working to make sure tools are updated to use the new model.
- Unlike the `Startup` class, the minimal host doesn't automatically configure a DI scope when instantiating the service provider. For contexts where a scope is required, it is necessary to invoke IServiceScope with IServiceScopeFactory.CreateScope to instantiate a new scope. For more information, see how to resolve a service at app startup.
- It's ***not*** possible to change any host settings such as app name, environment, or the content root after the creation of the WebApplicationBuilder. For detailed instructions on changing host settings, see Customize IHostBuilder or IWebHostBuilder. The following highlighted APIs throw an exception:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

// WebHost
```

```
try
{
    builder.WebHost.UseContentRoot(Directory.GetCurrentDirectory());
}
catch (Exception ex)
{
    Console.WriteLine(ex.Message);
}

try
{
    builder.WebHost.UseEnvironment(Environments.Staging);
}
catch (Exception ex)
{
    Console.WriteLine(ex.Message);
}

try
{
    builder.WebHost.UseSetting(WebHostDefaults.ApplicationKey,
"ApplicationName2");
}
catch (Exception ex)
{
    Console.WriteLine(ex.Message);
}

try
{
    builder.WebHost.UseSetting(WebHostDefaults.ContentRootKey,
Directory.GetCurrentDirectory());
}
catch (Exception ex)
{
    Console.WriteLine(ex.Message);
}

try
{
    builder.WebHost.UseSetting(WebHostDefaults.EnvironmentKey,
Environments.Staging);
}
catch (Exception ex)
{
    Console.WriteLine(ex.Message);
}

// Host
try
{
    builder.Host.UseEnvironment(Environments.Staging);
}
catch (Exception ex)
{
```

```
    Console.WriteLine(ex.Message);
}

try
{
    // TODO: This does not throw
    builder.Host.UseContentRoot(Directory.GetCurrentDirectory());
}
catch (Exception ex)
{
    Console.WriteLine(ex.Message);
}

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

- The `Startup` class can't be used from WebApplicationBuilder.Host or WebApplicationBuilder.WebHost. The following highlighted code throws an exception:

  C#

  ```
  var builder = WebApplication.CreateBuilder(args);

  try
  {
      builder.Host.ConfigureWebHostDefaults(webHostBuilder =>
      {
          webHostBuilder.UseStartup<Startup>();
      });
  }
  catch (Exception ex)
  {
      Console.WriteLine(ex.Message);
      throw;
  }
  ```

```
builder.Services.AddRazorPages();

var app = builder.Build();
```

C#

```
var builder = WebApplication.CreateBuilder(args);

try
{
    builder.WebHost.UseStartup<Startup>();
}
catch (Exception ex)
{
    Console.WriteLine(ex.Message);
    throw;
}

builder.Services.AddRazorPages();

var app = builder.Build();
```

- The IHostBuilder implementation on WebApplicationBuilder (`WebApplicationBuilder.Host`), doesn't defer execution of the ConfigureServices, ConfigureAppConfiguration, or ConfigureHostConfiguration methods. Not deferring execution allows code using WebApplicationBuilder to observe changes made to the `IServiceCollection` and `IConfiguration`. The following example only adds `Service1` as an `IService`:

C#

```
using Microsoft.Extensions.DependencyInjection.Extensions;

var builder = WebApplication.CreateBuilder(args);

builder.Host.ConfigureServices(services =>
{
    services.TryAddSingleton<IService, Service1>();
});

builder.Services.TryAddSingleton<IService, Service2>();

var app = builder.Build();

// Displays Service1 only.
Console.WriteLine(app.Services.GetRequiredService<IService>());

app.Run();

class Service1 : IService
```

```
{
}

class Service2 : IService
{
}

interface IService
{
}
```

In the preceding code, the `builder.Host.ConfigureServices` callback gets called inline rather than being deferred until `builder.Build` is called. This means that `Service1` gets added to the `IServiceCollection` before `Service2` and results in `Service1` being resolved for `IService`.

Building libraries for ASP.NET Core 6

The existing .NET ecosystem built extensibility around IServiceCollection, IHostBuilder, and IWebHostBuilder. These properties are available on WebApplicationBuilder as `Services`, `Host`, and `WebHost`.

`WebApplication` implements both Microsoft.AspNetCore.Builder.IApplicationBuilder and Microsoft.AspNetCore.Routing.IEndpointRouteBuilder.

We expect library authors to continue targeting `IHostBuilder`, `IWebHostBuilder`, `IApplicationBuilder`, and `IEndpointRouteBuilder` when building ASP.NET Core specific components. This ensures that your middleware, route handler, or other extensibility points continue to work across different hosting models.

Frequently asked questions (FAQ)

- **Is the new minimal hosting model less capable?**

  No. The new hosting model is functionally equivalent for 98% of scenarios supported by `IHostBuilder` and the `IWebHostBuilder`. There are some advanced scenarios that require specific workarounds on `IHostBuilder`, but we expect those to be extremely rare.

- **Is the generic hosting model deprecated?**

  No. The generic hosting model is an alternative model that is supported indefinitely. The generic host underpins the new hosting model and is still the

primary way to host worker-based applications.

- **Do I have to migrate to the new hosting model?**

  No. The new hosting model is the preferred way to host new apps using .NET 6 and later, but you aren't forced to change the project layout in existing apps. This means apps can upgrade from .NET 5 to .NET 6 by changing the target framework in the project file from `net5.0` to `net6.0`. For more information, see the Update the target framework section in this article. However, we recommend apps migrate to the new hosting model to take advantage of new features only available to the new hosting model.

- **Do I have to use top-level statements?**

  No. The new project templates all use top-level statements, but the new hosting APIs can be used in any .NET 6 app to host a webserver or web app.

- **Where do I put state that was stored as fields in my `Program` or `Startup` class?**

  We strongly recommend using dependency injection (DI) to flow state in ASP.NET Core apps.

  There are two approaches to storing state outside of DI:

  - Store the state in another class. Storing in a class assumes a static state that can be accessed from anywhere in the app.
  - Use the `Program` class generated by top level statements to store state. Using `Program` to store state is the semantic approach:

    C#

    ```
    var builder = WebApplication.CreateBuilder(args);

    ConfigurationValue = builder.Configuration["SomeKey"] ?? "Hello";

    var app = builder.Build();

    app.MapGet("/", () => ConfigurationValue);

    app.Run();

    partial class Program
    {
        public static string? ConfigurationValue { get; private set; }
    }
    ```

- **What if I was using a custom dependency injection container?**

  Custom DI containers are supported. For an example, see Custom dependency injection (DI) container.

- **Do `WebApplicationFactory` and `TestServer` still work?**

  Yes. `WebApplicationFactory<TEntryPoint>` is the way to test the new hosting model. For an example, see Test with WebApplicationFactory or TestServer.

Blazor

After following the guidance earlier in this article to update an app to 6.0, adopt specific features by following the links in What's new in ASP.NET Core 6.0.

To adopt all of the new 6.0 features for Blazor apps, we recommend the following process:

- Create a new 6.0 Blazor project from one of the Blazor project templates. For more information, see Tooling for ASP.NET Core Blazor.
- Move the app's components and code to the 6.0 app making modifications to adopt the new 6.0 features.

Migrating SPA projects

Migrating Angular apps from SPA extensions

See this GitHub issue

Migrating React apps from SPA extensions

See **Migrating React applications from Spa Extensions** in this GitHub issue

Update Docker images

For apps using Docker, update your *Dockerfile* `FROM` statements and scripts. Use a base image that includes the ASP.NET Core 6.0 runtime. Consider the following `docker pull` command difference between ASP.NET Core 5.0 and 6.0:

```
diff
```

```
- docker pull mcr.microsoft.com/dotnet/aspnet:5.0
+ docker pull mcr.microsoft.com/dotnet/aspnet:6.0
```

See GitHub issue Breaking Change: Default console logger format set to JSON.

Changes to the ASP.NET Core Razor SDK

The Razor compiler now leverages the new source generators feature to generate compiled C# files from the Razor views and pages in a project. In previous versions:

- The compilation relied on the `RazorGenerate` and `RazorCompile` targets to produce the generated code. These targets are no longer valid. In .NET 6, both code generation and compilation are supported by a single call to the compiler. `RazorComponentGenerateDependsOn` is still supported to specify dependencies that are required before the build runs.
- A separate Razor assembly, `AppName.Views.dll`, was generated that contained the compiled view types in an application. This behavior has been deprecated and a single assembly `AppName.dll` is produced that contains both the app types and the generated views.
- The app types in `AppName.Views.dll` were public. In .NET 6, the app types are in `AppName.dll` but are `internal sealed`. Apps doing type discover on `AppName.Views.dll` won't be able to do type discover on `AppName.dll`. The following shows the API change:

diff

```
- public class Views_Home_Index :
global::Microsoft.AspNetCore.Mvc.Razor.RazorPage<dynamic>
+ internal sealed class Views_Home_Index :
global::Microsoft.AspNetCore.Mvc.Razor.RazorPage<dynamic>
```

Make the following changes:

- The following properties are no longer applicable with the single-step compilation model.
  - `RazorTargetAssemblyAttribute`
  - `RazorTargetName`
  - `EnableDefaultRazorTargetAssemblyInfoAttributes`
  - `UseRazorBuildServer`
  - `GenerateRazorTargetAssemblyInfo`
  - `GenerateMvcApplicationPartsAssemblyAttributes`

For more information, see Razor compiler no longer produces a Views assembly.

Project templates use Duende Identity Server

Project templates now use Duende Identity Server.

> **Important**
>
> Duende Identity Server is an open source product with a reciprocal license agreement. If you plan to use Duende Identity Server in production, you might be required to obtain a commercial licence from Duende Software and pay a license fee. For more information, see Duende Software: Licenses.
>
> To learn how to use Microsoft Azure Active Directory for ASP.NET Core Identity, see Identity (dotnet/aspnetcore GitHub repository).

Add a `DbSet<Key>` property named `Keys` to every `IdentityDbContext` to satisfy a new requirement from the updated version of `IPersistedGrantDbContext`. The keys are required as part of the contract with Duende Identity Server's stores.

```
C#

public DbSet<Key> Keys { get; set; }
```

> **Note**
>
> Existing migrations must be recreated for Duende Identity Server.

Code samples migrated to ASP.NET Core 6.0

Code samples migrated to the new minimal hosting model in 6.0

Review breaking changes

See the following resources:

- Identity: Default Bootstrap version of UI changed
- Breaking changes for migration from version 5.0 to 6.0: Includes ASP.NET Core and Entity Framework Core.

- Announcements GitHub repository (aspnet/Announcements, 6.0.0 label): Includes breaking and non-breaking information.

Nullable reference types (NRTs) and .NET compiler null-state static analysis

ASP.NET Core project templates use nullable reference types (NRTs), and the .NET compiler performs null-state static analysis. These features were released with C# 8 and are enabled by default for apps generated using ASP.NET Core 6.0 (C# 10) or later.

The .NET compiler's null-state static analysis warnings can either serve as a guide for updating a documentation example or sample app locally or be ignored. Null-state static analysis can be disabled by setting Nullable to disable in the app's project file, which we only recommend for documentation examples and sample apps if the compiler warnings are distracting while learning about .NET. ***We don't recommend disabling null-state checking in production projects.***

For more information on NRTs, the MSBuild `Nullable` property, and updating apps (including `#pragma` guidance), see the following resources in the C# documentation:

- Nullable reference types
- Nullable reference types (C# reference)
- Learn techniques to resolve nullable warnings
- Update a codebase with nullable reference types to improve null diagnostic warnings
- Attributes for null-state static analysis
- ! (null-forgiving) operator (C# reference)

ASP.NET Core Module (ANCM)

If the ASP.NET Core Module (ANCM) wasn't a selected component when Visual Studio was installed or if a prior version of the ANCM was installed on the system, download the latest .NET Core Hosting Bundle Installer (direct download) and run the installer. For more information, see Hosting Bundle.

Application name change

In .NET 6, WebApplicationBuilder normalizes the content root path to end with a DirectorySeparatorChar. Most apps migrating from HostBuilder or WebHostBuilder

won't have the same app name because they aren't normalized. For more information, see SetApplicationName

- Code samples migrated to the new minimal hosting model in 6.0

Code samples migrated to the new minimal hosting model in ASP.NET Core 6.0

Article • 07/14/2023

This article provides samples of code migrated to ASP.NET Core 6.0. ASP.NET Core 6.0 uses a new minimal hosting model. For more information, see New hosting model.

Middleware

The following code adds the Static File Middleware to an ASP.NET Core 5 app:

C#

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.UseStaticFiles();
    }
}
```

The following code adds the Static File Middleware to an ASP.NET Core 6 app:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.UseStaticFiles();

app.Run();
```

WebApplication.CreateBuilder initializes a new instance of the WebApplicationBuilder class with preconfigured defaults. For more information, see ASP.NET Core Middleware

Routing

The following code adds an endpoint to an ASP.NET Core 5 app:

C#

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.UseRouting();
        app.UseEndpoints(endpoints =>
        {
            endpoints.MapGet("/", () => "Hello World");
        });
    }
}
```

In .NET 6, routes can be added directly to the WebApplication without an explicit call to UseEndpoints or UseRouting. The following code adds an endpoint to an ASP.NET Core 6 app:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Note: Routes added directly to the WebApplication execute at the ***end*** of the pipeline.

Change the content root, app name, and environment

ASP.NET Core 5

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .UseContentRoot(Directory.GetCurrentDirectory())
        .UseEnvironment(Environments.Staging)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>()
                      .UseSetting(WebHostDefaults.ApplicationKey,
                                  typeof(Program).Assembly.FullName);
        });
```

ASP.NET Core 6

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    ApplicationName = typeof(Program).Assembly.FullName,
    ContentRootPath = Directory.GetCurrentDirectory(),
    EnvironmentName = Environments.Staging,
    WebRootPath = "customwwwroot"
});

Console.WriteLine($"Application Name:
{builder.Environment.ApplicationName}");
Console.WriteLine($"Environment Name:
{builder.Environment.EnvironmentName}");
Console.WriteLine($"ContentRoot Path:
{builder.Environment.ContentRootPath}");
Console.WriteLine($"WebRootPath: {builder.Environment.WebRootPath}");

var app = builder.Build();
```

For more information, see ASP.NET Core fundamentals overview

Change the content root, app name, and environment by environment variables or command line

The following table shows the environment variable and command-line argument used to change the content root, app name, and environment:

Expand table

feature	Environment variable	Command-line argument
Application name	ASPNETCORE_APPLICATIONNAME	--applicationName
Environment name	ASPNETCORE_ENVIRONMENT	--environment
Content root	ASPNETCORE_CONTENTROOT	--contentRoot

Add configuration providers

ASP.NET Core 5

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureAppConfiguration(config =>
        {
            config.AddIniFile("appsettings.ini");
        })
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

ASP.NET Core 6

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Configuration.AddIniFile("appsettings.ini");

var app = builder.Build();
```

For detailed information, see File configuration providers in Configuration in ASP.NET Core.

Add logging providers

ASP.NET Core 5

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureLogging(logging =>
        {
            logging.AddJsonConsole();
        })
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

ASP.NET Core 6

C#

```
var builder = WebApplication.CreateBuilder(args);

// Configure JSON logging to the console.
builder.Logging.AddJsonConsole();

var app = builder.Build();
```

For more information, see Logging in .NET Core and ASP.NET Core.

Add services

ASP.NET Core 5

C#

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        // Add the memory cache services
        services.AddMemoryCache();

        // Add a custom scoped service
        services.AddScoped<ITodoRepository, TodoRepository>();
    }
}
```

ASP.NET Core 6

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add the memory cache services.
builder.Services.AddMemoryCache();

// Add a custom scoped service.
builder.Services.AddScoped<ITodoRepository, TodoRepository>();
var app = builder.Build();
```

For more information, see Dependency injection in ASP.NET Core.

Customize IHostBuilder or IWebHostBuilder

Customize IHostBuilder

ASP.NET Core 5

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureHostOptions(o => o.ShutdownTimeout =
TimeSpan.FromSeconds(30));
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

ASP.NET Core 6

C#

```
var builder = WebApplication.CreateBuilder(args);

// Wait 30 seconds for graceful shutdown.
builder.Host.ConfigureHostOptions(o => o.ShutdownTimeout =
TimeSpan.FromSeconds(30));

var app = builder.Build();
```

Customize IWebHostBuilder

ASP.NET Core 5

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            // Change the HTTP server implementation to be HTTP.sys based.
            webBuilder.UseHttpSys()
                      .UseStartup<Startup>();
        });
```

ASP.NET Core 6

C#

```
var builder = WebApplication.CreateBuilder(args);

// Change the HTTP server implementation to be HTTP.sys based.
// Windows only.
builder.WebHost.UseHttpSys();

var app = builder.Build();
```

Change the web root

By default, the web root is relative to the content root in the `wwwroot` folder. Web root is where the static files middleware looks for static files. Web root can be changed by setting the WebRootPath property on WebApplicationOptions:

ASP.NET Core 5

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            // Look for static files in webroot.
            webBuilder.UseWebRoot("webroot")
                      .UseStartup<Startup>();
        });
```

ASP.NET Core 6

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    // Look for static files in webroot
    WebRootPath = "webroot"
});

var app = builder.Build();
```

Custom dependency injection (DI) container

The following .NET 5 and .NET 6 samples use Autofac

ASP.NET Core 5

Program class

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .UseServiceProviderFactory(new AutofacServiceProviderFactory())
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

Startup

C#

```
public class Startup
{
    public void ConfigureContainer(ContainerBuilder containerBuilder)
    {
    }
}
```

ASP.NET Core 6

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Host.UseServiceProviderFactory(new AutofacServiceProviderFactory());

// Register services directly with Autofac here. Don't
// call builder.Populate(), that happens in AutofacServiceProviderFactory.
builder.Host.ConfigureContainer<ContainerBuilder>(builder =>
builder.RegisterModule(new MyApplicationModule()));

var app = builder.Build();
```

Access additional services

`Startup.Configure` can inject any service added via the IServiceCollection.

ASP.NET Core 5

C#

```
public class Startup
{
    // This method gets called by the runtime. Use this method to add
services
    // to the container.
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddSingleton<IService, Service>();
    }

    // Anything added to the service collection can be injected into
Configure.
    public void Configure(IApplicationBuilder app,
                          IWebHostEnvironment env,
                          IHostApplicationLifetime lifetime,
                          IService service,
                          ILogger<Startup> logger)
    {
        lifetime.ApplicationStarted.Register(() =>
            logger.LogInformation(
                "The application {Name} started in the injected {Service}",
                env.ApplicationName, service));
    }
}
```

ASP.NET Core 6

In ASP.NET Core 6:

- There are a few common services available as top level properties on WebApplication.
- Additional services need to be manually resolved from the `IServiceProvider` via WebApplication.Services.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddSingleton<IService, Service>();

var app = builder.Build();
```

```
IService service = app.Services.GetRequiredService<IService>();
ILogger logger = app.Logger;
IHostApplicationLifetime lifetime = app.Lifetime;
IWebHostEnvironment env = app.Environment;

lifetime.ApplicationStarted.Register(() =>
    logger.LogInformation(
        $"The application {env.ApplicationName} started" +
        $" with injected {service}"));
```

Test with WebApplicationFactory or TestServer

ASP.NET Core 5

In the following samples, the test project uses `TestServer` and WebApplicationFactory<TEntryPoint>. These ship as separate packages that require explicit reference:

WebApplicationFactory

XML

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore.Mvc.Testing" Version="
{Version}" />
</ItemGroup>
```

TestServer

XML

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore.TestHost" Version="
{Version}" />
</ItemGroup>
```

ASP.NET Core 5 code

C#

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
```

```
    {
        services.AddSingleton<IHelloService, HelloService>();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env,
IHelloService helloService)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        app.UseRouting();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapGet("/", async context =>
            {
                await
context.Response.WriteAsync(helloService.HelloMessage);
            });
        });
    }
}
```

With TestServer

C#

```
[Fact]
public async Task HelloWorld()
{
    using var host = Host.CreateDefaultBuilder()
        .ConfigureWebHostDefaults(builder =>
        {
            // Use the test server and point to the application's startup
            builder.UseTestServer()
                    .UseStartup<WebApplication1.Startup>();
        })
        .ConfigureServices(services =>
        {
            // Replace the service
            services.AddSingleton<IHelloService, MockHelloService>();
        })
        .Build();

    await host.StartAsync();

    var client = host.GetTestClient();

    var response = await client.GetStringAsync("/");
```

```
    Assert.Equal("Test Hello", response);
}

class MockHelloService : IHelloService
{
    public string HelloMessage => "Test Hello";
}
```

With WebApplicationFactory

C#

```
[Fact]
public async Task HelloWorld()
{
    var application = new WebApplicationFactory<Program>()
        .WithWebHostBuilder(builder =>
        {
            builder.ConfigureServices(services =>
            {
                services.AddSingleton<IHelloService, MockHelloService>();
            });
        });

    var client = application.CreateClient();

    var response = await client.GetStringAsync("/");

    Assert.Equal("Test Hello", response);
}

class MockHelloService : IHelloService
{
    public string HelloMessage => "Test Hello";
}
```

ASP.NET Core 6

C#

```

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddSingleton<IHelloService, HelloService>();

var app = builder.Build();

var helloService = app.Services.GetRequiredService<IHelloService>();

app.MapGet("/", async context =>
```

```
{
    await context.Response.WriteAsync(helloService.HelloMessage);
});

app.Run();
```

Project file (.csproj)

The project file can contain one of the following:

XML

```
<ItemGroup>
    <InternalsVisibleTo Include="MyTestProject" />
</ItemGroup>
```

Or

```
[assembly: InternalsVisibleTo("MyTestProject")]
```

An alternative solution is to make the `Program` class public. `Program` can be made public with Top-level statements by defining a `public partial Program` class in the project or in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

// ... Configure services, routes, etc.

app.Run();

public partial class Program { }
```

C#

```
[Fact]
public async Task HelloWorld()
{
    var application = new WebApplicationFactory<Program>()
        .WithWebHostBuilder(builder =>
        {
            builder.ConfigureServices(services =>
            {
```

```
                services.AddSingleton<IHelloService, MockHelloService>();
            });
        });

    var client = application.CreateClient();

    var response = await client.GetStringAsync("/");

    Assert.Equal("Test Hello", response);
}

class MockHelloService : IHelloService
{
    public string HelloMessage => "Test Hello";
}
```

The .NET 5 version and .NET 6 version with the `WebApplicationFactory` are identical by design.

Migrate from ASP.NET Core 3.1 to 6.0

Article • 06/04/2022

This article explains how to update an existing ASP.NET Core 3.1 project to ASP.NET Core 6.0. To upgrade from ASP.NET Core 5.0 to 6.0, see Migrate from ASP.NET Core 5.0 to 6.0.

Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.
- .NET 6.0 SDK

Update .NET SDK version in `global.json`

If you rely upon a global.json file to target a specific .NET SDK version, update the `version` property to the .NET 6.0 SDK version that's installed. For example:

diff

```
{
  "sdk": {
-    "version": "3.1.200"
+    "version": "6.0.100"
  }
}
```

Update the target framework

Update the project file's Target Framework Moniker (TFM) to `net6.0`:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
-    <TargetFramework>netcoreapp3.1</TargetFramework>
+    <TargetFramework>net6.0</TargetFramework>
  </PropertyGroup>
```

```
</Project>
```

Update package references

In the project file, update each Microsoft.AspNetCore.* , Microsoft.EntityFrameworkCore.* , Microsoft.Extensions.* , and System.Net.Http.Json package reference's `Version` attribute to 6.0.0 or later. For example:

diff

```
<ItemGroup>
-    <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="3.1.6" />
-    <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="3.1.6" />
-    <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="3.1.6" />
-    <PackageReference Include="System.Net.Http.Json" Version="3.2.1" />
+    <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="6.0.0" />
+    <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="6.0.0" />
+    <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="6.0.0" />
+    <PackageReference Include="System.Net.Http.Json" Version="6.0.0" />
</ItemGroup>
```

Delete `bin` and `obj` folders

You may need to delete the `bin` and `obj` folders. Run `dotnet nuget locals --clear all` to clear the NuGet package cache.

Minimal hosting model

The ASP.NET Core templates generate code using the new minimal hosting model. The minimal hosting model unifies `Startup.cs` and `Program.cs` into a single `Program.cs` file. `ConfigureServices` and `Configure` are no longer used. Apps migrating from ASP.NET Core 3.1 to 6.0 don't need to use the minimal hosting model, using `Startup` and the Generic Host used by the ASP.NET Core 3.1 templates is fully supported.

To use `Startup` with the new minimal hosting model, see Use Startup with the new minimal hosting model.

To migrate to the new minimal hosting model using the following pattern used by the ASP.NET Core 6.0 templates, see Code samples migrated to the new minimal hosting model in ASP.NET Core 6.0 and Migrate from ASP.NET Core 5.0 to 6.0

Update Razor class libraries (RCLs)

Migrate Razor class libraries (RCLs) to take advantage of new APIs or features that are introduced as part of ASP.NET Core 6.0.

To update a RCL that targets components:

1. Update the following properties in the project file:

   diff

   ```
   <Project Sdk="Microsoft.NET.Sdk.Razor">
     <PropertyGroup>
   -     <TargetFramework>netstandard2.0</TargetFramework>
   -     <RazorLangVersion>3.0</RazorLangVersion>
   +     <TargetFramework>net6.0</TargetFramework>
     </PropertyGroup>
   ```

2. Update other packages to their latest versions. The latest versions can be found at NuGet.org.

To update an RCL targeting MVC, update the following properties in the project file:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
-    <TargetFramework>netcoreapp3.1</TargetFramework>
+    <TargetFramework>net6.0</TargetFramework>
     <AddRazorSupportForMvc>true</AddRazorSupportForMvc>
  </PropertyGroup>
```

Blazor

To adopt all of the 5.0 features and 6.0 features for Blazor apps, we recommend the following process:

- Create a new 6.0 Blazor project from one of the Blazor project templates. For more information, see Tooling for ASP.NET Core Blazor.

- Move the app's components and code to the 6.0 app making modifications to adopt the new 5.0 and 6.0 features.

Update Docker images

For apps using Docker, update your *Dockerfile* `FROM` statements and scripts. Use a base image that includes the ASP.NET Core 6.0 runtime. Consider the following `docker pull` command difference between ASP.NET Core 3.1 and 6.0:

```
diff
```

```
- docker pull mcr.microsoft.com/dotnet/core/aspnet:3.1
+ docker pull mcr.microsoft.com/dotnet/aspnet:6.0
```

As part of the move to ".NET" as the product name, the Docker images moved from the `mcr.microsoft.com/dotnet/core` repositories to `mcr.microsoft.com/dotnet`. For more information, see .NET 5.0 - Docker Repo Name Change (dotnet/dotnet-docker #1939).

Model binding changes in ASP.NET Core MVC and Razor Pages

`DateTime` values are model bound as UTC times

In ASP.NET Core 3.1 and earlier, `DateTime` values were model-bound as local time, where the timezone was determined by the server. `DateTime` values bound from input formatting (JSON) and `DateTimeOffset` values were bound as UTC timezones.

In ASP.NET Core 5.0 and later, model binding consistently binds `DateTime` values with the UTC timezone.

To retain the previous behavior, remove the `DateTimeModelBinderProvider` in `Startup.ConfigureServices`:

```
C#
```

```
services.AddControllersWithViews(options =>
    options.ModelBinderProviders.RemoveType<DateTimeModelBinderProvider>());
```

`ComplexObjectModelBinderProvider` \ `ComplexObjectModelBinder` replace `ComplexTypeModelBinderProvider` \ `ComplexTypeModelBinder`

To add support for model binding C# 9 record types, the ComplexTypeModelBinderProvider is:

- Annotated as obsolete.
- No longer registered by default.

Apps that rely on the presence of the `ComplexTypeModelBinderProvider` in the `ModelBinderProviders` collection need to reference the new binder provider:

diff

```
- var complexModelBinderProvider =
options.ModelBinderProviders.OfType<ComplexTypeModelBinderProvider>();
+ var complexModelBinderProvider =
options.ModelBinderProviders.OfType<ComplexObjectModelBinderProvider>();
```

`UseDatabaseErrorPage` obsolete

The ASP.NET Core 3.1 templates that include an option for individual user accounts generate a call to UseDatabaseErrorPage. `UseDatabaseErrorPage` is now obsolete and should be replaced with a combination of `AddDatabaseDeveloperPageExceptionFilter` and `UseMigrationsEndPoint`, as shown in the following code:

diff

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
+   services.AddDatabaseDeveloperPageExceptionFilter();
    services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddRazorPages();
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
```

```
+       app.UseMigrationsEndPoint();
-       app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }
```

For more information, see Obsoleting DatabaseErrorPage middleware (dotnet/aspnetcore #24987).

ASP.NET Core Module (ANCM)

If the ASP.NET Core Module (ANCM) wasn't a selected component when Visual Studio was installed or if a prior version of the ANCM was installed on the system, download the latest .NET Core Hosting Bundle Installer (direct download) and run the installer. For more information, see Hosting Bundle.

Application name change

In .NET 6, WebApplicationBuilder normalizes the content root path to end with a DirectorySeparatorChar. Most apps migrating from HostBuilder or WebHostBuilder won't have the same app name because they aren't normalized. For more information, see SetApplicationName

Review breaking changes

See the following resources:

- Identity: Default Bootstrap version of UI changed
- Breaking changes for migration from version 3.1 to 5.0. ASP.NET Core and Entity Framework Core are also included in the list.
- Breaking changes for migration from version 5.0 to 6.0: Includes ASP.NET Core and Entity Framework Core.
- Announcements GitHub repository (aspnet/Announcements, 6.0.0 label): Includes breaking and non-breaking information.
- Announcements GitHub repository (aspnet/Announcements, 5.0.0 label): Includes breaking and non-breaking information.

Migrate from ASP.NET Core 3.1 to 5.0

Article • 10/08/2024

This article explains how to update an existing ASP.NET Core 3.1 project to ASP.NET Core 5.0. For instructions on how to migrate from ASP.NET Core 3.1 to ASP.NET Core 6.0, see Migrate from ASP.NET Core 3.1 to 6.0.

Prerequisites

Visual Studio

- Visual Studio 2019 16.8 or later with the **ASP.NET and web development** workload
- .NET 5.0 SDK

Update .NET Core SDK version in global.json

If you rely upon a global.json file to target a specific .NET Core SDK version, update the `version` property to the .NET 5.0 SDK version that's installed. For example:

diff

```
{
  "sdk": {
-    "version": "3.1.200"
+    "version": "5.0.100"
  }
}
```

Update the target framework

If updating a Blazor WebAssembly project, skip to the Update Blazor WebAssembly projects section. For any other ASP.NET Core project type, update the project file's Target Framework Moniker (TFM) to `net5.0`:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

```
  <PropertyGroup>
-    <TargetFramework>netcoreapp3.1</TargetFramework>
+    <TargetFramework>net5.0</TargetFramework>
  </PropertyGroup>

</Project>
```

Delete `bin` and `obj` folders

You may need to delete the `bin` and `obj` folders. Run `dotnet nuget locals --clear all` to clear the NuGet package cache.

Changes to Blazor app routing logic in 5.0.1 and further 5.x releases up to 6.0

The computation of route precedence changed in the ASP.NET Core 5.0.1 patch release. This might affect you if you've defined catch-all routes or routes with optional parameters.

Old behavior

With the prior behavior in ASP.NET Core 5.0.0 or earlier, routes with lower precedence, such as `{*slug}`, are matched before routes with higher precedence, such as `/customer/{id}`.

New behavior

The new behavior in ASP.NET Core 5.0.1 or later more closely matches the routing behavior defined in ASP.NET Core apps, where the framework computes and establishes the route precedence for each segment first and only uses the length of the route to break ties as a secondary criteria.

Reason for change

The original behavior is considered a bug in the implementation because our goal is for the Blazor routing system to behave in the same way as the ASP.NET Core routing system for the subset of features supported by Blazor routing.

Recommended action

Add the `PreferExactMatches` attribute to the `Router` component in the `App.razor` file to opt into the correct behavior:

razor

```
<Router AppAssembly="@typeof(Program).Assembly" PreferExactMatches="@true">
```

When `PreferExactMatches` is set to `@true`, route matching prefers exact matches over wildcards.

> **ⓘ Important**
>
> All apps should explicitly set `PreferExactMatches` to `@true`.
>
> The ability to set `PreferExactMatches` to `@false` or leave it unset *is only provided for backward compatibility*.
>
> When .NET 6 is released, the router will always prefer exact matches, and the `PreferExactMatches` option won't be available.

Update Blazor WebAssembly and Blazor Server projects

The guidance in this section applies to both Blazor hosting models. Sections following this section provide additional guidance specific to hosting models and app types. Apply the guidance from all relevant sections to your app.

1. In `wwwroot/index.html` of a Blazor WebAssembly app or the `Pages/_Host.cshtml` of a Blazor Server app, add a `<link>` element to the `<head>` element for styles. In the following `<link>` element `href` attribute values, the placeholder `{ASSEMBLY NAME}` is the app's assembly name.

   diff

   ```
   +<link href="{ASSEMBLY NAME}.styles.css" rel="stylesheet" />
   ```

   Standalone Blazor WebAssembly or Blazor Server example:

   diff

```
+<link href="BlazorSample.styles.css" rel="stylesheet" />
```

`Client` project of a hosted Blazor WebAssembly solution example:

diff

```
+<link href="BlazorSample.Client.styles.css" rel="stylesheet" />
```

2. Include a new namespace in the app's `_Imports.razor` file for component virtualization, Microsoft.AspNetCore.Components.Web.Virtualization. The following `_Imports.razor` files show the default namespaces in apps generated from the Blazor project templates. The placeholder `{ASSEMBLY NAME}` is the app's assembly name.

   Blazor WebAssembly (`_Imports.razor`):

   razor

   ```
   @using System.Net.Http
   @using System.Net.Http.Json
   @using Microsoft.AspNetCore.Components.Forms
   @using Microsoft.AspNetCore.Components.Routing
   @using Microsoft.AspNetCore.Components.Web
   @using Microsoft.AspNetCore.Components.Web.Virtualization
   @using Microsoft.AspNetCore.Components.WebAssembly.Http
   @using Microsoft.JSInterop
   @using {ASSEMBLY NAME}
   @using {ASSEMBLY NAME}.Shared
   ```

   Blazor Server (`_Imports.razor`):

   razor

   ```
   @using System.Net.Http
   @using Microsoft.AspNetCore.Authorization
   @using Microsoft.AspNetCore.Components.Authorization
   @using Microsoft.AspNetCore.Components.Forms
   @using Microsoft.AspNetCore.Components.Routing
   @using Microsoft.AspNetCore.Components.Web
   @using Microsoft.AspNetCore.Components.Web.Virtualization
   @using Microsoft.JSInterop
   @using {ASSEMBLY NAME}
   @using {ASSEMBLY NAME}.Shared
   ```

3. In the `MainLayout` component (`Shared/MainLayout.razor`), surround the component's HTML markup with a `<div>` element that has a `class` attribute set to `page`:

```razor
<div class="page">

    ...

</div>
```

4. Add the following files to the `Shared` folder:

`MainLayout.razor.css`:

```css
.page {
    position: relative;
    display: flex;
    flex-direction: column;
}

.main {
    flex: 1;
}

.sidebar {
    background-image: linear-gradient(180deg, rgb(5, 39, 103) 0%,
#3a0647 70%);
}

.top-row {
    background-color: #f7f7f7;
    border-bottom: 1px solid #d6d5d5;
    justify-content: flex-end;
    height: 3.5rem;
    display: flex;
    align-items: center;
}

    .top-row ::deep a, .top-row .btn-link {
        white-space: nowrap;
        margin-left: 1.5rem;
    }

    .top-row a:first-child {
        overflow: hidden;
        text-overflow: ellipsis;
    }
```

```
@media (max-width: 767.98px) {
    .top-row:not(.auth) {
        display: none;
    }

    .top-row.auth {
        justify-content: space-between;
    }

    .top-row a, .top-row .btn-link {
        margin-left: 0;
    }
}

@media (min-width: 768px) {
    .page {
        flex-direction: row;
    }

    .sidebar {
        width: 250px;
        height: 100vh;
        position: sticky;
        top: 0;
    }

    .top-row {
        position: sticky;
        top: 0;
        z-index: 1;
    }

    .main > div {
        padding-left: 2rem !important;
        padding-right: 1.5rem !important;
    }
}
```

`NavMenu.razor.css`:

```css
.navbar-toggler {
    background-color: rgba(255, 255, 255, 0.1);
}

.top-row {
    height: 3.5rem;
    background-color: rgba(0,0,0,0.4);
}

.navbar-brand {
```

```
    font-size: 1.1rem;
}

.oi {
    width: 2rem;
    font-size: 1.1rem;
    vertical-align: text-top;
    top: -2px;
}

.nav-item {
    font-size: 0.9rem;
    padding-bottom: 0.5rem;
}

    .nav-item:first-of-type {
        padding-top: 1rem;
    }

    .nav-item:last-of-type {
        padding-bottom: 1rem;
    }

    .nav-item ::deep a {
        color: #d7d7d7;
        border-radius: 4px;
        height: 3rem;
        display: flex;
        align-items: center;
        line-height: 3rem;
    }

.nav-item ::deep a.active {
    background-color: rgba(255,255,255,0.25);
    color: white;
}

.nav-item ::deep a:hover {
    background-color: rgba(255,255,255,0.1);
    color: white;
}

@media (min-width: 768px) {
    .navbar-toggler {
        display: none;
    }

    .collapse {
        /* Never collapse the sidebar for wide screens */
        display: block;
    }
}
```

5. The latest base `wwwroot/css/app.css` file of a Blazor WebAssembly app or `wwwroot/css/site.css` file of a Blazor Server app includes the following styles. Remove extra styles leaving the following styles and any that you've added to the app.

   The following stylesheet only includes base styles and does **not** include custom styles added by the developer:

   ```css
   html, body {
       font-family: 'Helvetica Neue', Helvetica, Arial, sans-serif;
   }

   a, .btn-link {
       color: #0366d6;
   }

   .btn-primary {
       color: #fff;
       background-color: #1b6ec2;
       border-color: #1861ac;
   }

   .content {
       padding-top: 1.1rem;
   }

   .valid.modified:not([type=checkbox]) {
       outline: 1px solid #26b050;
   }

   .invalid {
       outline: 1px solid red;
   }

   .validation-message {
       color: red;
   }

   #blazor-error-ui {
       background: lightyellow;
       bottom: 0;
       box-shadow: 0 -1px 2px rgba(0, 0, 0, 0.2);
       display: none;
       left: 0;
       padding: 0.6rem 1.25rem 0.7rem 1.25rem;
       position: fixed;
       width: 100%;
       z-index: 1000;
   }
   ```

```
#blazor-error-ui .dismiss {
    cursor: pointer;
    position: absolute;
    right: 0.75rem;
    top: 0.5rem;
}
```

> **Note**
>
> The preceding example doesn't show the `@import` directive for Open Iconic icons (`open-iconic-bootstrap.css`), provided by the Blazor project template. Open Iconic was abandoned by its maintainers.

Update Blazor WebAssembly projects

Follow the guidance in the preceding Update Blazor WebAssembly and Blazor Server projects section.

For a Blazor WebAssembly project, including the *`Client`* project of a hosted Blazor solution, apply the following changes to the project file:

1. Update the SDK from `Microsoft.NET.Sdk.Web` to `Microsoft.NET.Sdk.BlazorWebAssembly`:

   diff

   ```
   - <Project Sdk="Microsoft.NET.Sdk.Web">
   + <Project Sdk="Microsoft.NET.Sdk.BlazorWebAssembly">
   ```

   > **Note**
   >
   > This update only applies to standalone Blazor WebAssembly projects and the *`Client`* projects of hosted Blazor solutions.

2. Update the following properties:

   diff

   ```
   <Project Sdk="Microsoft.NET.Sdk.BlazorWebAssembly">

     <PropertyGroup>
   -     <TargetFramework>netstandard2.1</TargetFramework>
   -     <RazorLangVersion>3.0</RazorLangVersion>
   ```

```
+     <TargetFramework>net5.0</TargetFramework>
  </PropertyGroup>
```

3. Remove the package reference to Microsoft.AspNetCore.Components.WebAssembly.Build:

```
diff

<ItemGroup>
-    <PackageReference
Include="Microsoft.AspNetCore.Components.WebAssembly.Build"
Version="3.2.1" PrivateAssets="all" />
```

4. Update other packages to their latest versions. The latest versions can be found at NuGet.org.

5. In `wwwroot/index.html`, change the element that loads the `App` component to a `<div>` element with an `id` set to `app`:

```
diff

-<app>Loading...</app>
+<div id="app">Loading...</div>
```

6. In `Program.Main` (`Program.cs`), change the reference to the `<app>` element to a CSS selector by adding a hash `#` to it:

```
diff

-builder.RootComponents.Add<App>("app");
+builder.RootComponents.Add<App>("#app");
```

7. In `Program.Main` (`Program.cs`), change a default transient `HttpClient` registration to scoped, if present:

```
diff

-builder.Services.AddTransient(sp => new HttpClient
-    { BaseAddress = new Uri(builder.HostEnvironment.BaseAddress) });
+builder.Services.AddScoped(sp => new HttpClient
+    { BaseAddress = new Uri(builder.HostEnvironment.BaseAddress) });
```

8. In `Program.Main` (`Program.cs`) of the **`Client`** app of hosted Blazor solutions:

- Optionally, substitute `builder.HostEnvironment.BaseAddress` for string client base addresses.
- Change any named transient client factory registrations to scoped.

diff

```
-builder.Services.AddHttpClient("{APP NAMESPACE}.ServerAPI",
-    client => client.BaseAddress = new Uri("https://localhost:5001"))
-    .AddHttpMessageHandler<BaseAddressAuthorizationMessageHandler>();
-builder.Services.AddTransient(sp =>
sp.GetRequiredService<IHttpClientFactory>()
-    .CreateClient("{APP NAMESPACE}.ServerAPI"));
+builder.Services.AddHttpClient("{APP NAMESPACE}.ServerAPI",
+    client => client.BaseAddress = new
Uri(builder.HostEnvironment.BaseAddress))
+    .AddHttpMessageHandler<BaseAddressAuthorizationMessageHandler>();
+builder.Services.AddScoped(sp =>
sp.GetRequiredService<IHttpClientFactory>()
+    .CreateClient("{APP NAMESPACE}.ServerAPI"));
```

In the preceding code, the `{APP NAMESPACE}` placeholder is the app's namespace.

Standalone Blazor WebAssembly app with Microsoft Accounts

Follow the guidance in the preceding Update Blazor WebAssembly and Blazor Server projects and Update Blazor WebAssembly projects sections.

For a standalone Blazor WebAssembly app registered in the Azure portal to use Microsoft Entra ID (ME-ID) for Microsoft Accounts:

- The app requires the `openid` and `offline_access` scopes:

C#

```
options.ProviderOptions.DefaultAccessTokenScopes.Add("openid");
options.ProviderOptions.DefaultAccessTokenScopes.Add("offline_access");
```

- In the Azure portal app registration **Authentication** blade:

  1. Remove the **Web** platform configuration.
  2. Add a **Single-page application** platform configuration with the app's redirect URI.
  3. Disable **Implicit grant** for **Access tokens** and **ID tokens**.

For more information, see Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Accounts.

Standalone Blazor WebAssembly app with Microsoft Entra ID (ME-ID)

Follow the guidance in the preceding Update Blazor WebAssembly and Blazor Server projects and Update Blazor WebAssembly projects sections.

For a standalone Blazor WebAssembly app registered in the Azure portal to use Microsoft Entra ID (ME-ID):

- The app requires the `https://graph.microsoft.com/User.Read` scope:

  ```
  C#

  options.ProviderOptions.DefaultAccessTokenScopes
      .Add("https://graph.microsoft.com/User.Read");
  ```

- In the Azure portal app registration **Authentication** blade:

  1. Remove the **Web** platform configuration.
  2. Add a **Single-page application** platform configuration with the app's redirect URI.
  3. Disable **Implicit grant** for **Access tokens** and **ID tokens**.

For more information, see Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Entra ID.

Standalone Blazor WebAssembly app with Azure Active Directory (AAD) B2C

Follow the guidance in the preceding Update Blazor WebAssembly and Blazor Server projects and Update Blazor WebAssembly projects sections.

For a standalone Blazor WebAssembly app registered in the Azure portal to use Azure Active Directory (AAD) B2C:

- The app requires the `openid` and `offline_access` scopes:

  ```
  C#

  options.ProviderOptions.DefaultAccessTokenScopes.Add("openid");
  ```

```
options.ProviderOptions.DefaultAccessTokenScopes.Add("offline_access");
```

- In the Azure portal app registration **Authentication** blade:

  1. Remove the **Web** platform configuration.
  2. Add a **Single-page application** platform configuration with the app's redirect URI.
  3. Disable **Implicit grant** for **Access tokens** and **ID tokens**.

For more information, see Secure an ASP.NET Core Blazor WebAssembly standalone app with Azure Active Directory B2C.

Hosted Blazor WebAssembly app with Microsoft Entra ID (ME-ID) or AAD B2C

Follow the guidance in the preceding Update Blazor WebAssembly and Blazor Server projects and Update Blazor WebAssembly projects sections.

The `Client` app registration of a hosted Blazor solution that uses AAD or AAD B2C for user authentication should use a **Single-page application** Azure Apps platform configuration.

In the Azure portal `Client` app registration **Authentication** blade:

1. Remove the **Web** platform configuration.
2. Add a **Single-page application** platform configuration with the app's redirect URI.
3. Disable **Implicit grant** for **Access tokens** and **ID tokens**.

For more information, see:

- Secure a hosted ASP.NET Core Blazor WebAssembly app with Microsoft Entra ID
- Secure a hosted ASP.NET Core Blazor WebAssembly app with Azure Active Directory B2C

Update the Server project of a hosted Blazor solution

Follow the guidance in the preceding sections:

- Update Blazor WebAssembly and Blazor Server projects
- Update Blazor WebAssembly projects
- The section that applies to the app's provider with Azure Active Directory:
  - Standalone Blazor WebAssembly app with Microsoft Accounts
  - Standalone Blazor WebAssembly app with Microsoft Entra ID (ME-ID)

- Standalone Blazor WebAssembly app with Azure Active Directory (AAD) B2C

Update the `Server` project of a hosted Blazor solution as an ASP.NET Core app following the general guidance in this article.

Additionally, `Server` projects that authenticate users to client Blazor WebAssembly apps with Microsoft Entra ID (ME-ID) or B2C should adopt new Microsoft Identity v2.0 packages:

For AAD:

diff

```
-<PackageReference Include="Microsoft.AspNetCore.Authentication.AzureAD.UI"
Version="..." />
+<PackageReference Include="Microsoft.Identity.Web" Version="{VERSION}" />
+<PackageReference Include="Microsoft.Identity.Web.UI" Version="{VERSION}"
/>
```

For AAD B2C:

diff

```
-<PackageReference
Include="Microsoft.AspNetCore.Authentication.AzureADB2C.UI" Version="..." />
+<PackageReference Include="Microsoft.Identity.Web" Version="{VERSION}" />
+<PackageReference Include="Microsoft.Identity.Web.UI" Version="{VERSION}"
/>
```

For the preceding package references, determine the package versions for the `{VERSION}` placeholders at NuGet.org:

- Microsoft.Identity.Web
- Microsoft.Identity.Web.UI

Note

The SDK of the `Server` project in a hosted Blazor WebAssembly solution remains `Microsoft.NET.Sdk.Web`:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

For more information, see:

- Secure a hosted ASP.NET Core Blazor WebAssembly app with Microsoft Entra ID
- Secure a hosted ASP.NET Core Blazor WebAssembly app with Azure Active Directory B2C

Clean and rebuild the solution

After migrating the app or solution to .NET 5, clean and rebuild the app or solution. If package incompatibilities exist between new package references and cached packages:

1. Clear NuGet package caches by executing the following dotnet nuget locals command in a command shell:

   .NET CLI

   ```
   dotnet nuget locals --clear all
   ```

2. Clean and rebuild the app or solution.

Troubleshoot

Follow the *Troubleshoot* guidance at the end of the Blazor WebAssembly security topic that applies to your app:

Standalone Blazor WebAssembly apps:

- General guidance for OIDC providers and the WebAssembly Authentication Library
- Microsoft Accounts
- Microsoft Entra ID (ME-ID)
- Azure Active Directory (AAD) B2C

Hosted Blazor WebAssembly apps:

- Microsoft Entra ID (ME-ID)
- Azure Active Directory (AAD) B2C
- Identity Server

Unauthorized client for Microsoft Entra ID (ME-ID)

After upgrading a Blazor WebAssembly app that uses AAD for authentication, you may receive the following error on the login callback to the app after the user signs in with AAD:

> info: Microsoft.AspNetCore.Authorization.DefaultAuthorizationService[2]
> Authorization failed. These requirements were not met:
> DenyAnonymousAuthorizationRequirement: Requires an authenticated user.

Login callback error from AAD:

- Error: `unauthorized_client`
- Description: `AADB2C90058: The provided application is not configured to allow public clients.`

To resolve the error:

1. In the Azure portal, access the app's manifest.
2. Set the allowPublicClient attribute to `null` or `true`.

Update a Blazor Progressive Web Application (PWA)

Add the following item to the PWA app's project file:

XML

```
<ItemGroup>
  <ServiceWorker Include="wwwroot\service-worker.js"
    PublishedContent="wwwroot\service-worker.published.js" />
</ItemGroup>
```

Remove preview CSS isolation stylesheet link

If the project's `wwwroot/index.html` (Blazor WebAssembly) or `Pages/_Host.cshtml` (Blazor Server) contains a stylesheet `<link>` element for `scoped.styles.css` from an earlier 5.0 preview release, remove the `<link>` tag:

diff

```
-<link href="_framework/scoped.styles.css/" rel="stylesheet" />
```

Update Razor class libraries (RCLs)

Migrate Razor class libraries (RCLs) to take advantage of new APIs or features that are introduced as part of ASP.NET Core 5.0.

To update a RCL that targets components:

1. Update the following properties in the project file:

   diff

   ```
   <Project Sdk="Microsoft.NET.Sdk.Razor">

     <PropertyGroup>
   -     <TargetFramework>netstandard2.0</TargetFramework>
   -     <RazorLangVersion>3.0</RazorLangVersion>
   +     <TargetFramework>net5.0</TargetFramework>
     </PropertyGroup>
   ```

2. Update other packages to their latest versions. The latest versions can be found at NuGet.org.

To update an RCL targeting MVC, update the following properties in the project file:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
-     <TargetFramework>netcoreapp3.1</TargetFramework>
+     <TargetFramework>net5.0</TargetFramework>
    <AddRazorSupportForMvc>true</AddRazorSupportForMvc>
  </PropertyGroup>
```

Update package references

In the project file, update each Microsoft.AspNetCore.*, Microsoft.EntityFrameworkCore.*, Microsoft.Extensions.*, and System.Net.Http.Json package reference's `Version` attribute to 5.0.0 or later. For example:

diff

```
<ItemGroup>
-     <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="3.1.6" />
-     <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="3.1.6">
-     <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
```

```
Version="3.1.6" />
-    <PackageReference Include="System.Net.Http.Json" Version="3.2.1" />
+    <PackageReference Include="Microsoft.AspNetCore.JsonPatch"
Version="5.0.0" />
+    <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="5.0.0">
+    <PackageReference Include="Microsoft.Extensions.Caching.Abstractions"
Version="5.0.0" />
+    <PackageReference Include="System.Net.Http.Json" Version="5.0.0" />
</ItemGroup>
```

Update Docker images

For apps using Docker, update your *Dockerfile* `FROM` statements and scripts. Use a base image that includes the ASP.NET Core 5.0 runtime. Consider the following `docker pull` command difference between ASP.NET Core 3.1 and 5.0:

diff

```
- docker pull mcr.microsoft.com/dotnet/core/aspnet:3.1
+ docker pull mcr.microsoft.com/dotnet/aspnet:5.0
```

As part of the move to ".NET" as the product name, the Docker images moved from the `mcr.microsoft.com/dotnet/core` repositories to `mcr.microsoft.com/dotnet`. For more information, see dotnet/dotnet-docker#1939.

Model binding changes in ASP.NET Core MVC and Razor Pages

DateTime values are model bound as UTC times

In ASP.NET Core 3.1 and earlier, `DateTime` values were model-bound as local time, where the timezone was determined by the server. `DateTime` values bound from input formatting (JSON) and `DateTimeOffset` values were bound as UTC timezones.

In ASP.NET Core 5.0 and later, model binding consistently binds `DateTime` values with the UTC timezone.

To retain the previous behavior, remove the `DateTimeModelBinderProvider` in `Startup.ConfigureServices`:

C#

```
services.AddControllersWithViews(options =>
    options.ModelBinderProviders.RemoveType<DateTimeModelBinderProvider>());
```

ComplexObjectModelBinderProvider \ ComplexObjectModelBinder replace ComplexTypeModelBinderProvider \ ComplexTypeModelBinder

To add support for model binding C# 9 record types, the ComplexTypeModelBinderProvider is:

- Annotated as obsolete.
- No longer registered by default.

Apps that rely on the presence of the `ComplexTypeModelBinderProvider` in the `ModelBinderProviders` collection need to reference the new binder provider:

diff

```
- var complexModelBinderProvider =
options.ModelBinderProviders.OfType<ComplexTypeModelBinderProvider>();
+ var complexModelBinderProvider =
options.ModelBinderProviders.OfType<ComplexObjectModelBinderProvider>();
```

UseDatabaseErrorPage obsolete

The ASP.NET Core 3.1 templates that include an option for individual user accounts generate a call to UseDatabaseErrorPage. `UseDatabaseErrorPage` is now obsolete and should be replaced with a combination of `AddDatabaseDeveloperPageExceptionFilter` and `UseMigrationsEndPoint`, as shown in the following code:

diff

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
+   services.AddDatabaseDeveloperPageExceptionFilter();
    services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddRazorPages();
```

```
}

public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
+       app.UseMigrationsEndPoint();
-       app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }
```

For more information, see this GitHub issue.

ASP.NET Core Module (ANCM)

If the ASP.NET Core Module (ANCM) wasn't a selected component when Visual Studio was installed or if a prior version of the ANCM was installed on the system, download the latest .NET Core Hosting Bundle Installer (direct download) and run the installer. For more information, see Hosting Bundle.

Package reference changes affecting some NuGet packages

With the migration of some `Microsoft.Extensions.*` NuGet packages from the dotnet/extensions repository to dotnet/runtime, as described in Migrating dotnet/extensions content to dotnet/runtime and dotnet/aspnetcore (aspnet/Announcements #411), packaging changes are being applied to some of the migrated packages. These changes often result in namespace changes for .NET API.

To research APIs further for app namespace changes when migrating to 5.0, use the .NET API browser.

Migrate Microsoft.Identity.Web

The following wiki pages explain how to migrate Microsoft.Identity.Web from ASP.NET Core 3.1 to 5.0:

- Microsoft.Identity.Web in web apps

- Microsoft.Identity.Web in web APIs

The following tutorials also explain the migration:

- An ASP.NET Core Web app signing-in users with the Microsoft identity platform in your organization. See **Option 2: Create the sample from the command line**.
- Sign-in a user with the Microsoft identity platform in a WPF Desktop application and call an ASP.NET Core Web API. See **How was the code created**.

Review breaking changes

For breaking changes from .NET Core 3.1 to .NET 5.0, see Breaking changes for migration from version 3.1 to 5.0. ASP.NET Core and Entity Framework Core are also included in the list.

Migrate from ASP.NET Core 3.0 to 3.1

Article • 06/18/2024

By Scott Addie

This article explains how to update an existing ASP.NET Core 3.0 project to ASP.NET Core 3.1.

Prerequisites

Visual Studio

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK

Update .NET Core SDK version in global.json

If you rely upon a global.json file to target a specific .NET Core SDK version, update the `version` property to the 3.1 SDK version that's installed. For example:

diff

```
{
  "sdk": {
-    "version": "3.0.101"
+    "version": "3.1.101"
  }
}
```

Update the target framework

In the project file, update the Target Framework Moniker (TFM) to `netcoreapp3.1`:

diff

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
-    <TargetFramework>netcoreapp3.0</TargetFramework>
```

```
+    <TargetFramework>netcoreapp3.1</TargetFramework>
  </PropertyGroup>

</Project>
```

Update package references

In the project file, update each `Microsoft.AspNetCore.*` package reference's `Version` attribute to 3.1.0 or later. For example:

diff

```
<ItemGroup>
-    <PackageReference Include="Microsoft.AspNetCore.Mvc.NewtonsoftJson"
Version="3.0.0" />
-    <PackageReference
Include="Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation" Version="3.0.0"
Condition="'$(Configuration)' == 'Debug'" />
+    <PackageReference Include="Microsoft.AspNetCore.Mvc.NewtonsoftJson"
Version="3.1.1" />
+    <PackageReference
Include="Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation" Version="3.1.1"
Condition="'$(Configuration)' == 'Debug'" />
</ItemGroup>
```

Update Docker images

For apps using Docker, use a base image that includes ASP.NET Core 3.1. For example:

Console

```
docker pull mcr.microsoft.com/dotnet/aspnet:3.1
```

React to SameSite cookie changes

The `SameSite` attribute implementations for HTTP cookies changed between ASP.NET Core 3.0 and 3.1. For actions to be taken, see the following resources:

- Work with SameSite cookies in ASP.NET Core
- aspnet/Announcements#390
- Upcoming SameSite cookie changes in ASP.NET and ASP.NET Core

Publish with Visual Studio

In the `.pubxml` file update the `TargetFramework` to 3.1:

XML

```
- <TargetFramework>netcoreapp3.0</TargetFramework>
+ <TargetFramework>netcoreapp3.1</TargetFramework>
```

Review breaking changes

Review 3.0-to-3.1 breaking changes across .NET Core, ASP.NET Core, and Entity Framework Core at Breaking changes for migration from version 3.0 to 3.1.

Optional changes

The following changes are optional.

Use the Component Tag Helper

ASP.NET Core 3.1 introduces a `Component` Tag Helper. The Tag Helper can replace the `RenderComponentAsync<TComponent>` HTML helper method in a Blazor project. For example:

diff

```
- @(await Html.RenderComponentAsync<Counter>(RenderMode.ServerPrerendered,
new { IncrementAmount = 10 }))
+ <component type="typeof(Counter)" render-mode="ServerPrerendered" param-
IncrementAmount="10" />
```

For more information, see Prerender and integrate ASP.NET Core Razor components.

ASP.NET Core Module (ANCM)

If the ASP.NET Core Module (ANCM) wasn't a selected component when Visual Studio was installed or if a prior version of the ANCM was installed on the system, download the latest .NET Core Hosting Bundle Installer (direct download) and run the installer. For more information, see Hosting Bundle.

Migrate from ASP.NET Core 2.2 to 3.0

Article • 08/30/2024

By Scott Addie and Rick Anderson

This article explains how to update an existing ASP.NET Core 2.2 project to ASP.NET Core 3.0. It might be helpful to create a new ASP.NET Core 3.0 project to:

- Compare with the ASP.NET Core 2.2 code.
- Copy the relevant changes to your ASP.NET Core 3.0 project.

Prerequisites

Visual Studio

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core 3.0 SDK

Update .NET Core SDK version in global.json

If your solution relies upon a global.json file to target a specific .NET Core SDK version, update its `version` property to the 3.0 version installed on your machine:

JSON

```
{
  "sdk": {
    "version": "3.0.100"
  }
}
```

Update the project file

Update the Target Framework

ASP.NET Core 3.0 and later only run on .NET Core. Set the Target Framework Moniker (TFM) to `netcoreapp3.0`:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

</Project>
```

Remove obsolete package references

A large number of NuGet packages aren't produced for ASP.NET Core 3.0. Such package references should be removed from your project file. Consider the following project file for an ASP.NET Core 2.2 web app:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.2</TargetFramework>
    <AspNetCoreHostingModel>InProcess</AspNetCoreHostingModel>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.App"/>
    <PackageReference Include="Microsoft.AspNetCore.Razor.Design"
Version="2.2.0" PrivateAssets="All" />
  </ItemGroup>

</Project>
```

The updated project file for ASP.NET Core 3.0:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
  </PropertyGroup>

</Project>
```

The updated ASP.NET Core 3.0 project file:

- In the `<PropertyGroup>`:

    - Updates the TFM to `netcoreapp3.0`
    - Removes the `<AspNetCoreHostingModel>` element. For more information, see In-process hosting model in this document.

- In the `<ItemGroup>`:
    - `Microsoft.AspNetCore.App` is removed. For more information, see Framework reference in this document.
    - `Microsoft.AspNetCore.Razor.Design` is removed and in the following list of packages no longer being produced.

To see the full list of packages that are no longer produced, select the following expand list:

▼ Click to expand the list of packages no longer being produced

- Microsoft.AspNetCore
- Microsoft.AspNetCore.All
- Microsoft.AspNetCore.App
- Microsoft.AspNetCore.Antiforgery
- Microsoft.AspNetCore.Authentication
- Microsoft.AspNetCore.Authentication.Abstractions
- Microsoft.AspNetCore.Authentication.Cookies
- Microsoft.AspNetCore.Authentication.Core
- Microsoft.AspNetCore.Authentication.OAuth
- Microsoft.AspNetCore.Authorization.Policy
- Microsoft.AspNetCore.CookiePolicy
- Microsoft.AspNetCore.Cors
- Microsoft.AspNetCore.Diagnostics
- Microsoft.AspNetCore.Diagnostics.HealthChecks

Review breaking changes

Review breaking changes

Framework reference

Features of ASP.NET Core that were available through one of the packages listed above are available as part of the `Microsoft.AspNetCore.App` shared framework. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and includes a runtime component and a targeting pack. For more information, see The shared framework.

- Projects that target the `Microsoft.NET.Sdk.Web` SDK implicitly reference the `Microsoft.AspNetCore.App` framework.

  No additional references are required for these projects:

  XML

  ```
  <Project Sdk="Microsoft.NET.Sdk.Web">
    <PropertyGroup>
      <TargetFramework>netcoreapp3.0</TargetFramework>
    </PropertyGroup>
      ...
  </Project>
  ```

- Projects that target `Microsoft.NET.Sdk` or `Microsoft.NET.Sdk.Razor` SDK, should add an explicit `FrameworkReference` to `Microsoft.AspNetCore.App`:

  XML

  ```
  <Project Sdk="Microsoft.NET.Sdk.Razor">
    <PropertyGroup>
      <TargetFramework>netcoreapp3.0</TargetFramework>
    </PropertyGroup>

    <ItemGroup>
      <FrameworkReference Include="Microsoft.AspNetCore.App" />
    </ItemGroup>
      ...
  </Project>
  ```

Framework-dependent builds using Docker

Framework-dependent builds of console apps that use a package that depends on the ASP.NET Core shared framework may give the following runtime error:

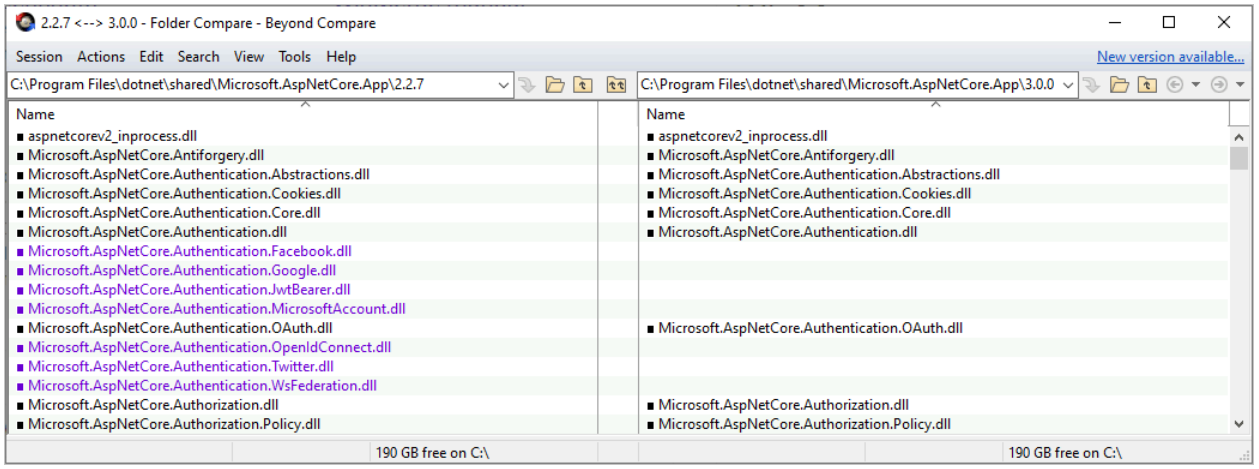
Console

```
It was not possible to find any compatible framework version
The specified framework 'Microsoft.AspNetCore.App', version '3.0.0' was not
found.
  - No frameworks were found.
```

`Microsoft.AspNetCore.App` is the shared framework containing the ASP.NET Core runtime and is only present on the `dotnet/core/aspnet` Docker image. The 3.0 SDK reduces the size of framework-dependent builds using ASP.NET Core by not including duplicate copies of libraries that are available in the shared framework. This is a potential savings of up to 18 MB, but it requires that the ASP.NET Core runtime be present / installed to run the app.

To determine if the app has a dependency (either direct or indirect) on the ASP.NET Core shared framework, examine the `runtimeconfig.json` file generated during a build/publish of your app. The following JSON file shows a dependency on the ASP.NET Core shared framework:

JSON



```
{
  "runtimeOptions": {
    "tfm": "netcoreapp3.0",
    "framework": {
      "name": "Microsoft.AspNetCore.App",
      "version": "3.0.0"
    },
    "configProperties": {
      "System.GC.Server": true
    }
  }
}
```

If your app is using Docker, use a base image that includes ASP.NET Core 3.0. For example, `docker pull mcr.microsoft.com/dotnet/core/aspnet:3.0`.

Add package references for removed assemblies

ASP.NET Core 3.0 removes some assemblies that were previously part of the `Microsoft.AspNetCore.App` package reference. To visualize which assemblies were

removed, compare the two shared framework folders. For example, a comparison of versions 2.2.7 and 3.0.0:

To continue using features provided by the removed assemblies, reference the 3.0 versions of the corresponding packages:

- A template-generated web app with **Individual User Accounts** requires adding the following packages:

  XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp3.0</TargetFramework>
    <UserSecretsId>My-secret</UserSecretsId>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference
Include="Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore"
Version="3.0.0" />
    <PackageReference
Include="Microsoft.AspNetCore.Identity.EntityFrameworkCore"
Version="3.0.0" />
    <PackageReference Include="Microsoft.AspNetCore.Identity.UI"
Version="3.0.0" />
    <PackageReference Include="Microsoft.EntityFrameworkCore.SqlServer"
Version="3.0.0" />
    <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="3.0.0" />
  </ItemGroup>

</Project>
```

- Microsoft.EntityFrameworkCore

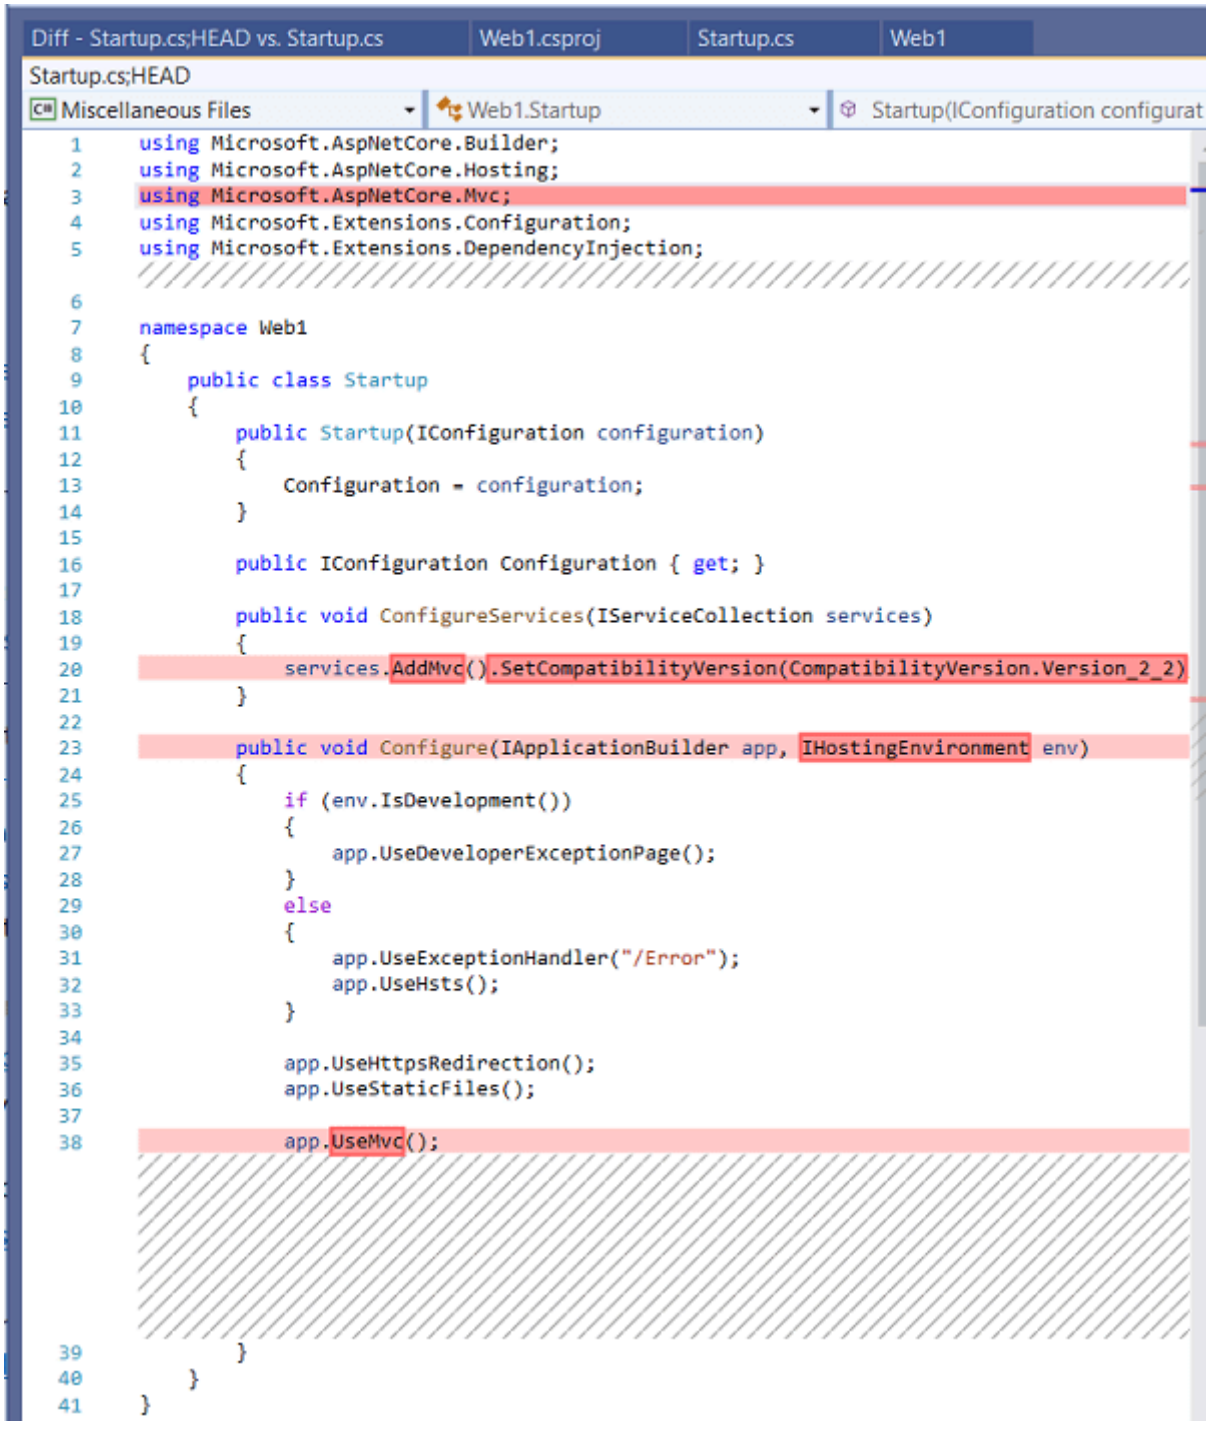
For more information on referencing the database provider-specific package, see Database Providers.

- Identity UI

  Support for Identity UI can be added by referencing the Microsoft.AspNetCore.Identity.UI package.

- SPA Services
  - Microsoft.AspNetCore.SpaServices
  - Microsoft.AspNetCore.SpaServices.Extensions

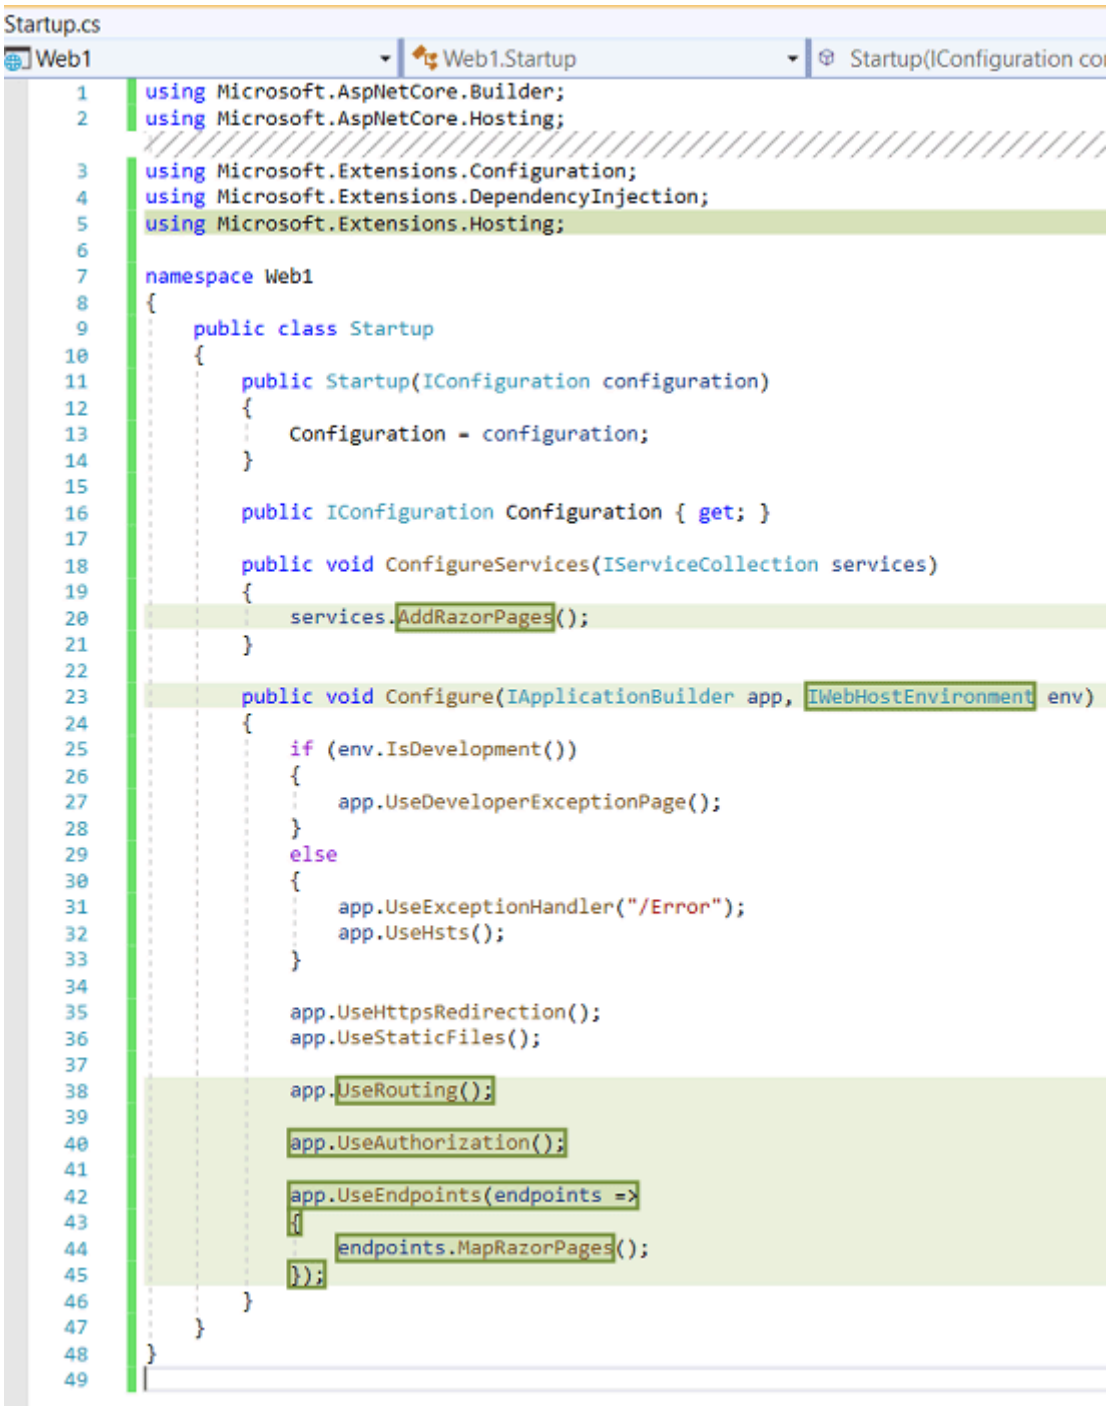
- Authentication: Support for third-party authentication flows are available as NuGet packages:
  - Facebook OAuth (Microsoft.AspNetCore.Authentication.Facebook)
  - Google OAuth (Microsoft.AspNetCore.Authentication.Google)
  - Microsoft Account authentication (Microsoft.AspNetCore.Authentication.MicrosoftAccount)
  - OpenID Connect authentication (Microsoft.AspNetCore.Authentication.OpenIdConnect)
  - OpenID Connect bearer token (Microsoft.AspNetCore.Authentication.JwtBearer)
  - Twitter OAuth (Microsoft.AspNetCore.Authentication.Twitter)
  - WsFederation authentication (Microsoft.AspNetCore.Authentication.WsFederation)



- Formatting and content negotiation support for `System.Net.HttpClient`: The Microsoft.AspNet.WebApi.Client NuGet package provides useful extensibility to `System.Net.HttpClient` with APIs such as `ReadAsAsync` and `PostJsonAsync`. However, this package depends on `Newtonsoft.Json`, not `System.Text.Json`. That means, for example, that serialization property names specified by `JsonPropertyNameAttribute` (`System.Text.Json`) are ignored. There's a newer NuGet package that contains similar extension methods but uses `System.Text.Json`: System.Net.Http.Json.

- Razor runtime compilation: Support for runtime compilation of Razor views and pages is now part of Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation.

- MVC `Newtonsoft.Json` (Json.NET) support: Support for using MVC with `Newtonsoft.Json` is now part of Microsoft.AspNetCore.Mvc.NewtonsoftJson.



Startup changes

The following image shows the deleted and changed lines in an ASP.NET Core 2.2 Razor Pages Web app:

In the preceding image, deleted code is shown in red. The deleted code doesn't show cookie options code, which was deleted prior to comparing the files.

The following image shows the added and changed lines in an ASP.NET Core 3.0 Razor Pages Web app:

In the preceding image, added code is shown in green. For information on the following changes:

- `services.AddMvc` to `services.AddRazorPages`, see MVC service registration in this document.
- `CompatibilityVersion`, see Compatibility version for ASP.NET Core MVC.
- `IHostingEnvironment` to `IWebHostEnvironment`, see this GitHub announcement.
- `app.UseAuthorization` was added to the templates to show the order authorization middleware must be added. If the app doesn't use authorization, you can safely remove the call to `app.UseAuthorization`.
- `app.UseEndpoints`, see Razor Pages or Migrate Startup.Configure in this document.

Analyzer support

Projects that target `Microsoft.NET.Sdk.Web` implicitly reference analyzers previously shipped as part of the Microsoft.AspNetCore.Mvc.Analyzers package. No additional references are required to enable these.

If your app uses API analyzers previously shipped using the Microsoft.AspNetCore.Mvc.Api.Analyzers package, edit your project file to reference the analyzers shipped as part of the .NET Core Web SDK:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">
    <PropertyGroup>
        <TargetFramework>netcoreapp3.0</TargetFramework>
        <IncludeOpenAPIAnalyzers>true</IncludeOpenAPIAnalyzers>
    </PropertyGroup>

    ...
</Project>
```

Razor class library

Razor class library projects that provide UI components for MVC must set the `AddRazorSupportForMvc` property in the project file:

XML

```
<PropertyGroup>
  <AddRazorSupportForMvc>true</AddRazorSupportForMvc>
</PropertyGroup>
```

In-process hosting model

Projects default to the in-process hosting model in ASP.NET Core 3.0 or later. You may optionally remove the `<AspNetCoreHostingModel>` property in the project file if its value is `InProcess`.

Kestrel

Configuration

Migrate Kestrel configuration to the web host builder provided by `ConfigureWebHostDefaults` (`Program.cs`):

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.ConfigureKestrel(serverOptions =>
            {
                // Set properties and call methods on options
            })
            .UseStartup<Startup>();
        });
```

If the app creates the host manually with `ConfigureWebHost` instead of `ConfigureWebHostDefaults`, call `UseKestrel` on the web host builder:

C#

```
public static void Main(string[] args)
{
    var host = new HostBuilder()
        .UseContentRoot(Directory.GetCurrentDirectory())
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder.UseKestrel(serverOptions =>
            {
                // Set properties and call methods on options
            })
            .UseIISIntegration()
            .UseStartup<Startup>();
        })
        .Build();

    host.Run();
}
```

Connection Middleware replaces Connection Adapters

Connection Adapters (`Microsoft.AspNetCore.Server.Kestrel.Core.Adapter.Internal.IConnectionAdapter`) have been removed from Kestrel. Replace Connection Adapters with Connection Middleware. Connection Middleware is similar to HTTP Middleware in the ASP.NET Core pipeline but for lower-level connections. HTTPS and connection logging:

- Have been moved from Connection Adapters to Connection Middleware.
- These extension methods work as in previous versions of ASP.NET Core.

For more information, see the TlsFilterConnectionHandler example in the ListenOptions.Protocols section of the Kestrel article.

Transport abstractions moved and made public

The Kestrel transport layer has been exposed as a public interface in `Connections.Abstractions`. As part of these updates:

- `Microsoft.AspNetCore.Server.Kestrel.Transport.Abstractions` and associated types have been removed.
- NoDelay was moved from ListenOptions to the transport options.
- `Microsoft.AspNetCore.Server.Kestrel.Transport.Abstractions.Internal.SchedulingMode` was removed from KestrelServerOptions.

For more information, see the following GitHub resources:

- Client/server networking abstractions (dotnet/AspNetCore #10308)
- Implement new bedrock listener abstraction and re-plat Kestrel on top (dotnet/AspNetCore #10321)

Kestrel Request trailer headers

For apps that target earlier versions of ASP.NET Core:

- Kestrel adds HTTP/1.1 chunked trailer headers into the request headers collection.
- Trailers are available after the request body is read to the end.

This causes some concerns about ambiguity between headers and trailers, so the trailers have been moved to a new collection (`RequestTrailerExtensions`) in 3.0.

HTTP/2 request trailers are:

- Not available in ASP.NET Core 2.2.
- Available in 3.0 as `RequestTrailerExtensions`.

New request extension methods are present to access these trailers. As with HTTP/1.1, trailers are available after the request body is read to the end.

For the 3.0 release, the following `RequestTrailerExtensions` methods are available:

- `GetDeclaredTrailers`: Gets the request `Trailer` header that lists which trailers to expect after the body.
- `SupportsTrailers`: Indicates if the request supports receiving trailer headers.
- `CheckTrailersAvailable`: Checks if the request supports trailers and if they're available to be read. This check doesn't assume that there are trailers to read. There might be no trailers to read even if `true` is returned by this method.
- `GetTrailer`: Gets the requested trailing header from the response. Check `SupportsTrailers` before calling `GetTrailer`, or a NotSupportedException may occur if the request doesn't support trailing headers.

For more information, see Put request trailers in a separate collection (dotnet/AspNetCore #10410).

AllowSynchronousIO disabled

`AllowSynchronousIO` enables or disables synchronous I/O APIs, such as `HttpRequest.Body.Read`, `HttpResponse.Body.Write`, and `Stream.Flush`. These APIs are a source of thread starvation leading to app crashes. In 3.0, `AllowSynchronousIO` is disabled by default. For more information, see the Synchronous I/O section in the Kestrel article.

If synchronous I/O is needed, it can be enabled by configuring the `AllowSynchronousIO` option on the server being used (when calling `ConfigureKestrel`, for example, if using Kestrel). Note that servers (Kestrel, HttpSys, TestServer, etc.) all have their own `AllowSynchronousIO` option that won't affect other servers. Synchronous I/O can be enabled for all servers on a per-request basis using the `IHttpBodyControlFeature.AllowSynchronousIO` option:

C#

```
var syncIOFeature = HttpContext.Features.Get<IHttpBodyControlFeature>();

if (syncIOFeature != null)
{
    syncIOFeature.AllowSynchronousIO = true;
}
```

If you have trouble with TextWriter implementations or other streams that call synchronous APIs in Dispose, call the new DisposeAsync API instead.

For more information, see [Announcement] AllowSynchronousIO disabled in all servers (dotnet/AspNetCore #7644).

Output formatter buffering

Newtonsoft.Json, XmlSerializer, and DataContractSerializer based output formatters only support synchronous serialization. To allow these formatters to work with the AllowSynchronousIO restrictions of the server, MVC buffers the output of these formatters before writing to disk. As a result of buffering, MVC will include the Content-Length header when responding using these formatters.

System.Text.Json supports asynchronous serialization and consequently the `System.Text.Json` based formatter does not buffer. Consider using this formatter for improved performance.

To disable buffering, applications can configure SuppressOutputFormatterBuffering in their startup:

```
C#

services.AddControllers(options => options.SuppressOutputFormatterBuffering
= true)
```

Note that this may result in the application throwing a runtime exception if `AllowSynchronousIO` isn't also configured.

Microsoft.AspNetCore.Server.Kestrel.Https assembly removed

In ASP.NET Core 2.1, the contents of *Microsoft.AspNetCore.Server.Kestrel.Https.dll* were moved to *Microsoft.AspNetCore.Server.Kestrel.Core.dll*. This was a non-breaking update using `TypeForwardedTo` attributes. For 3.0, the empty *Microsoft.AspNetCore.Server.Kestrel.Https.dll* assembly and the NuGet package have been removed.

Libraries referencing Microsoft.AspNetCore.Server.Kestrel.Https should update ASP.NET Core dependencies to 2.1 or later.

Apps and libraries targeting ASP.NET Core 2.1 or later should remove any direct references to the Microsoft.AspNetCore.Server.Kestrel.Https package.

Newtonsoft.Json (Json.NET) support

As part of the work to improve the ASP.NET Core shared framework, Newtonsoft.Json (Json.NET) has been removed from the ASP.NET Core shared framework.

The default JSON serializer for ASP.NET Core is now System.Text.Json, which is new in .NET Core 3.0. Consider using `System.Text.Json` when possible. It's high-performance and doesn't require an additional library dependency. However, since `System.Text.Json` is new, it might currently be missing features that your app needs. For more information, see How to migrate from Newtonsoft.Json to System.Text.Json.

Use Newtonsoft.Json in an ASP.NET Core 3.0 SignalR project

- Install the Microsoft.AspNetCore.SignalR.Protocols.NewtonsoftJson NuGet package.
- On the client, chain an `AddNewtonsoftJsonProtocol` method call to the `HubConnectionBuilder` instance:

```
C#

new HubConnectionBuilder()
    .WithUrl("/chathub")
    .AddNewtonsoftJsonProtocol(...)
    .Build();
```

- On the server, chain an `AddNewtonsoftJsonProtocol` method call to the `AddSignalR` method call in `Startup.ConfigureServices`:

```
C#

services.AddSignalR()
    .AddNewtonsoftJsonProtocol(...);
```

Use Newtonsoft.Json in an ASP.NET Core 3.0 MVC project

- Install the Microsoft.AspNetCore.Mvc.NewtonsoftJson package.
- Update `Startup.ConfigureServices` to call `AddNewtonsoftJson`.

```
C#

services.AddMvc()
    .AddNewtonsoftJson();
```

`AddNewtonsoftJson` is compatible with the new MVC service registration methods:

- `AddRazorPages`
- `AddControllersWithViews`
- `AddControllers`

```
C#

services.AddControllers()
    .AddNewtonsoftJson();
```

`Newtonsoft.Json` settings can be set in the call to `AddNewtonsoftJson`:

```
C#

services.AddMvc()
    .AddNewtonsoftJson(options =>
           options.SerializerSettings.ContractResolver =
              new CamelCasePropertyNamesContractResolver());
```

Note: If the `AddNewtonsoftJson` method isn't available, make sure that you installed the Microsoft.AspNetCore.Mvc.NewtonsoftJson package. A common error is to install the Newtonsoft.Json package instead of the Microsoft.AspNetCore.Mvc.NewtonsoftJson package.

For more information, see Add Newtonsoft.Json-based JSON format support.

MVC service registration

ASP.NET Core 3.0 adds new options for registering MVC scenarios inside `Startup.ConfigureServices`.

Three new top-level extension methods related to MVC scenarios on `IServiceCollection` are available. Templates use these new methods instead of `AddMvc`. However, `AddMvc` continues to behave as it has in previous releases.

The following example adds support for controllers and API-related features, but not views or pages. The API template uses this code:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers();
}
```

The following example adds support for controllers, API-related features, and views, but not pages. The Web Application (MVC) template uses this code:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
}
```

The following example adds support for Razor Pages and minimal controller support. The Web Application template uses this code:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();
}
```

The new methods can also be combined. The following example is equivalent to calling `AddMvc` in ASP.NET Core 2.2:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();
    services.AddRazorPages();
}
```

Routing startup code

If an app calls `UseMvc` or `UseSignalR`, migrate the app to Endpoint Routing if possible. To improve Endpoint Routing compatibility with previous versions of MVC, we've reverted some of the changes in URL generation introduced in ASP.NET Core 2.2. If you experienced problems using Endpoint Routing in 2.2, expect improvements in ASP.NET Core 3.0 with the following exceptions:

- If the app implements `IRouter` or inherits from `Route`, use DynamicRouteValuesTransformer as the replacement.
- If the app directly accesses `RouteData.Routers` inside MVC to parse URLs, you can replace this with use of LinkParser.ParsePathByEndpointName.
  - Define the route with a route name.

- Use `LinkParser.ParsePathByEndpointName` and pass in the desired route name.

Endpoint Routing supports the same route pattern syntax and route pattern authoring features as `IRouter`. Endpoint Routing supports `IRouteConstraint`. Endpoint routing supports `[Route]`, `[HttpGet]`, and the other MVC routing attributes.

For most applications, only `Startup` requires changes.

Migrate Startup.Configure

General advice:

- Add `UseRouting`.
- If the app calls `UseStaticFiles`, place `UseStaticFiles` **before** `UseRouting`.
- If the app uses authentication/authorization features such as `AuthorizePage` or `[Authorize]`, place the call to `UseAuthentication` and `UseAuthorization`: **after**, `UseRouting` and `UseCors`, but before `UseEndpoints`:

```
C#
```

```
public void Configure(IApplicationBuilder app)
{
  ...

  app.UseStaticFiles();

  app.UseRouting();
  app.UseCors();

  app.UseAuthentication();
  app.UseAuthorization();

  app.UseEndpoints(endpoints => {
     endpoints.MapControllers();
  });
```

- Replace `UseMvc` or `UseSignalR` with `UseEndpoints`.
- If the app uses CORS scenarios, such as `[EnableCors]`, place the call to `UseCors` before any other middleware that use CORS (for example, place `UseCors` before `UseAuthentication`, `UseAuthorization`, and `UseEndpoints`).
- Replace `IHostingEnvironment` with `IWebHostEnvironment` and add a `using` statement for the Microsoft.AspNetCore.Hosting namespace.

- Replace `IApplicationLifetime` with IHostApplicationLifetime (Microsoft.Extensions.Hosting namespace).
- Replace `EnvironmentName` with Environments (Microsoft.Extensions.Hosting namespace).

The following code is an example of `Startup.Configure` in a typical ASP.NET Core 2.2 app:

C#

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseStaticFiles();

    app.UseAuthentication();

    app.UseSignalR(hubs =>
    {
        hubs.MapHub<ChatHub>("/chat");
    });

    app.UseMvc(routes =>
    {
        routes.MapRoute("default", "
{controller=Home}/{action=Index}/{id?}");
    });
}
```

After updating the previous `Startup.Configure` code:

C#

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseStaticFiles();

    app.UseRouting();

    app.UseCors();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>("/chat");
```

```
        endpoints.MapControllerRoute("default", "
{controller=Home}/{action=Index}/{id?}");
    });
}
```

> ⚠ **Warning**
>
> For most apps, calls to `UseAuthentication`, `UseAuthorization`, and `UseCors` must appear between the calls to `UseRouting` and `UseEndpoints` to be effective.

Health Checks

Health Checks use endpoint routing with the Generic Host. In `Startup.Configure`, call `MapHealthChecks` on the endpoint builder with the endpoint URL or relative path:

C#

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health");
});
```

Health Checks endpoints can:

- Specify one or more permitted hosts/ports.
- Require authorization.
- Require CORS.

For more information, see Health checks in ASP.NET Core.

Security middleware guidance

Support for authorization and CORS is unified around the middleware approach. This allows use of the same middleware and functionality across these scenarios. An updated authorization middleware is provided in this release, and CORS Middleware is enhanced so that it can understand the attributes used by MVC controllers.

CORS

Previously, CORS could be difficult to configure. Middleware was provided for use in some use cases, but MVC filters were intended to be used **without** the middleware in other use cases. With ASP.NET Core 3.0, we recommend that all apps that require CORS

use the CORS Middleware in tandem with Endpoint Routing. `UseCors` can be provided with a default policy, and `[EnableCors]` and `[DisableCors]` attributes can be used to override the default policy where required.

In the following example:

- CORS is enabled for all endpoints with the `default` named policy.
- The `MyController` class disables CORS with the `[DisableCors]` attribute.

C#

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseCors("default");

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}

[DisableCors]
public class MyController : ControllerBase
{
    ...
}
```

Authorization

In earlier versions of ASP.NET Core, authorization support was provided via the `[Authorize]` attribute. Authorization middleware wasn't available. In ASP.NET Core 3.0, authorization middleware is required. We recommend placing the ASP.NET Core Authorization Middleware (`UseAuthorization`) immediately after `UseAuthentication`. The Authorization Middleware can also be configured with a default policy, which can be overridden.

In ASP.NET Core 3.0 or later, `UseAuthorization` is called in `Startup.Configure`, and the following `HomeController` requires a signed in user:

C#

```
public void Configure(IApplicationBuilder app)
{
```

```
    ...

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}

public class HomeController : Controller
{
    [Authorize]
    public IActionResult BuyWidgets()
    {
        ...
    }
}
```

When using endpoint routing, we recommend against configuring AuthorizeFilter and instead relying on the Authorization middleware. If the app uses an `AuthorizeFilter` as a global filter in MVC, we recommend refactoring the code to provide a policy in the call to `AddAuthorization`.

The `DefaultPolicy` is initially configured to require authentication, so no additional configuration is required. In the following example, MVC endpoints are marked as `RequireAuthorization` so that all requests must be authorized based on the `DefaultPolicy`. However, the `HomeController` allows access without the user signing into the app due to `[AllowAnonymous]`:

C#

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute().RequireAuthorization();
    });
}
```

```
[AllowAnonymous]
public class HomeController : Controller
{
    ...
}
```

Authorization for specific endpoints

Authorization can also be configured for specific classes of endpoints. The following code is an example of converting an MVC app that configured a global `AuthorizeFilter` to an app with a specific policy requiring authorization:

C#

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    static readonly string _RequireAuthenticatedUserPolicy =
                            "RequireAuthenticatedUserPolicy";
    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddDbContext<ApplicationDbContext>(options =>
            options.UseSqlServer(
                Configuration.GetConnectionString("DefaultConnection")));
        services.AddDefaultIdentity<IdentityUser>(
                 options => options.SignIn.RequireConfirmedAccount = true)
            .AddEntityFrameworkStores<ApplicationDbContext>();

        // Pre 3.0:
        // services.AddMvc(options => options.Filters.Add(new
AuthorizeFilter(...));

        services.AddControllersWithViews();
        services.AddRazorPages();
        services.AddAuthorization(o =>
o.AddPolicy(_RequireAuthenticatedUserPolicy,
                        builder => builder.RequireAuthenticatedUser()));

    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
```

```
            app.UseDatabaseErrorPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            app.UseHsts();
        }
        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthentication();
        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapDefaultControllerRoute()
                .RequireAuthorization(_RequireAuthenticatedUserPolicy);
            endpoints.MapRazorPages();
        });
    }
}
```

Policies can also be customized. The `DefaultPolicy` is configured to require authentication:

C#

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddDbContext<ApplicationDbContext>(options =>
            options.UseSqlServer(
                Configuration.GetConnectionString("DefaultConnection")));
        services.AddDefaultIdentity<IdentityUser>(
                 options => options.SignIn.RequireConfirmedAccount = true)
            .AddEntityFrameworkStores<ApplicationDbContext>();

        services.AddControllersWithViews();
        services.AddRazorPages();
```

```
        services.AddAuthorization(options =>
        {
            options.DefaultPolicy = new AuthorizationPolicyBuilder()
              .RequireAuthenticatedUser()
              .Build();
        });

    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
            app.UseDatabaseErrorPage();
        }
        else
        {
            app.UseExceptionHandler("/Home/Error");
            app.UseHsts();
        }
        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthentication();
        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapDefaultControllerRoute().RequireAuthorization();
            endpoints.MapRazorPages();
        });
    }
}
```

C#

```
[AllowAnonymous]
public class HomeController : Controller
{
```

Alternatively, all endpoints can be configured to require authorization without `[Authorize]` or `RequireAuthorization` by configuring a `FallbackPolicy`. The `FallbackPolicy` is different from the `DefaultPolicy`. The `DefaultPolicy` is triggered by `[Authorize]` or `RequireAuthorization`, while the `FallbackPolicy` is triggered when no other policy is set. `FallbackPolicy` is initially configured to allow requests without authorization.

The following example is the same as the preceding `DefaultPolicy` example but uses the `FallbackPolicy` to always require authentication on all endpoints except when `[AllowAnonymous]` is specified:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    ...

    services.AddAuthorization(options =>
    {
        options.FallbackPolicy = new AuthorizationPolicyBuilder()
          .RequireAuthenticatedUser()
          .Build();
    });
}

public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
    });
}

[AllowAnonymous]
public class HomeController : Controller
{
    ...
}
```

Authorization by middleware works without the framework having any specific knowledge of authorization. For instance, health checks has no specific knowledge of authorization, but health checks can have a configurable authorization policy applied by the middleware.

Additionally, each endpoint can customize its authorization requirements. In the following example, `UseAuthorization` processes authorization with the `DefaultPolicy`, but the `/healthz` health check endpoint requires an `admin` user:

C#

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints
            .MapHealthChecks("/healthz")
            .RequireAuthorization(new AuthorizeAttribute(){ Roles = "admin",
});
    });
}
```

Protection is implemented for some scenarios. Endpoints Middleware throws an exception if an authorization or CORS policy is skipped due to missing middleware. Analyzer support to provide additional feedback about misconfiguration is in progress.

Custom authorization handlers

If the app uses custom authorization handlers, endpoint routing passes a different resource type to handlers than MVC. Handlers that expect the authorization handler context resource to be of type AuthorizationFilterContext (the resource type provided by MVC filters) will need to be updated to handle resources of type RouteEndpoint (the resource type given to authorization handlers by endpoint routing).

MVC still uses `AuthorizationFilterContext` resources, so if the app uses MVC authorization filters along with endpoint routing authorization, it may be necessary to handle both types of resources.

SignalR

Mapping of SignalR hubs now takes place inside `UseEndpoints`.

Map each hub with `MapHub`. As in previous versions, each hub is explicitly listed.

In the following example, support for the `ChatHub` SignalR hub is added:

C#

```
public void Configure(IApplicationBuilder app)
{
```

```
    ...

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>();
    });
}
```

There is a new option for controlling message size limits from clients. For example, in `Startup.ConfigureServices`:

C#

```
services.AddSignalR(hubOptions =>
{
    hubOptions.MaximumReceiveMessageSize = 32768;
});
```

In ASP.NET Core 2.2, you could set the `TransportMaxBufferSize` and that would effectively control the maximum message size. In ASP.NET Core 3.0, that option now only controls the maximum size before backpressure is observed.

SignalR assemblies in shared framework

ASP.NET Core SignalR server-side assemblies are now installed with the .NET Core SDK. For more information, see Remove obsolete package references in this document.

MVC controllers

Mapping of controllers now takes place inside `UseEndpoints`.

Add `MapControllers` if the app uses attribute routing. Since routing includes support for many frameworks in ASP.NET Core 3.0 or later, adding attribute-routed controllers is opt-in.

Replace the following:

- `MapRoute` with `MapControllerRoute`
- `MapAreaRoute` with `MapAreaControllerRoute`

Since routing now includes support for more than just MVC, the terminology has changed to make these methods clearly state what they do. Conventional routes such as

`MapControllerRoute`/`MapAreaControllerRoute`/`MapDefaultControllerRoute` are applied in the order that they're added. Place more specific routes (such as routes for an area) first.

In the following example:

- `MapControllers` adds support for attribute-routed controllers.
- `MapAreaControllerRoute` adds a conventional route for controllers in an area.
- `MapControllerRoute` adds a conventional route for controllers.

C#

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
        endpoints.MapAreaControllerRoute(
            "admin",
            "admin",
            "Admin/{controller=Home}/{action=Index}/{id?}");
        endpoints.MapControllerRoute(
            "default", "{controller=Home}/{action=Index}/{id?}");
    });
}
```

Async suffix removal from controller action names

In ASP.NET Core 3.0, ASP.NET Core MVC removes the `Async` suffix from controller action names. Both routing and link generation are impacted by this new default. For example:

C#

```
public class ProductsController : Controller
{
    public async Task<IActionResult> ListAsync()
    {
        var model = await _dbContext.Products.ToListAsync();
        return View(model);
    }
}
```

Prior to ASP.NET Core 3.0:

- The preceding action could be accessed at the *Products/ListAsync* route.

- Link generation required specifying the `Async` suffix. For example:

```
CSHTML
<a asp-controller="Products" asp-action="ListAsync">List</a>
```

In ASP.NET Core 3.0:

- The preceding action can be accessed at the *Products/List* route.
- Link generation doesn't require specifying the `Async` suffix. For example:

```
CSHTML
<a asp-controller="Products" asp-action="List">List</a>
```

This change doesn't affect names specified using the [ActionName] attribute. The default behavior can be disabled with the following code in `Startup.ConfigureServices`:

```
C#
services.AddMvc(options =>
    options.SuppressAsyncSuffixInActionNames = false);
```

Changes to link generation

There are some differences in link generation (using `Url.Link` and similar APIs, for example). These include:

- By default, when using endpoint routing, casing of route parameters in generated URIs is not necessarily preserved. This behavior can be controlled with the `IOutboundParameterTransformer` interface.
- Generating a URI for an invalid route (a controller/action or page that doesn't exist) will produce an empty string under endpoint routing instead of producing an invalid URI.
- Ambient values (route parameters from the current context) are not automatically used in link generation with endpoint routing. Previously, when generating a link to another action (or page), unspecified route values would be inferred from the *current* routes ambient values. When using endpoint routing, all route parameters must be specified explicitly during link generation.

Razor Pages

Mapping Razor Pages now takes place inside `UseEndpoints`.

Add `MapRazorPages` if the app uses Razor Pages. Since Endpoint Routing includes support for many frameworks, adding Razor Pages is now opt-in.

In the following `Startup.Configure` method, `MapRazorPages` adds support for Razor Pages:

C#

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

Use MVC without Endpoint Routing

Using MVC via `UseMvc` or `UseMvcWithDefaultRoute` in ASP.NET Core 3.0 requires an explicit opt-in inside `Startup.ConfigureServices`. This is required because MVC must know whether it can rely on the authorization and CORS Middleware during initialization. An analyzer is provided that warns if the app attempts to use an unsupported configuration.

If the app requires legacy `IRouter` support, disable `EnableEndpointRouting` using any of the following approaches in `Startup.ConfigureServices`:

C#

```
services.AddMvc(options => options.EnableEndpointRouting = false);
```

C#

```
services.AddControllers(options => options.EnableEndpointRouting = false);
```

C#

```
services.AddControllersWithViews(options => options.EnableEndpointRouting =
```

```
false);
```

C#

```
services.AddRazorPages().AddMvcOptions(options =>
options.EnableEndpointRouting = false);
```

Health checks

Health checks can be used as a *router-ware* with Endpoint Routing.

Add `MapHealthChecks` to use health checks with Endpoint Routing. The `MapHealthChecks` method accepts arguments similar to `UseHealthChecks`. The advantage of using `MapHealthChecks` over `UseHealthChecks` is the ability to apply authorization and to have greater fine-grained control over the matching policy.

In the following example, `MapHealthChecks` is called for a health check endpoint at `/healthz`:

C#

```
public void Configure(IApplicationBuilder app)
{
    ...

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHealthChecks("/healthz", new HealthCheckOptions() { });
    });
}
```

HostBuilder replaces WebHostBuilder

The ASP.NET Core 3.0 templates use Generic Host. Previous versions used Web Host. The following code shows the ASP.NET Core 3.0 template generated `Program` class:

C#

```
// requires using Microsoft.AspNetCore.Hosting;
// requires using Microsoft.Extensions.Hosting;

public class Program
{
```

```
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code shows the ASP.NET Core 2.2 template-generated `Program` class:

C#

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

IWebHostBuilder remains in 3.0 and is the type of the `webBuilder` seen in the preceding code sample. WebHostBuilder will be deprecated in a future release and replaced by `HostBuilder`.

The most significant change from `WebHostBuilder` to `HostBuilder` is in dependency injection (DI). When using `HostBuilder`, you can only inject the following into `Startup`'s constructor:

- IConfiguration
- IHostEnvironment
- IWebHostEnvironment

The `HostBuilder` DI constraints:

- Enable the DI container to be built only one time.
- Avoids the resulting object lifetime issues like resolving multiple instances of singletons.

For more information, see Avoiding Startup service injection in ASP.NET Core 3 .

AddAuthorization moved to a different assembly

The ASP.NET Core 2.2 and lower `AddAuthorization` methods in *Microsoft.AspNetCore.Authorization.dll*:

- Have been renamed `AddAuthorizationCore`.
- Have been moved to *Microsoft.AspNetCore.Authorization.Policy.dll*.

Apps that are using both *Microsoft.AspNetCore.Authorization.dll* and *Microsoft.AspNetCore.Authorization.Policy.dll* aren't impacted.

Apps that are not using *Microsoft.AspNetCore.Authorization.Policy.dll* should do one of the following:

- Add a reference to *Microsoft.AspNetCore.Authorization.Policy.dll*. This approach works for most apps and is all that is required.
- Switch to using `AddAuthorizationCore`

For more information, see Breaking change in AddAuthorization(o =>) overload lives in a different assembly #386.

Identity UI

Identity UI updates for ASP.NET Core 3.0:

- Add a package reference to Microsoft.AspNetCore.Identity.UI.
- Apps that don't use Razor Pages must call `MapRazorPages`. See Razor Pages in this document.
- Bootstrap 4 is the default UI framework. Set an `IdentityUIFrameworkVersion` project property to change the default. For more information, see this GitHub announcement.

SignalR

The SignalR JavaScript client has changed from `@aspnet/signalr` to `@microsoft/signalr`. To react to this change, change the references in `package.json` files, `require` statements, and ECMAScript `import` statements.

System.Text.Json is the default protocol

`System.Text.Json` is now the default Hub protocol used by both the client and server.

In `Startup.ConfigureServices`, call `AddJsonProtocol` to set serializer options.

Server:

```
C#

services.AddSignalR(...)
        .AddJsonProtocol(options =>
        {
            options.PayloadSerializerOptions.WriteIndented = false;
        })
```

Client:

```
C#

new HubConnectionBuilder()
    .WithUrl("/chathub")
    .AddJsonProtocol(options =>
    {
        options.PayloadSerializerOptions.WriteIndented = false;
    })
    .Build();
```

Switch to Newtonsoft.Json

If you're using features of Newtonsoft.Json that aren't supported in System.Text.Json, you can switch back to `Newtonsoft.Json`. See Use Newtonsoft.Json in an ASP.NET Core 3.0 SignalR project earlier in this article.

Redis distributed caches

The Microsoft.Extensions.Caching.Redis package isn't available for ASP.NET Core 3.0 or later apps. Replace the package reference with Microsoft.Extensions.Caching.StackExchangeRedis. For more information, see Distributed caching in ASP.NET Core.

Opt in to runtime compilation

Prior to ASP.NET Core 3.0, runtime compilation of views was an implicit feature of the framework. Runtime compilation supplements build-time compilation of views. It allows

the framework to compile Razor views and pages (`.cshtml` files) when the files are modified, without having to rebuild the entire app. This feature supports the scenario of making a quick edit in the IDE and refreshing the browser to view the changes.

In ASP.NET Core 3.0, runtime compilation is an opt-in scenario. Build-time compilation is the only mechanism for view compilation that's enabled by default. The runtime relies on Visual Studio or dotnet-watch in Visual Studio Code to rebuild the project when it detects changes to `.cshtml` files. In Visual Studio, changes to `.cs`, `.cshtml`, or `.razor` files in the project being run (`Ctrl+F5`), but not debugged (`F5`), trigger recompilation of the project.

To enable runtime compilation in your ASP.NET Core 3.0 project:

1. Install the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation NuGet package.
2. Update `Startup.ConfigureServices` to call `AddRazorRuntimeCompilation`:

   For ASP.NET Core MVC, use the following code:

   ```
   C#

   services.AddControllersWithViews()
       .AddRazorRuntimeCompilation(...);
   ```

   For ASP.NET Core Razor Pages, use the following code:

   ```
   C#

   services.AddRazorPages()
       .AddRazorRuntimeCompilation(...);
   ```

The sample at https://github.com/aspnet/samples/tree/main/samples/aspnetcore/mvc/runtimecompilation shows an example of enabling runtime compilation conditionally in Development environments.

For more information on Razor file compilation, see Razor file compilation in ASP.NET Core.

Migrate libraries via multi-targeting

Libraries often need to support multiple versions of ASP.NET Core. Most libraries that were compiled against previous versions of ASP.NET Core should continue working without issues. The following conditions require the app to be cross-compiled:

- The library relies on a feature that has a binary breaking change.
- The library wants to take advantage of new features in ASP.NET Core 3.0.

For example:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFrameworks>netcoreapp3.0;netstandard2.0</TargetFrameworks>
  </PropertyGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netcoreapp3.0'">
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

  <ItemGroup Condition="'$(TargetFramework)' == 'netstandard2.0'">
    <PackageReference Include="Microsoft.AspNetCore" Version="2.1.0" />
  </ItemGroup>
</Project>
```

Use `#ifdefs` to enable ASP.NET Core 3.0-specific APIs:

C#

```
var webRootFileProvider =
#if NETCOREAPP3_0
    GetRequiredService<IWebHostEnvironment>().WebRootFileProvider;
#elif NETSTANDARD2_0
    GetRequiredService<IHostingEnvironment>().WebRootFileProvider;
#else
#error unknown target framework
#endif
```

For more information on using ASP.NET Core APIs in a class library, see Use ASP.NET Core APIs in a class library.

Miscellaneous changes

The validation system in .NET Core 3.0 and later treats non-nullable parameters or bound properties as if they had a `[Required]` attribute. For more information, see [Required] attribute.

Publish

Delete the *bin* and *obj* folders in the project directory.

TestServer

For apps that use TestServer directly with the Generic Host, create the `TestServer` on an IWebHostBuilder in ConfigureWebHost:

C#

```
[Fact]
public async Task GenericCreateAndStartHost_GetTestServer()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .Configure(app => { });
        })
    .StartAsync();

    var response = await host.GetTestServer().CreateClient().GetAsync("/");

    Assert.Equal(HttpStatusCode.NotFound, response.StatusCode);
}
```

Breaking API changes

Review breaking changes:

- Complete list of breaking changes in the ASP.NET Core 3.0 release
- Breaking API changes in Antiforgery, CORS, Diagnostics, MVC, and Routing. This list includes breaking changes for compatibility switches.
- For a summary of 2.2-to-3.0 breaking changes across .NET Core, ASP.NET Core, and Entity Framework Core, see Breaking changes for migration from version 2.2 to 3.0.

Endpoint routing with catch-all parameter

.NET Core 3.0 on Azure App Service

The rollout of .NET Core to Azure App Service is finished. .NET Core 3.0 is available in all Azure App Service datacenters.

ASP.NET Core Module (ANCM)

If the ASP.NET Core Module (ANCM) wasn't a selected component when Visual Studio was installed or if a prior version of the ANCM was installed on the system, download the latest .NET Core Hosting Bundle Installer (direct download) and run the installer. For more information, see Hosting Bundle.

Migrate from ASP.NET Core 2.1 to 2.2

Article • 06/18/2024

By Scott Addie

This article explains how to update an existing ASP.NET Core 2.1 project to ASP.NET Core 2.2.

Prerequisites

Visual Studio

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

> ⚠ **Warning**
>
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

Update Target Framework Moniker (TFM)

Projects targeting .NET Core should use the TFM of a version greater than or equal to .NET Core 2.2. In the project file, update the `<TargetFramework>` node's inner text with `netcoreapp2.2`:

XML

```xml
<TargetFramework>netcoreapp2.2</TargetFramework>
```

Projects targeting .NET Framework may continue to use the TFM of a version greater than or equal to .NET Framework 4.6.1:

XML

```xml
<TargetFramework>net461</TargetFramework>
```

Adopt the IIS in-process hosting model

To adopt the in-process hosting model for IIS, add the `<AspNetCoreHostingModel>` property with a value of `InProcess` to a `<PropertyGroup>` in the project file:

XML

```
<AspNetCoreHostingModel>InProcess</AspNetCoreHostingModel>
```

The in-process hosting model isn't supported for ASP.NET Core apps targeting .NET Framework.

For more information, see ASP.NET Core Module (ANCM) for IIS.

Update a custom web.config file

For projects that use a custom *web.config* file in the project root to generate their published *web.config* file:

- In the `<handlers>` entry that adds the ASP.NET Core Module (`name="aspNetCore"`), change the `modules` attribute value from `AspNetCoreModule` to `AspNetCoreModuleV2`.
- In the `<aspNetCore>` element, add the hosting model attribute (`hostingModel="InProcess"`).

For more information and example *web.config* files, see ASP.NET Core Module (ANCM) for IIS.

Update package references

If targeting .NET Core, remove the metapackage reference's `Version` attribute in the project file. Inclusion of a `Version` attribute results in the following warning:

Console

```
A PackageReference to 'Microsoft.AspNetCore.App' specified a Version of
`2.2.0`. Specifying the version of this package is not recommended. For more
information, see https://aka.ms/sdkimplicitrefs
```

For more information, see Microsoft.AspNetCore.App metapackage for ASP.NET Core.

The metapackage reference should resemble the following `<PackageReference />` node:

XML

```xml
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore.App" />
</ItemGroup>
```

If targeting .NET Framework, update each package reference's `Version` attribute to 2.2.0 or later. Here are the package references in a typical ASP.NET Core 2.2 project targeting .NET Framework:

XML

```xml
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore" Version="2.2.0" />
  <PackageReference Include="Microsoft.AspNetCore.CookiePolicy"
Version="2.2.0" />
  <PackageReference Include="Microsoft.AspNetCore.HttpsPolicy"
Version="2.2.0" />
  <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.2.0" />
  <PackageReference Include="Microsoft.AspNetCore.StaticFiles"
Version="2.2.0" />
</ItemGroup>
```

If referencing the Microsoft.AspNetCore.Razor.Design package, update its `Version` attribute to 2.2.0 or later. Failure to do so results in the following error:

Console

```
Detected package downgrade: Microsoft.AspNetCore.Razor.Design from 2.2.0 to
2.1.2. Reference the package directly from the project to select a different
version.
```

Update .NET Core SDK version in global.json

If your solution relies upon a global.json file to target a specific .NET Core SDK version, update its `version` property to the 2.2 version installed on your machine:

JSON

```json
{
  "sdk": {
    "version": "2.2.100"
  }
}
```

Update launch settings

If using Visual Studio Code, update the project's launch settings file (`.vscode/launch.json`). The `program` path should reference the new TFM:

JSON

```
{
    "version": "0.2.0",
    "configurations": [
        {
            "name": ".NET Core Launch (web)",
            "type": "coreclr",
            "request": "launch",
            "preLaunchTask": "build",
            "program": "${workspaceFolder}/bin/Debug/netcoreapp2.2/test-
app.dll",
            "args": [],
            "cwd": "${workspaceFolder}",
            "stopAtEntry": false,
            "internalConsoleOptions": "openOnSessionStart",
            "launchBrowser": {
                "enabled": true,
                "args": "${auto-detect-url}",
                "windows": {
                    "command": "cmd.exe",
                    "args": "/C start ${auto-detect-url}"
                },
                "osx": {
                    "command": "open"
                },
                "linux": {
                    "command": "xdg-open"
                }
            },
            "env": {
                "ASPNETCORE_ENVIRONMENT": "Development"
            },
            "sourceFileMap": {
                "/Views": "${workspaceFolder}/Views"
            }
        },
        {
            "name": ".NET Core Attach",
            "type": "coreclr",
            "request": "attach",
            "processId": "${command:pickProcess}"
        }
    ]
}
```

Update Kestrel configuration

If the app calls UseKestrel by calling `CreateDefaultBuilder` in the CreateWebHostBuilder method of the `Program` class, call `ConfigureKestrel` to configure Kestrel server instead of `UseKestrel` in order to avoid conflicts with the IIS in-process hosting model:

C#

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureKestrel((context, options) =>
        {
            // Set properties and call methods on options
        });
```

If the app doesn't call `CreateDefaultBuilder` and builds the host manually in the `Program` class, call UseKestrel **before** calling `ConfigureKestrel`:

C#

```
public static void Main(string[] args)
{
    var host = new WebHostBuilder()
        .UseContentRoot(Directory.GetCurrentDirectory())
        .UseKestrel()
        .UseIISIntegration()
        .UseStartup<Startup>()
        .ConfigureKestrel((context, options) =>
        {
            // Set properties and call methods on options
        })
        .Build();

    host.Run();
}
```

For more information, see Kestrel web server in ASP.NET Core.

Update compatibility version

Update the compatibility version in `Startup.ConfigureServices` to `Version_2_2`:

C#

```
services.AddMvc()
```

```
        .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
```

Update CORS policy

In ASP.NET Core 2.2, the CORS middleware responds with a wildcard origin (`*`) if a policy allows any origin and allows credentials. Credentials aren't supported when a wildcard origin (`*`) is specified, and browsers will disallow the CORS request. For more information, including options for correcting the problem on the client, see the MDN web docs.

To correct this problem on the server, take one of the following actions:

- Modify the CORS policy to no longer allow credentials. That is, remove the call to AllowCredentials when configuring the policy.
- If credentials are required for the CORS request to succeed, modify the policy to specify allowed hosts. For example, use `builder.WithOrigins("https://api.example1.com", "https://example2.com")` instead of using AllowAnyOrigin.

Update Docker images

The following table shows the Docker image tag changes:

Expand table

2.1	2.2
`microsoft/dotnet:2.1-aspnetcore-runtime`	`mcr.microsoft.com/dotnet/core/aspnet:2.2`
`microsoft/dotnet:2.1-sdk`	`mcr.microsoft.com/dotnet/core/sdk:2.2`

Change the `FROM` lines in your *Dockerfile* to use the new image tags in the preceding table's 2.2 column.

Build manually in Visual Studio when using IIS in-process hosting

Visual Studio's **Auto build on browser request** experience doesn't function with the IIS in-process hosting model. You must manually rebuild the project when using in-process

hosting. Improvements to this experience are planned for a future release of Visual Studio.

Update logging code

Recommended logging configuration code didn't change from 2.1 to 2.2, but some 1.x coding patterns that still worked in 2.1 no longer work in 2.2.

If your app does logging provider initialization, filtering, and configuration loading in the `Startup` class, move that code to `Program.Main`:

- Provider initialization:

  1.x example:

  ```
  C#

  public void Configure(IApplicationBuilder app, ILoggerFactory
  loggerFactory)
  {
      loggerFactory.AddConsole();
  }
  ```

  2.2 example:

  ```
  C#

  public static void Main(string[] args)
  {
      var webHost = new WebHostBuilder()
          // ...
          .ConfigureLogging((hostingContext, logging) =>
          {
              logging.AddConsole();
          })
          // ...
  }
  ```

- Filtering:

  1.x example:

  ```
  C#

  public void Configure(IApplicationBuilder app, ILoggerFactory
  loggerFactory)
  ```

```
{
    loggerFactory.AddConsole(LogLevel.Information);
    // or
    loggerFactory.AddConsole((category, level) =>
        category == "A" || level == LogLevel.Critical);
}
```

2.2 example:

```C#
public static void Main(string[] args)
{
    var webHost = new WebHostBuilder()
        // ...
        .ConfigureLogging((hostingContext, logging) =>
        {
            logging.AddConsole()
                   .AddFilter<ConsoleLoggerProvider>
                       (category: null, level: LogLevel.Information)
                   // or
                   .AddFilter<ConsoleLoggerProvider>
                       ((category, level) => category == "A" ||
                           level == LogLevel.Critical)
            );
        })
        // ...
}
```

- Configuration loading:

  1.x example:

```C#
public void Configure(IApplicationBuilder app, ILoggerFactory
loggerFactory)
{
    loggerFactory.AddConsole(Configuration);
}
```

  2.2 example:

```C#
public static void Main(string[] args)
{
    var webHost = new WebHostBuilder()
        // ...
        .ConfigureLogging((hostingContext, logging) =>
```

```
        {

logging.AddConfiguration(hostingContext.Configuration.GetSection("Loggi
ng"));
            logging.AddConsole();
        })
        // ...
}
```

For more information, see Logging in .NET Core and ASP.NET Core

ASP.NET Core Module (ANCM)

If the ASP.NET Core Module (ANCM) wasn't a selected component when Visual Studio was installed or if a prior version of the ANCM was installed on the system, download the latest .NET Core Hosting Bundle Installer (direct download) and run the installer. For more information, see Hosting Bundle.

Migrate from Microsoft.Extensions.Logging 2.1 to 2.2 or 3.0

Article • 06/03/2022

This article outlines the common steps for migrating a non-ASP.NET Core application that uses `Microsoft.Extensions.Logging` from 2.1 to 2.2 or 3.0.

2.1 to 2.2

Manually create `ServiceCollection` and call `AddLogging`.

2.1 example:

C#

```
using (var loggerFactory = new LoggerFactory())
{
    loggerFactory.AddConsole();

    // use loggerFactory
}
```

2.2 example:

C#

```
var serviceCollection = new ServiceCollection();
serviceCollection.AddLogging(builder => builder.AddConsole());

using (var serviceProvider = serviceCollection.BuildServiceProvider())
using (var loggerFactory = serviceProvider.GetService<ILoggerFactory>())
{
    // use loggerFactory
}
```

2.1 to 3.0

In 3.0, use `LoggingFactory.Create`.

2.1 example:

C#

```
using (var loggerFactory = new LoggerFactory())
{
    loggerFactory.AddConsole();

    // use loggerFactory
}
```

3.0 example:

C#

```
using (var loggerFactory = LoggerFactory.Create(builder =>
builder.AddConsole()))
{
    // use loggerFactory
}
```

Migrate from ASP.NET Core 2.0 to 2.1

Article • 08/30/2024

By Rick Anderson

See What's new in ASP.NET Core 2.1 for an overview of the new features in ASP.NET Core 2.1.

This article:

- Covers the basics of migrating an ASP.NET Core 2.0 app to 2.1.
- Provides an overview of the changes to the ASP.NET Core web application templates.

A quick way to get an overview of the changes in 2.1 is to:

- Create an ASP.NET Core 2.0 web app named WebApp1.
- Commit the WebApp1 in a source control system.
- Delete WebApp1 and create an ASP.NET Core 2.1 web app named WebApp1 in the same place.
- Review the changes in the 2.1 version.

This article provides an overview on migration to ASP.NET Core 2.1. It doesn't contain a complete list of all changes needed to migrate to version 2.1. Some projects might require more steps depending on the options selected when the project was created and modifications made to the project.

Update the project file to use 2.1 versions

Update the project file:

- Change the target framework to .NET Core 2.1 by updating the project file to `<TargetFramework>netcoreapp2.1</TargetFramework>`.
- Replace the package reference for `Microsoft.AspNetCore.All` with a package reference for `Microsoft.AspNetCore.App`. You may need to add dependencies that were removed from `Microsoft.AspNetCore.All`. For more information, see Microsoft.AspNetCore.All metapackage for ASP.NET Core 2.0 and Microsoft.AspNetCore.App metapackage for ASP.NET Core.
- Remove the "Version" attribute on the package reference to `Microsoft.AspNetCore.App`. Projects that use `<Project Sdk="Microsoft.NET.Sdk.Web">` don't need to set the version. The version is implied

by the target framework and selected to best match the way ASP.NET Core 2.1 works. For more information, see the Rules for projects targeting the shared framework section.

- For apps that target the .NET Framework, update each package reference to 2.1.
- Remove references to <**DotNetCliToolReference**> elements for the following packages. These tools are bundled by default in the .NET CLI and don't need to be installed separately.
  - Microsoft.DotNet.Watcher.Tools (`dotnet watch`)
  - Microsoft.EntityFrameworkCore.Tools.DotNet (`dotnet ef`)
  - Microsoft.Extensions.Caching.SqlConfig.Tools (`dotnet sql-cache`)
  - Microsoft.Extensions.SecretManager.Tools (`dotnet user-secrets`)
- Optional: you can remove the <**DotNetCliToolReference**> element for `Microsoft.VisualStudio.Web.CodeGeneration.Tools`. You can replace this tool with a globally installed version by running `dotnet tool install -g dotnet-aspnet-codegenerator`.
- For 2.1, a Razor class library is the recommended solution to distribute Razor files. If your app uses embedded views, or otherwise relies on runtime compilation of Razor files, add `<CopyRefAssembliesToPublishDirectory>true</CopyRefAssembliesToPublishDirectory>` to a `<PropertyGroup>` in your project file.

The following markup shows the template-generated 2.0 project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">
  <PropertyGroup>
    <TargetFramework>netcoreapp2.0</TargetFramework>
    <UserSecretsId>aspnet-{Project Name}-{GUID}</UserSecretsId>
  </PropertyGroup>
  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.All" Version="2.0.9" />
    <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="2.0.3" PrivateAssets="All" />
    <PackageReference
Include="Microsoft.VisualStudio.Web.CodeGeneration.Design" Version="2.0.4"
PrivateAssets="All" />
  </ItemGroup>
  <ItemGroup>
    <DotNetCliToolReference
Include="Microsoft.EntityFrameworkCore.Tools.DotNet" Version="2.0.3" />
    <DotNetCliToolReference
Include="Microsoft.Extensions.SecretManager.Tools" Version="2.0.2" />
    <DotNetCliToolReference
Include="Microsoft.VisualStudio.Web.CodeGeneration.Tools" Version="2.0.4" />
```

```
  </ItemGroup>
</Project>
```

The following markup shows the template-generated 2.1 project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>netcoreapp2.1</TargetFramework>
    <UserSecretsId>aspnet-{Project Name}-{GUID}</UserSecretsId>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.App" />
    <PackageReference
Include="Microsoft.VisualStudio.Web.CodeGeneration.Design" Version="2.1.1"
PrivateAssets="All" />
  </ItemGroup>

</Project>
```

Rules for projects targeting the shared framework

A *shared framework* is a set of assemblies (*.dll* files) that are not in the app's folders. The shared framework must be installed on the machine to run the app. For more information, see The shared framework.

ASP.NET Core 2.1 includes the following shared frameworks:

- Microsoft.AspNetCore.App
- Microsoft.AspNetCore.All

The version specified by the package reference is the *minimum required* version. For example, a project referencing the 2.1.1 versions of these packages won't run on a machine with only the 2.1.0 runtime installed.

Known issues for projects targeting a shared framework:

- The .NET Core 2.1.300 SDK (first included in Visual Studio 15.6) set the implicit version of `Microsoft.AspNetCore.App` to 2.1.0 which caused conflicts with Entity Framework Core 2.1.1. The recommended solution is to upgrade the .NET Core

SDK to 2.1.301 or later. For more information, see Packages that share dependencies with Microsoft.AspNetCore.App cannot reference patch versions.

- All projects that must use `Microsoft.AspNetCore.All` or `Microsoft.AspNetCore.App` should add a package reference for the package in the project file, even if they contain a project reference to another project using `Microsoft.AspNetCore.All` or `Microsoft.AspNetCore.App`.

  Example:
  - `MyApp` has a package reference to `Microsoft.AspNetCore.App`.
  - `MyApp.Tests` has a project reference to `MyApp.csproj`.

  Add a package reference for `Microsoft.AspNetCore.App` to `MyApp.Tests`. For more information, see Integration testing is hard to set up and may break on shared framework servicing.

Update to the 2.1 Docker images

In ASP.NET Core 2.1, the Docker images migrated to the dotnet/dotnet-docker GitHub repository. The following table shows the Docker image and tag changes:

Expand table

2.0	2.1
microsoft/aspnetcore:2.0	microsoft/dotnet:2.1-aspnetcore-runtime
microsoft/aspnetcore-build:2.0	microsoft/dotnet:2.1-sdk

Change the `FROM` lines in your *Dockerfile* to use the new image names and tags in the preceding table's 2.1 column. For more information, see Migrating from aspnetcore docker repos to dotnet.

Changes to take advantage of the new code-based idioms that are recommended in ASP.NET Core 2.1

Changes to Main

The following images show the changes made to the templated generated `Program.cs` file.

```
namespace WebApp1
{
    public class Program
    {
        public static void Main(string[] args)
        {
            BuildWebHost(args).Run();
        }

        public static IWebHost BuildWebHost(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>()
                .Build();
    }
}
```

The preceding image shows the 2.0 version with the deletions in red.

The following image shows the 2.1 code. The code in green replaced the 2.0 version:

```
namespace WebApp1
{
    public class Program
    {
        public static void Main(string[] args)
        {
            CreateWebHostBuilder(args).Build().Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();

    }
}
```

The following code shows the 2.1 version of `Program.cs`:

C#

```
namespace WebApp1
{
    public class Program
    {
        public static void Main(string[] args)
        {
            CreateWebHostBuilder(args).Build().Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();
```

```
    }
}
```

The new `Main` replaces the call to `BuildWebHost` with CreateWebHostBuilder. IWebHostBuilder was added to support a new integration test infrastructure.

Changes to Startup

The following code shows the changes to 2.1 template generated code. All changes are newly added code, except that `UseBrowserLink` has been removed:

C#

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;

namespace WebApp1
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.Configure<CookiePolicyOptions>(options =>
            {
                // This lambda determines whether user consent for non-
essential cookies is needed for a given request.
                options.CheckConsentNeeded = context => true;
                options.MinimumSameSitePolicy = SameSiteMode.None;
            });

            services.AddMvc()
                .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);
        }

        public void Configure(IApplicationBuilder app, IHostingEnvironment
env)
        {
            if (env.IsDevelopment())
            {
```

```
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseStaticFiles();
            app.UseCookiePolicy();
            // If the app uses Session or TempData based on Session:
            // app.UseSession();

            app.UseMvc();
        }
    }
}
```

The preceding code changes are detailed in:

- GDPR support in ASP.NET Core for `CookiePolicyOptions` and `UseCookiePolicy`.
- HTTP Strict Transport Security Protocol (HSTS) for `UseHsts`.
- Require HTTPS for `UseHttpsRedirection`.
- SetCompatibilityVersion for `SetCompatibilityVersion(CompatibilityVersion.Version_2_1)`.

Changes to authentication code

ASP.NET Core 2.1 provides ASP.NET Core Identity as a Razor class library (RCL).

The default 2.1 Identity UI doesn't currently provide significant new features over the 2.0 version. Replacing Identity with the RCL package is optional. The advantages to replacing the template generated Identity code with the RCL version include:

- Many files are moved out of your source tree.
- Any bug fixes or new features to Identity are included in the Microsoft.AspNetCore.App metapackage. You automatically get the updated Identity when `Microsoft.AspNetCore.App` is updated.

If you've made non-trivial changes to the template generated Identity code:

- The preceding advantages probably do **not** justify converting to the RCL version.
- You can keep your ASP.NET Core 2.0 Identity code, it's fully supported.

Identity 2.1 exposes endpoints with the `Identity` area. For example, the follow table shows examples of Identity endpoints that change from 2.0 to 2.1:

Expand table

2.0 URL	2.1 URL
/Account/Login	/Identity/Account/Login
/Account/Logout	/Identity/Account/Logout
/Account/Manage	/Identity/Account/Manage

Applications that have code using Identity and replace 2.0 Identity UI with the 2.1 Identity Library need to take into account Identity URLs have `/Identity` segment prepended to the URIs. One way to handle the new Identity endpoints is to set up redirects, for example from `/Account/Login` to `/Identity/Account/Login`.

Update Identity to version 2.1

The following options are available to update Identity to 2.1.

- Use the Identity UI 2.0 code with no changes. Using Identity UI 2.0 code is fully supported. This is a good approach when significant changes have been made to the generated Identity code.
- Delete your existing Identity 2.0 code and Scaffold Identity into your project. Your project will use the ASP.NET Core Identity Razor class library. You can generate code and UI for any of the Identity UI code that you modified. Apply your code changes to the newly scaffolded UI code.
- Delete your existing Identity 2.0 code and Scaffold Identity into your project with the option to **Override all files**.

Replace Identity 2.0 UI with the Identity 2.1 Razor class library

This section outlines the steps to replace the ASP.NET Core 2.0 template-generated Identity code with the ASP.NET Core Identity Razor class library. The following steps are for a Razor Pages project, but the approach for an MVC project is similar.

- Verify the project file is updated to use 2.1 versions
- Delete the following folders and all the files in them:
  - *Controllers*
  - *Pages/Account/*

    - *Extensions*
- Build the project.
- Scaffold Identity into your project:
    - Select the projects exiting *_Layout.cshtml* file.
    - Select the + icon on the right side of the **Data context class**. Accept the default name.
    - Select **Add** to create a new Data context class. Creating a new data context is required for to scaffold. You remove the new data context in the next section.

Update after scaffolding Identity

- Delete the Identity scaffolder generated `IdentityDbContext` derived class in the *Areas/Identity/Data/* folder.

- Delete `Areas/Identity/IdentityHostingStartup.cs`.

- Update the *_LoginPartial.cshtml* file:
    - Move *Pages/_LoginPartial.cshtml* to *Pages/Shared/_LoginPartial.cshtml*.
    - Add `asp-area="Identity"` to the form and anchor links.
    - Update the `<form />` element to `<form asp-area="Identity" asp-page="/Account/Logout" asp-route-returnUrl="@Url.Page("/Index", new { area = "" })" method="post" id="logoutForm" class="navbar-right">`.

    The following code shows the updated *_LoginPartial.cshtml* file:

CSHTML

```
@using Microsoft.AspNetCore.Identity

@inject SignInManager<ApplicationUser> SignInManager
@inject UserManager<ApplicationUser> UserManager

@if (SignInManager.IsSignedIn(User))
{
    <form asp-area="Identity" asp-page="/Account/Logout" asp-route-
returnUrl="@Url.Page("/Index", new { area = "" })" method="post"
id="logoutForm" class="navbar-right">
        <ul class="nav navbar-nav navbar-right">
            <li>
                <a asp-area="Identity" asp-page="/Account/Manage/Index"
title="Manage">Hello @UserManager.GetUserName(User)!</a>
            </li>
            <li>
                <button type="submit" class="btn btn-link navbar-btn
navbar-link">Log out</button>
            </li>
        </ul>
```

```
        </form>
    }
    else
    {
        <ul class="nav navbar-nav navbar-right">
            <li><a asp-area="Identity" asp-
    page="/Account/Register">Register</a></li>
            <li><a asp-area="Identity" asp-page="/Account/Login">Log in</a>
    </li>
        </ul>
    }
```

Update `ConfigureServices` with the following code:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>

options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection"))
);

    services.AddDefaultIdentity<ApplicationUser>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

    services.AddMvc();

    // Register no-op EmailSender used by account confirmation and password
reset
    // during development
    services.AddSingleton<IEmailSender, EmailSender>();
}
```

Changes to Razor Pages projects Razor files

The layout file

- Move *Pages/_Layout.cshtml* to *Pages/Shared/_Layout.cshtml*
- In *Areas/Identity/Pages/_ViewStart.cshtml*, change `Layout = "/Pages/_Layout.cshtml"` to `Layout = "/Pages/Shared/_Layout.cshtml"`.
- The *_Layout.cshtml* file has the following changes:
  - `<partial name="_CookieConsentPartial" />` is added. For more information, see GDPR support in ASP.NET Core.

    - jQuery changes from 2.2.0 to 3.3.1.

_ValidationScriptsPartial.cshtml

- *Pages/_ValidationScriptsPartial.cshtml* moves to *Pages/Shared/_ValidationScriptsPartial.cshtml*.
- *jquery.validate/1.14.0* changes to *jquery.validate/1.17.0*.

New files

The following files are added:

- `Privacy.cshtml`
- `Privacy.cshtml.cs`

See GDPR support in ASP.NET Core for information on the preceding files.

Changes to MVC projects Razor files

The layout file

The `Layout.cshtml` file has the following changes:

- `<partial name="_CookieConsentPartial" />` is added.
- jQuery changes from 2.2.0 to 3.3.1

_ValidationScriptsPartial.cshtml

jquery.validate/1.14.0 changes to *jquery.validate/1.17.0*

New files and action methods

The following are added:

- `Views/Home/Privacy.cshtml`
- The `Privacy` action method is added to the Home controller.

See GDPR support in ASP.NET Core for information on the preceding files.

Changes to the launchSettings.json file

As ASP.NET Core apps now use HTTPS by default, the `Properties/launchSettings.json` file has changed.

The following JSON shows the earlier 2.0 template-generated `launchSettings.json` file:

JSON

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:1799/",
      "sslPort": 0
    }
  },
  "profiles": {
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "WebApp1": {
      "commandName": "Project",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      },
      "applicationUrl": "http://localhost:1798/"
    }
  }
}
```

The following JSON shows the new 2.1 template-generated `launchSettings.json` file:

JSON

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:39191",
      "sslPort": 44390
    }
  },
  "profiles": {
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
```

```
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "WebApp1": {
      "commandName": "Project",
      "launchBrowser": true,
      "applicationUrl": "https://localhost:5001;http://localhost:5000",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    }
  }
}
```

For more information, see Enforce HTTPS in ASP.NET Core.

Breaking changes

FileResult Range header

FileResult no longer processes the Accept-Ranges header by default. To enable the `Accept-Ranges` header, set EnableRangeProcessing to `true`.

ControllerBase.File and PhysicalFile Range header

The following ControllerBase methods no longer processes the Accept-Ranges header by default:

- Overloads of ControllerBase.File
- ControllerBase.PhysicalFile

To enable the `Accept-Ranges` header, set the `EnableRangeProcessing` parameter to `true`.

ASP.NET Core Module (ANCM)

If the ASP.NET Core Module (ANCM) wasn't a selected component when Visual Studio was installed or if a prior version of the ANCM was installed on the system, download the latest .NET Core Hosting Bundle Installer (direct download) and run the installer. For more information, see Hosting Bundle.

Additional changes

- SetCompatibilityVersion
- Libuv transport configuration

Migrate from ASP.NET Core 1.x to 2.0

Article • 06/18/2024

By Scott Addie

In this article, we walk you through updating an existing ASP.NET Core 1.x project to ASP.NET Core 2.0. Migrating your application to ASP.NET Core 2.0 enables you to take advantage of many new features and performance improvements.

Existing ASP.NET Core 1.x applications are based off of version-specific project templates. As the ASP.NET Core framework evolves, so do the project templates and the starter code contained within them. In addition to updating the ASP.NET Core framework, you need to update the code for your application.

Prerequisites

See Get Started with ASP.NET Core.

Update Target Framework Moniker (TFM)

Projects targeting .NET Core should use the TFM of a version greater than or equal to .NET Core 2.0. Search for the `<TargetFramework>` node in the `.csproj` file, and replace its inner text with `netcoreapp2.0`:

XML

```xml
<TargetFramework>netcoreapp2.0</TargetFramework>
```

Projects targeting .NET Framework should use the TFM of a version greater than or equal to .NET Framework 4.6.1. Search for the `<TargetFramework>` node in the `.csproj` file, and replace its inner text with `net461`:

XML

```xml
<TargetFramework>net461</TargetFramework>
```

> **Note**
>
> .NET Core 2.0 offers a much larger surface area than .NET Core 1.x. If you're targeting .NET Framework solely because of missing APIs in .NET Core 1.x, targeting

.NET Core 2.0 is likely to work.

If the project file contains `<RuntimeFrameworkVersion>1.{sub-version}</RuntimeFrameworkVersion>`, see this GitHub issue.

Update .NET Core SDK version in global.json

If your solution relies upon a global.json file to target a specific .NET Core SDK version, update its `version` property to use the 2.0 version installed on your machine:

JSON

```
{
  "sdk": {
    "version": "2.0.0"
  }
}
```

Update package references

The `.csproj` file in a 1.x project lists each NuGet package used by the project.

In an ASP.NET Core 2.0 project targeting .NET Core 2.0, a single metapackage reference in the `.csproj` file replaces the collection of packages:

XML

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore.All" Version="2.0.9" />
</ItemGroup>
```

All the features of ASP.NET Core 2.0 and Entity Framework Core 2.0 are included in the metapackage.

ASP.NET Core 2.0 projects targeting .NET Framework should continue to reference individual NuGet packages. Update the `Version` attribute of each `<PackageReference />` node to 2.0.0.

For example, here's the list of `<PackageReference />` nodes used in a typical ASP.NET Core 2.0 project targeting .NET Framework:

XML

```
<ItemGroup>
  <PackageReference Include="Microsoft.AspNetCore" Version="2.0.0" />
  <PackageReference Include="Microsoft.AspNetCore.Authentication.Cookies"
Version="2.0.0" />
  <PackageReference
Include="Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore"
Version="2.0.0" />
  <PackageReference
Include="Microsoft.AspNetCore.Identity.EntityFrameworkCore" Version="2.0.0"
/>
  <PackageReference Include="Microsoft.AspNetCore.Mvc" Version="2.0.0" />
  <PackageReference Include="Microsoft.AspNetCore.Mvc.Razor.ViewCompilation"
Version="2.0.0" PrivateAssets="All" />
  <PackageReference Include="Microsoft.AspNetCore.StaticFiles"
Version="2.0.0" />
  <PackageReference Include="Microsoft.EntityFrameworkCore.Design"
Version="2.0.0" PrivateAssets="All" />
  <PackageReference Include="Microsoft.EntityFrameworkCore.SqlServer"
Version="2.0.0" />
  <PackageReference Include="Microsoft.EntityFrameworkCore.Tools"
Version="2.0.0" PrivateAssets="All" />
  <PackageReference Include="Microsoft.VisualStudio.Web.BrowserLink"
Version="2.0.0" />
  <PackageReference
Include="Microsoft.VisualStudio.Web.CodeGeneration.Design" Version="2.0.0"
PrivateAssets="All" />
</ItemGroup>
```

The package `Microsoft.Extensions.CommandLineUtils` has been retired. It is still available but unsupported.

Update .NET CLI tools

In the `.csproj` file, update the `Version` attribute of each `<DotNetCliToolReference />` node to 2.0.0.

For example, here's the list of CLI tools used in a typical ASP.NET Core 2.0 project targeting .NET Core 2.0:

XML

```
<ItemGroup>
  <DotNetCliToolReference
Include="Microsoft.EntityFrameworkCore.Tools.DotNet" Version="2.0.0" />
  <DotNetCliToolReference Include="Microsoft.Extensions.SecretManager.Tools"
Version="2.0.0" />
  <DotNetCliToolReference
```

```
Include="Microsoft.VisualStudio.Web.CodeGeneration.Tools" Version="2.0.0" />
</ItemGroup>
```

Rename Package Target Fallback property

The `.csproj` file of a 1.x project used a `PackageTargetFallback` node and variable:

XML

```
<PackageTargetFallback>$(PackageTargetFallback);portable-
net45+win8+wp8+wpa81;</PackageTargetFallback>
```

Rename both the node and variable to `AssetTargetFallback`:

XML

```
<AssetTargetFallback>$(AssetTargetFallback);portable-net45+win8+wp8+wpa81;
</AssetTargetFallback>
```

Update Main method in Program.cs

In 1.x projects, the `Main` method of `Program.cs` looked like this:

C#

```
using System.IO;
using Microsoft.AspNetCore.Hosting;

namespace AspNetCoreDotNetCore1App
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = new WebHostBuilder()
                .UseKestrel()
                .UseContentRoot(Directory.GetCurrentDirectory())
                .UseIISIntegration()
                .UseStartup<Startup>()
                .UseApplicationInsights()
                .Build();

            host.Run();
        }
    }
}
```

In 2.0 projects, the `Main` method of `Program.cs` has been simplified:

C#

```
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;

namespace AspNetCoreDotNetCore2App
{
    public class Program
    {
        public static void Main(string[] args)
        {
            BuildWebHost(args).Run();
        }

        public static IWebHost BuildWebHost(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>()
                .Build();
    }
}
```

The adoption of this new 2.0 pattern is highly recommended and is required for product features like Entity Framework (EF) Core Migrations to work. For example, running `Update-Database` from the Package Manager Console window or `dotnet ef database update` from the command line (on projects converted to ASP.NET Core 2.0) generates the following error:

```
Unable to create an object of type '<Context>'. Add an implementation of
'IDesignTimeDbContextFactory<Context>' to the project, or see
https://go.microsoft.com/fwlink/?linkid=851728 for additional patterns
supported at design time.
```

Add configuration providers

In 1.x projects, adding configuration providers to an app was accomplished via the `Startup` constructor. The steps involved creating an instance of `ConfigurationBuilder`, loading applicable providers (environment variables, app settings, etc.), and initializing a member of `IConfigurationRoot`.

C#

```
public Startup(IHostingEnvironment env)
{
    var builder = new ConfigurationBuilder()
        .SetBasePath(env.ContentRootPath)
        .AddJsonFile("appsettings.json", optional: false, reloadOnChange:
true)
        .AddJsonFile($"appsettings.{env.EnvironmentName}.json", optional:
true);

    if (env.IsDevelopment())
    {
        builder.AddUserSecrets<Startup>();
    }

    builder.AddEnvironmentVariables();
    Configuration = builder.Build();
}

public IConfigurationRoot Configuration { get; }
```

The preceding example loads the `Configuration` member with configuration settings from `appsettings.json` as well as any `appsettings.{Environment}.json` file matching the `IHostingEnvironment.EnvironmentName` property. The location of these files is at the same path as `Startup.cs`.

In 2.0 projects, the boilerplate configuration code inherent to 1.x projects runs behind-the-scenes. For example, environment variables and app settings are loaded at startup. The equivalent `Startup.cs` code is reduced to `IConfiguration` initialization with the injected instance:

C#

```
public Startup(IConfiguration configuration)
{
    Configuration = configuration;
}

public IConfiguration Configuration { get; }
```

To remove the default providers added by `WebHostBuilder.CreateDefaultBuilder`, invoke the `Clear` method on the `IConfigurationBuilder.Sources` property inside of `ConfigureAppConfiguration`. To add providers back, utilize the `ConfigureAppConfiguration` method in `Program.cs`:

C#

```
public static void Main(string[] args)
{
    BuildWebHost(args).Run();
}

public static IWebHost BuildWebHost(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureAppConfiguration((hostContext, config) =>
        {
            // delete all default configuration providers
            config.Sources.Clear();
            config.AddJsonFile("myconfig.json", optional: true);
        })
        .Build();
```

The configuration used by the `CreateDefaultBuilder` method in the preceding code snippet can be seen here.

For more information, see Configuration in ASP.NET Core.

Move database initialization code

In 1.x projects using EF Core 1.x, a command such as `dotnet ef migrations add` does the following:

1. Instantiates a `Startup` instance
2. Invokes the `ConfigureServices` method to register all services with dependency injection (including `DbContext` types)
3. Performs its requisite tasks

In 2.0 projects using EF Core 2.0, `Program.BuildWebHost` is invoked to obtain the application services. Unlike 1.x, this has the additional side effect of invoking `Startup.Configure`. If your 1.x app invoked database initialization code in its `Configure` method, unexpected problems can occur. For example, if the database doesn't yet exist, the seeding code runs before the EF Core Migrations command execution. This problem causes a `dotnet ef migrations list` command to fail if the database doesn't yet exist.

Consider the following 1.x seed initialization code in the `Configure` method of `Startup.cs`:

```
C#

app.UseMvc(routes =>
{
```

```
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});

SeedData.Initialize(app.ApplicationServices);
```

In 2.0 projects, move the `SeedData.Initialize` call to the `Main` method of `Program.cs`:

C#

```
var host = BuildWebHost(args);

using (var scope = host.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    try
    {
        // Requires using RazorPagesMovie.Models;
        SeedData.Initialize(services);
    }
    catch (Exception ex)
    {
        var logger = services.GetRequiredService<ILogger<Program>>();
        logger.LogError(ex, "An error occurred seeding the DB.");
    }
}

host.Run();
```

As of 2.0, it's bad practice to do anything in `BuildWebHost` except build and configure the web host. Anything that's about running the application should be handled outside of `BuildWebHost` — typically in the `Main` method of `Program.cs`.

Review Razor view compilation setting

Faster application startup time and smaller published bundles are of utmost importance to you. For these reasons, Razor view compilation is enabled by default in ASP.NET Core 2.0.

Setting the `MvcRazorCompileOnPublish` property to true is no longer required. Unless you're disabling view compilation, the property may be removed from the `.csproj` file.

When targeting .NET Framework, you still need to explicitly reference the Microsoft.AspNetCore.Mvc.Razor.ViewCompilation NuGet package in your `.csproj` file:

XML

```
<PackageReference Include="Microsoft.AspNetCore.Mvc.Razor.ViewCompilation"
Version="2.0.0" PrivateAssets="All" />
```

Rely on Application Insights "light-up" features

Effortless setup of application performance instrumentation is important. You can now rely on the new Application Insights "light-up" features available in the Visual Studio 2017 tooling.

ASP.NET Core 1.1 projects created in Visual Studio 2017 added Application Insights by default. If you're not using the Application Insights SDK directly, outside of `Program.cs` and `Startup.cs`, follow these steps:

1. If targeting .NET Core, remove the following `<PackageReference />` node from the `.csproj` file:

   XML

   ```
   <PackageReference Include="Microsoft.ApplicationInsights.AspNetCore"
   Version="2.0.0" />
   ```

2. If targeting .NET Core, remove the `UseApplicationInsights` extension method invocation from `Program.cs`:

   C#

   ```
   public static void Main(string[] args)
   {
       var host = new WebHostBuilder()
           .UseKestrel()
           .UseContentRoot(Directory.GetCurrentDirectory())
           .UseIISIntegration()
           .UseStartup<Startup>()
           .UseApplicationInsights()
           .Build();

       host.Run();
   }
   ```

3. Remove the Application Insights client-side API call from `_Layout.cshtml`. It comprises the following two lines of code:

CSHTML

```
@inject Microsoft.ApplicationInsights.AspNetCore.JavaScriptSnippet
JavaScriptSnippet
@Html.Raw(JavaScriptSnippet.FullScript)
```

If you are using the Application Insights SDK directly, continue to do so. The 2.0 metapackage includes the latest version of Application Insights, so a package downgrade error appears if you're referencing an older version.

Adopt authentication/Identity improvements

ASP.NET Core 2.0 has a new authentication model and a number of significant changes to ASP.NET Core Identity. If you created your project with Individual User Accounts enabled, or if you have manually added authentication or Identity, see Migrate Authentication and Identity to ASP.NET Core 2.0.

- Breaking Changes in ASP.NET Core 2.0

Migrate authentication and Identity to ASP.NET Core 2.0

Article • 06/18/2024

By Scott Addie and Hao Kung

ASP.NET Core 2.0 has a new model for authentication and Identity that simplifies configuration by using services. ASP.NET Core 1.x applications that use authentication or Identity can be updated to use the new model as outlined below.

Update namespaces

In 1.x, classes such `IdentityRole` and `IdentityUser` were found in the `Microsoft.AspNetCore.Identity.EntityFrameworkCore` namespace.

In 2.0, the Microsoft.AspNetCore.Identity namespace became the new home for several of such classes. With the default Identity code, affected classes include `ApplicationUser` and `Startup`. Adjust your `using` statements to resolve the affected references.

Authentication Middleware and services

In 1.x projects, authentication is configured via middleware. A middleware method is invoked for each authentication scheme you want to support.

The following 1.x example configures Facebook authentication with Identity in `Startup.cs`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddIdentity<ApplicationUser, IdentityRole>()
            .AddEntityFrameworkStores<ApplicationDbContext>();
}

public void Configure(IApplicationBuilder app, ILoggerFactory loggerfactory)
{
    app.UseIdentity();
    app.UseFacebookAuthentication(new FacebookOptions {
        AppId = Configuration["auth:facebook:appid"],
        AppSecret = Configuration["auth:facebook:appsecret"]
```

```
    });
}
```

In 2.0 projects, authentication is configured via services. Each authentication scheme is registered in the `ConfigureServices` method of `Startup.cs`. The `UseIdentity` method is replaced with `UseAuthentication`.

The following 2.0 example configures Facebook authentication with Identity in `Startup.cs`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddIdentity<ApplicationUser, IdentityRole>()
            .AddEntityFrameworkStores<ApplicationDbContext>();

    // If you want to tweak Identity cookies, they're no longer part of
IdentityOptions.
    services.ConfigureApplicationCookie(options => options.LoginPath =
"/Account/LogIn");
    services.AddAuthentication()
            .AddFacebook(options =>
            {
                options.AppId = Configuration["auth:facebook:appid"];
                options.AppSecret =
Configuration["auth:facebook:appsecret"];
            });
}

public void Configure(IApplicationBuilder app, ILoggerFactory loggerfactory)
{
    app.UseAuthentication();
}
```

The `UseAuthentication` method adds a single authentication middleware component, which is responsible for automatic authentication and the handling of remote authentication requests. It replaces all of the individual middleware components with a single, common middleware component.

Below are 2.0 migration instructions for each major authentication scheme.

Cookie-based authentication

Select one of the two options below, and make the necessary changes in `Startup.cs`:

1. Use cookies with Identity

- Replace `UseIdentity` with `UseAuthentication` in the `Configure` method:

```
C#

app.UseAuthentication();
```

- Invoke the `AddIdentity` method in the `ConfigureServices` method to add the cookie authentication services.

- Optionally, invoke the `ConfigureApplicationCookie` or `ConfigureExternalCookie` method in the `ConfigureServices` method to tweak the Identity cookie settings.

```
C#

services.AddIdentity<ApplicationUser, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

services.ConfigureApplicationCookie(options => options.LoginPath =
"/Account/LogIn");
```

2. Use cookies without Identity

- Replace the `UseCookieAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
C#

app.UseAuthentication();
```

- Invoke the `AddAuthentication` and `AddCookie` methods in the `ConfigureServices` method:

```
C#

// If you don't want the cookie to be automatically authenticated
and assigned to HttpContext.User,
// remove the CookieAuthenticationDefaults.AuthenticationScheme
parameter passed to AddAuthentication.
services.AddAuthentication(CookieAuthenticationDefaults.Authentica
tionScheme)
        .AddCookie(options =>
        {
            options.LoginPath = "/Account/LogIn";
```

```
            options.LogoutPath = "/Account/LogOff";
        });
```

JWT Bearer Authentication

Make the following changes in `Startup.cs`:

- Replace the `UseJwtBearerAuthentication` method call in the `Configure` method with `UseAuthentication`:

  ```
  C#

  app.UseAuthentication();
  ```

- Invoke the `AddJwtBearer` method in the `ConfigureServices` method:

  ```
  C#

  services.AddAuthentication(JwtBearerDefaults.AuthenticationScheme)
          .AddJwtBearer(options =>
          {
              options.Audience = "http://localhost:5001/";
              options.Authority = "http://localhost:5000/";
          });
  ```

  This code snippet doesn't use Identity, so the default scheme should be set by passing `JwtBearerDefaults.AuthenticationScheme` to the `AddAuthentication` method.

OpenID Connect (OIDC) authentication

Make the following changes in `Startup.cs`:

- Replace the `UseOpenIdConnectAuthentication` method call in the `Configure` method with `UseAuthentication`:

  ```
  C#

  app.UseAuthentication();
  ```

- Invoke the `AddOpenIdConnect` method in the `ConfigureServices` method:

  ```
  C#
  ```

```
services.AddAuthentication(options =>
{
    options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme =
OpenIdConnectDefaults.AuthenticationScheme;
})
.AddCookie()
.AddOpenIdConnect(options =>
{
    options.Authority = Configuration["auth:oidc:authority"];
    options.ClientId = Configuration["auth:oidc:clientid"];
});
```

- Replace the `PostLogoutRedirectUri` property in the `OpenIdConnectOptions` action with `SignedOutRedirectUri`:

```
C#

.AddOpenIdConnect(options =>
{
    options.SignedOutRedirectUri = "https://contoso.com";
});
```

Facebook authentication

Make the following changes in `Startup.cs`:

- Replace the `UseFacebookAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
C#

app.UseAuthentication();
```

- Invoke the `AddFacebook` method in the `ConfigureServices` method:

```
C#

services.AddAuthentication()
        .AddFacebook(options =>
        {
            options.AppId = Configuration["auth:facebook:appid"];
            options.AppSecret =
```

```
Configuration["auth:facebook:appsecret"];
        });
```

Google authentication

Make the following changes in `Startup.cs`:

- Replace the `UseGoogleAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
C#

app.UseAuthentication();
```

- Invoke the `AddGoogle` method in the `ConfigureServices` method:

```
C#

services.AddAuthentication()
        .AddGoogle(options =>
        {
            options.ClientId = Configuration["auth:google:clientid"];
            options.ClientSecret =
Configuration["auth:google:clientsecret"];
        });
```

Microsoft Account authentication

For more information on Microsoft account authentication, see this GitHub issue.

Make the following changes in `Startup.cs`:

- Replace the `UseMicrosoftAccountAuthentication` method call in the `Configure` method with `UseAuthentication`:

```
C#

app.UseAuthentication();
```

- Invoke the `AddMicrosoftAccount` method in the `ConfigureServices` method:

```
C#
```

```
services.AddAuthentication()
        .AddMicrosoftAccount(options =>
        {
            options.ClientId =
Configuration["auth:microsoft:clientid"];
            options.ClientSecret =
Configuration["auth:microsoft:clientsecret"];
        });
```

Twitter authentication

Make the following changes in `Startup.cs`:

- Replace the `UseTwitterAuthentication` method call in the `Configure` method with `UseAuthentication`:

  C#

  ```
  app.UseAuthentication();
  ```

- Invoke the `AddTwitter` method in the `ConfigureServices` method:

  C#

  ```
  services.AddAuthentication()
          .AddTwitter(options =>
          {
              options.ConsumerKey =
  Configuration["auth:twitter:consumerkey"];
              options.ConsumerSecret =
  Configuration["auth:twitter:consumersecret"];
          });
  ```

Setting default authentication schemes

In 1.x, the `AutomaticAuthenticate` and `AutomaticChallenge` properties of the AuthenticationOptions base class were intended to be set on a single authentication scheme. There was no good way to enforce this.

In 2.0, these two properties have been removed as properties on the individual `AuthenticationOptions` instance. They can be configured in the `AddAuthentication` method call within the `ConfigureServices` method of `Startup.cs`:

C#

```
services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme
);
```

In the preceding code snippet, the default scheme is set to `CookieAuthenticationDefaults.AuthenticationScheme` ("Cookies").

Alternatively, use an overloaded version of the `AddAuthentication` method to set more than one property. In the following overloaded method example, the default scheme is set to `CookieAuthenticationDefaults.AuthenticationScheme`. The authentication scheme may alternatively be specified within your individual `[Authorize]` attributes or authorization policies.

C#

```
services.AddAuthentication(options =>
{
    options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme =
OpenIdConnectDefaults.AuthenticationScheme;
});
```

Define a default scheme in 2.0 if one of the following conditions is true:

- You want the user to be automatically signed in
- You use the `[Authorize]` attribute or authorization policies without specifying schemes

An exception to this rule is the `AddIdentity` method. This method adds cookies for you and sets the default authenticate and challenge schemes to the application cookie `IdentityConstants.ApplicationScheme`. Additionally, it sets the default sign-in scheme to the external cookie `IdentityConstants.ExternalScheme`.

Use HttpContext authentication extensions

The `IAuthenticationManager` interface is the main entry point into the 1.x authentication system. It has been replaced with a new set of `HttpContext` extension methods in the `Microsoft.AspNetCore.Authentication` namespace.

For example, 1.x projects reference an `Authentication` property:

C#

```
// Clear the existing external cookie to ensure a clean login process
await HttpContext.Authentication.SignOutAsync(_externalCookieScheme);
```

In 2.0 projects, import the `Microsoft.AspNetCore.Authentication` namespace, and delete the `Authentication` property references:

C#

```
// Clear the existing external cookie to ensure a clean login process
await HttpContext.SignOutAsync(IdentityConstants.ExternalScheme);
```

Windows Authentication (HTTP.sys / IISIntegration)

There are two variations of Windows authentication:

- The host only allows authenticated users. This variation isn't affected by the 2.0 changes.
- The host allows both anonymous and authenticated users. This variation is affected by the 2.0 changes. For example, the app should allow anonymous users at the IIS or HTTP.sys layer but authorize users at the controller level. In this scenario, set the default scheme in the `Startup.ConfigureServices` method.

  For Microsoft.AspNetCore.Server.IISIntegration, set the default scheme to `IISDefaults.AuthenticationScheme`:

  C#

  ```
  using Microsoft.AspNetCore.Server.IISIntegration;

  services.AddAuthentication(IISDefaults.AuthenticationScheme);
  ```

  For Microsoft.AspNetCore.Server.HttpSys, set the default scheme to `HttpSysDefaults.AuthenticationScheme`:

  C#

  ```
  using Microsoft.AspNetCore.Server.HttpSys;

  services.AddAuthentication(HttpSysDefaults.AuthenticationScheme);
  ```

Failure to set the default scheme prevents the authorize (challenge) request from working with the following exception:

> `System.InvalidOperationException`: No authenticationScheme was specified, and there was no DefaultChallengeScheme found.

For more information, see Configure Windows Authentication in ASP.NET Core.

IdentityCookieOptions instances

A side effect of the 2.0 changes is the switch to using named options instead of cookie options instances. The ability to customize the Identity cookie scheme names is removed.

For example, 1.x projects use constructor injection to pass an `IdentityCookieOptions` parameter into `AccountController.cs` and `ManageController.cs`. The external cookie authentication scheme is accessed from the provided instance:

C#

```
public AccountController(
    UserManager<ApplicationUser> userManager,
    SignInManager<ApplicationUser> signInManager,
    IOptions<IdentityCookieOptions> identityCookieOptions,
    IEmailSender emailSender,
    ISmsSender smsSender,
    ILoggerFactory loggerFactory)
{
    _userManager = userManager;
    _signInManager = signInManager;
    _externalCookieScheme =
identityCookieOptions.Value.ExternalCookieAuthenticationScheme;
    _emailSender = emailSender;
    _smsSender = smsSender;
    _logger = loggerFactory.CreateLogger<AccountController>();
}
```

The aforementioned constructor injection becomes unnecessary in 2.0 projects, and the `_externalCookieScheme` field can be deleted:

C#

```
public AccountController(
    UserManager<ApplicationUser> userManager,
    SignInManager<ApplicationUser> signInManager,
    IEmailSender emailSender,
    ISmsSender smsSender,
```

```
    ILoggerFactory loggerFactory)
{
    _userManager = userManager;
    _signInManager = signInManager;
    _emailSender = emailSender;
    _smsSender = smsSender;
    _logger = loggerFactory.CreateLogger<AccountController>();
}
```

1.x projects used the `_externalCookieScheme` field as follows:

C#

```
// Clear the existing external cookie to ensure a clean login process
await HttpContext.Authentication.SignOutAsync(_externalCookieScheme);
```

In 2.0 projects, replace the preceding code with the following. The `IdentityConstants.ExternalScheme` constant can be used directly.

C#

```
// Clear the existing external cookie to ensure a clean login process
await HttpContext.SignOutAsync(IdentityConstants.ExternalScheme);
```

Resolve the newly added `SignOutAsync` call by importing the following namespace:

C#

```
using Microsoft.AspNetCore.Authentication;
```

Add IdentityUser POCO navigation properties

The Entity Framework (EF) Core navigation properties of the base `IdentityUser` POCO (Plain Old CLR Object) have been removed. If your 1.x project used these properties, manually add them back to the 2.0 project:

C#

```
/// <summary>
/// Navigation property for the roles this user belongs to.
/// </summary>
public virtual ICollection<IdentityUserRole<int>> Roles { get; } = new
List<IdentityUserRole<int>>();

/// <summary>
```

```
/// Navigation property for the claims this user possesses.
/// </summary>
public virtual ICollection<IdentityUserClaim<int>> Claims { get; } = new
List<IdentityUserClaim<int>>();

/// <summary>
/// Navigation property for this users login accounts.
/// </summary>
public virtual ICollection<IdentityUserLogin<int>> Logins { get; } = new
List<IdentityUserLogin<int>>();
```

To prevent duplicate foreign keys when running EF Core Migrations, add the following to your `IdentityDbContext` class' `OnModelCreating` method (after the `base.OnModelCreating();` call):

C#

```
protected override void OnModelCreating(ModelBuilder builder)
{
    base.OnModelCreating(builder);
    // Customize the ASP.NET Core Identity model and override the defaults
if needed.
    // For example, you can rename the ASP.NET Core Identity table names and
more.
    // Add your customizations after calling base.OnModelCreating(builder);

    builder.Entity<ApplicationUser>()
        .HasMany(e => e.Claims)
        .WithOne()
        .HasForeignKey(e => e.UserId)
        .IsRequired()
        .OnDelete(DeleteBehavior.Cascade);

    builder.Entity<ApplicationUser>()
        .HasMany(e => e.Logins)
        .WithOne()
        .HasForeignKey(e => e.UserId)
        .IsRequired()
        .OnDelete(DeleteBehavior.Cascade);

    builder.Entity<ApplicationUser>()
        .HasMany(e => e.Roles)
        .WithOne()
        .HasForeignKey(e => e.UserId)
        .IsRequired()
        .OnDelete(DeleteBehavior.Cascade);
}
```

Replace GetExternalAuthenticationSchemes

The synchronous method `GetExternalAuthenticationSchemes` was removed in favor of an asynchronous version. 1.x projects have the following code in `Controllers/ManageController.cs`:

C#

```
var otherLogins =
_signInManager.GetExternalAuthenticationSchemes().Where(auth =>
userLogins.All(ul => auth.AuthenticationScheme !=
ul.LoginProvider)).ToList();
```

This method appears in `Views/Account/Login.cshtml` too:

CSHTML

```
@{
    var loginProviders =
SignInManager.GetExternalAuthenticationSchemes().ToList();
    if (loginProviders.Count == 0)
    {
        <div>
            <p>
                There are no external authentication services configured.
See <a href="https://go.microsoft.com/fwlink/?LinkID=532715">this
article</a>
                for details on setting up this ASP.NET application to
support logging in via external services.
            </p>
        </div>
    }
    else
    {
        <form asp-controller="Account" asp-action="ExternalLogin" asp-route-
returnurl="@ViewData["ReturnUrl"]" method="post" class="form-horizontal">
            <div>
                <p>
                    @foreach (var provider in loginProviders)
                    {
                        <button type="submit" class="btn btn-default"
name="provider" value="@provider.AuthenticationScheme" title="Log in using
your @provider.DisplayName account">@provider.AuthenticationScheme</button>
                    }
                </p>
            </div>
        </form>
    }
}
```

In 2.0 projects, use the GetExternalAuthenticationSchemesAsync method. The change in `ManageController.cs` resembles the following code:

C#

```
var schemes = await _signInManager.GetExternalAuthenticationSchemesAsync();
var otherLogins = schemes.Where(auth => userLogins.All(ul => auth.Name !=
ul.LoginProvider)).ToList();
```

In `Login.cshtml`, the `AuthenticationScheme` property accessed in the `foreach` loop changes to `Name`:

CSHTML

```
@{
    var loginProviders = (await
SignInManager.GetExternalAuthenticationSchemesAsync()).ToList();
    if (loginProviders.Count == 0)
    {
        <div>
            <p>
                There are no external authentication services configured.
See <a href="https://go.microsoft.com/fwlink/?LinkID=532715">this
article</a>
                for details on setting up this ASP.NET application to
support logging in via external services.
            </p>
        </div>
    }
    else
    {
        <form asp-controller="Account" asp-action="ExternalLogin" asp-route-
returnurl="@ViewData["ReturnUrl"]" method="post" class="form-horizontal">
            <div>
                <p>
                    @foreach (var provider in loginProviders)
                    {
                        <button type="submit" class="btn btn-default"
name="provider" value="@provider.Name" title="Log in using your
@provider.DisplayName account">@provider.DisplayName</button>
                    }
                </p>
            </div>
        </form>
    }
}
```

ManageLoginsViewModel property change

A `ManageLoginsViewModel` object is used in the `ManageLogins` action of `ManageController.cs`. In 1.x projects, the object's `OtherLogins` property return type is

`IList<AuthenticationDescription>`. This return type requires an import of `Microsoft.AspNetCore.Http.Authentication`:

C#

```
using System.Collections.Generic;
using Microsoft.AspNetCore.Http.Authentication;
using Microsoft.AspNetCore.Identity;

namespace AspNetCoreDotNetCore1App.Models.ManageViewModels
{
    public class ManageLoginsViewModel
    {
        public IList<UserLoginInfo> CurrentLogins { get; set; }

        public IList<AuthenticationDescription> OtherLogins { get; set; }
    }
}
```

In 2.0 projects, the return type changes to `IList<AuthenticationScheme>`. This new return type requires replacing the `Microsoft.AspNetCore.Http.Authentication` import with a `Microsoft.AspNetCore.Authentication` import.

C#

```
using System.Collections.Generic;
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Identity;

namespace AspNetCoreDotNetCore2App.Models.ManageViewModels
{
    public class ManageLoginsViewModel
    {
        public IList<UserLoginInfo> CurrentLogins { get; set; }

        public IList<AuthenticationScheme> OtherLogins { get; set; }
    }
}
```

Upgrade from ASP.NET Framework to ASP.NET Core

Article • 04/13/2023

Why upgrade to the latest .NET

ASP.NET Core is the modern web framework for .NET. While ASP.NET Core has many similarities to ASP.NET in the .NET Framework, it's a new framework that's completely rewritten. ASP.NET apps updated to ASP.NET Core can benefit from improved performance and access to the latest web development features and capabilities.

ASP.NET Framework update approaches

Most non-trivial ASP.NET Framework apps should consider using the incremental upgrade approach. For more information, see Incremental ASP.NET to ASP.NET Core upgrade.

For ASP.NET MVC and Web API apps, see Learn to upgrade from ASP.NET MVC and Web API to ASP.NET Core MVC. For ASP.NET Framework Web Forms apps, see Learn to upgrade from ASP.NET Web Forms to ASP.NET Core.

Reliable web app patterns

See *The Reliable Web App Pattern for.NET* YouTube videos and article for guidance on creating a modern, reliable, performant, testable, cost-efficient, and scalable ASP.NET Core app, whether from scratch or refactoring an existing app.

URI decoding differences between ASP.NET to ASP.NET Core

ASP.NET Core has the following URI decoding differences with ASP.NET Framework:

Expand table

ASCII	Encoded	ASP.NET Core	ASP.NET Framework
`\`	`%5C`	`\`	`/`

ASCII	Encoded	ASP.NET Core	ASP.NET Framework
`/`	`%2F`	`%2F`	`/`

When decoding `%2F` on ASP.NET Core:

- The entire path gets unescaped except `%2F` because converting it to `/` would change the path structure. It can't be decoded until the path is split into segments.

To generate the value for `HttpRequest.Url`, use `new Uri(this.AspNetCoreHttpRequest.GetEncodedUrl());` to avoid `Uri` misinterpreting the values.

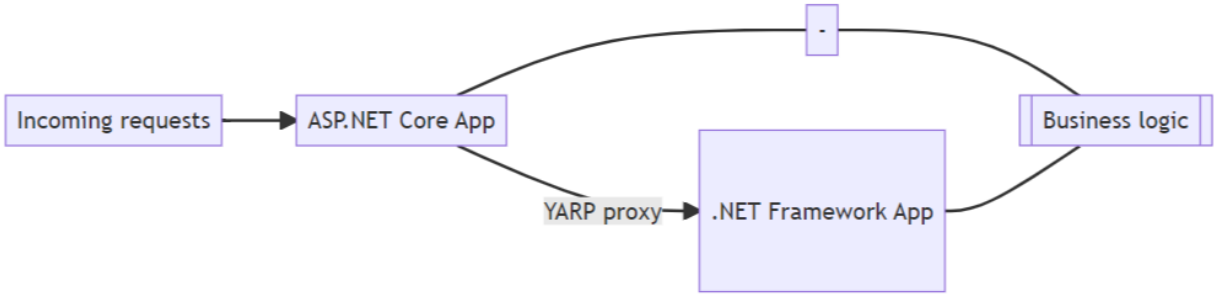
Incremental ASP.NET to ASP.NET Core update

Article • 10/04/2023

Updating an app from ASP.NET Framework to ASP.NET Core is non-trivial for the majority of production apps. These apps often incorporate new technologies as they become available and are often composed of many legacy decisions. This article provides guidance and links to tools for updating ASP.NET Framework apps to ASP.NET Core with as little change as possible.

One of the larger challenges is the pervasive use of HttpContext throughout a code base. Without the incremental approach and tools, a large scale rewrite is required to remove the HttpContext dependency. The adapters in dotnet/systemweb-adapters provide a set of runtime helpers to access the types used in the ASP.NET Framework app in a way that works in ASP.NET Core with minimal changes.

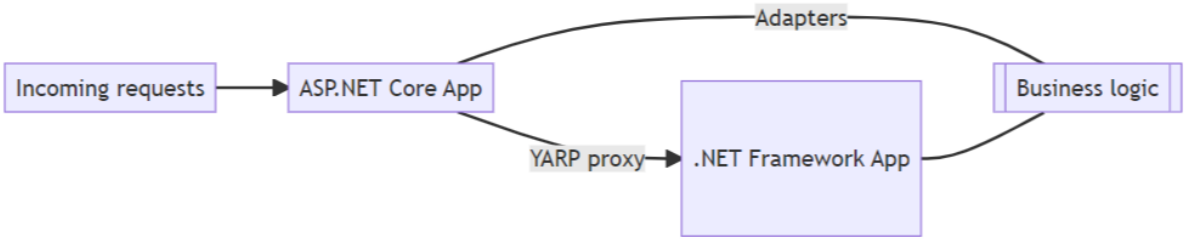
A complete migration may take considerable effort depending on the size of the app, dependencies, and non-portable APIs used. In order to keep deploying an app to production while working on updating, the best pattern is to follow is the Strangler Fig pattern. The *Strangler Fig pattern* allows for continual development on the old system with an incremental approach to replacing specific pieces of functionality with new services. This document describes how to apply the Strangler Fig pattern to an ASP.NET app updating towards ASP.NET Core.



If you'd like to skip this overview article and get started, see Get started.

App migration to ASP.NET Core

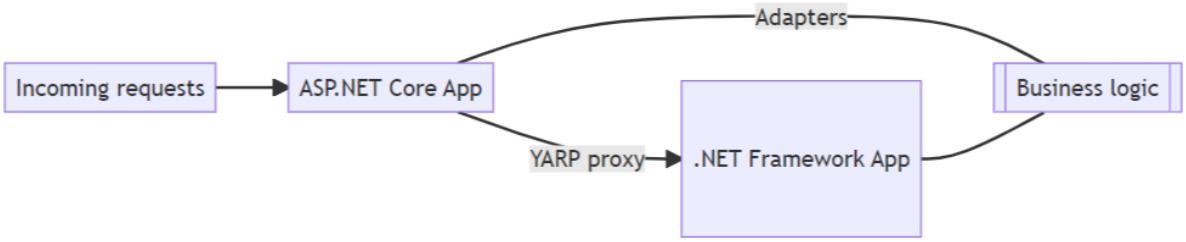
Before starting the migration, the app targets ASP.NET Framework and runs on Windows with its supporting libraries:



Migration starts by introducing a new app based on ASP.NET Core that becomes the entry point. Incoming requests go to the ASP.NET Core app, which either handles the request or proxies the request to the .NET Framework app via YARP. At first, the majority of code providing responses is in the .NET Framework app, but the ASP.NET Core app is now set up to start migrating routes:

To migrate business logic that relies on `HttpContext`, the libraries need to be built with `Microsoft.AspNetCore.SystemWebAdapters`. Building the libraries with `SystemWebAdapters` allows:

- The libraries to be built against .NET Framework, .NET Core, or .NET Standard 2.0.
- Ensures that the libraries are using APIs that are available on both ASP.NET Framework and ASP.NET Core.



Once the ASP.NET Core app using YARP is set up, you can start updating routes from ASP.NET Framework to ASP.NET Core. For example, WebAPI or MVC controller action methods,handlers, or some other implementation of a route. If the route is available in the ASP.NET Core app, it's matched and served.

During the migration process, additional services and infrastructure are identified that must be updated to run on .NET Core. Options listed in order of maintainability include:

1. Move the code to shared libraries
2. Link the code in the new project
3. Duplicate the code

Eventually, the ASP.NET Core app handles more of the routes than the .NET Framework app:

Once the ASP.NET Framework app is no longer needed and deleted:

- The app is running on the ASP.NET Core app stack, but is still using the adapters.
- The remaining migration work is removing the use of adapters.

The Visual Studio extension .NET Upgrade Assistant can help upgrade ASP.NET Framework web apps to ASP.NET Core. For more information see the blog post Upgrading your .NET projects with Visual Studio.

System.Web Adapters

The `Microsoft.AspNetCore.SystemWebAdapters` namespace is a collection of runtime helpers that facilitate using code written against `System.Web` while moving to ASP.NET Core. There are a few packages that may be used to use features from these adapters:

- `Microsoft.AspNetCore.SystemWebAdapters`: This package is used in supporting libraries and provide the System.Web APIs you may have taken a dependency on, such as `HttpContext` and others. This package targets .NET Standard 2.0, .NET 4.5+, and .NET 6+.
- `Microsoft.AspNetCore.SystemWebAdapters.FrameworkServices`: This package only targets .NET Framework and is intended to provide services to ASP.NET Framework applications that may need to provide incremental migrations. This is generally not expected to be referenced from libraries, but rather from the applications themselves.
- `Microsoft.AspNetCore.SystemWebAdapters.CoreServices`: This package only targets .NET 6+ and is intended to provide services to ASP.NET Core applications to configure behavior of `System.Web` APIs as well as opting into any behaviors for incremental migration. This is generally not expected to be referenced from libraries, but rather from the applications themselves.

- `Microsoft.AspNetCore.SystemWebAdapters.Abstractions`: This package is a supporting package that provides abstractions for services used by both the ASP.NET Core and ASP.NET Framework application such as session state serialization.

For examples of scenarios where this is useful, see the adapters article.

For guidance around usage, see the usage guidance article.

Get started with incremental ASP.NET to ASP.NET Core migration

Article • 03/17/2023

For a large migration, we recommend setting up a ASP.NET Core app that proxies to the original .NET Framework app. The new proxy enabled app is shown in the following image:

To understand how this approach is helpful in the migration process, see Incremental ASP.NET to ASP.NET Core migration. The rest of this article provides the steps to proceed with an incremental migration.

Set up ASP.NET Core Project

For ASP.NET MVC and Web API apps, see Learn to upgrade from ASP.NET MVC and Web API to ASP.NET Core MVC. For ASP.NET Framework Web Forms apps, see Learn to upgrade from ASP.NET Web Forms to ASP.NET Core.

Upgrade supporting libraries

If you have supporting libraries in your solution that you will need to use, they should be upgraded to .NET Standard 2.0, if possible. Upgrade Assistant is a great tool for this. If libraries are unable to target .NET Standard, you can target .NET 6 or later either along with the .NET Framework target in the original project or in a new project alongside the original.

The adapters can be used in these libraries to enable support for `System.Web.HttpContext` usage in class libraries. In order to enable `System.Web.HttpContext` usage in a library:

1. Remove reference to `System.Web` in the project file

2. Add the `Microsoft.AspNetCore.SystemWebAdapters` package
3. Enable multi-targeting and add a .NET 6 target or later, or convert the project to .NET Standard 2.0.
4. Ensure the target framework supports .NET Core. Multi-targeting can be used if .NET Standard 2.0 is not sufficient

This step may require a number of projects to change depending on your solution structure. Upgrade Assistant can help you identify which ones need to change and automate a number of steps in the process.

Enable Session Support

Session is a commonly used feature of ASP.NET that shares the name with a feature in ASP.NET Core the APIs are much different. See the documentation on session support.

Enable shared authentication support

It is possible to share authentication between the original ASP.NET app and the new ASP.NET Core app by using the `System.Web` adapters remote authentication feature. This feature allows the ASP.NET Core app to defer authentication to the ASP.NET app. See the remote app connection and remote authentication docs for more details.

General Usage Guidance

There are a number of differences between ASP.NET and ASP.NET Core that the adapters are able to help update. However, there are some features that require an opt-in as they incur some cost. There are also behaviors that cannot be adapted. See usage guidance for a list of these.

Collaborate with us on GitHub

The source for this content can be found on GitHub, where you can also create and review issues and pull requests. For more information, see our contributor guide.

System.Web adapters

Article • 10/04/2023

The main use case of the adapters in the dotnet/systemweb-adapters repository is to help developers who have taken a reliance on `System.Web` types within their class libraries as they want to move to ASP.NET Core.

An important feature of the adapters is the adapters allow the library to be used from ***both*** ASP.NET Framework and ASP.NET Core projects. Updating multiple ASP.NET Framework apps to ASP.NET Core often involves intermediate states where not all the apps have been fully updated. By using the `System.Web` adapters, the library can be used both from ASP.NET Core callers and ASP.NET Framework callers that haven't been upgraded.

Let's take a look at an example using the adapters moving from .NET Framework to ASP.NET Core.

ASP.NET Framework

Consider a controller that does something such as:

cs

```cs
public class SomeController : Controller
{
  public ActionResult Index()
  {
    SomeOtherClass.SomeMethod(HttpContext.Current);
  }
}
```

which then has logic in a separate assembly passing that HttpContext around until finally, some inner method does some logic on it such as:

cs

```cs
public class Class2
{
  public bool PerformSomeCheck(HttpContext context)
  {
    return context.Request.Headers["SomeHeader"] == "ExpectedValue";
  }
}
```

ASP.NET Core

In order to run the above logic in ASP.NET Core, a developer will need to add the `Microsoft.AspNetCore.SystemWebAdapters` package, that will enable the projects to work on both platforms.

The libraries would need to be updated to understand the adapters, but it will be as simple as adding the package and recompiling. If these are the only dependencies a system has on `System.Web.dll`, then the libraries will be able to target .NET Standard 2.0 to facilitate a simpler building process while migrating.

The controller in ASP.NET Core will now look like this:

```cs
public class SomeController : Controller
{
  [Route("/")]
  public IActionResult Index()
  {
    SomeOtherClass.SomeMethod(HttpContext);
  }
}
```

Notice that since there's a HttpContext property, they can pass that through, but it generally looks the same. Using implicit conversions, the HttpContext can be converted into the adapter that could then be passed around through the levels utilizing the code in the same way.

Remote app setup

Article • 05/04/2023

In some incremental upgrade scenarios, it's useful for the new ASP.NET Core app to be able to communicate with the original ASP.NET app.

Specifically, this capability is used, currently, for remote app authentication and remote session features.

Configuration

To enable the ASP.NET Core app to communicate with the ASP.NET app, it's necessary to make a couple small changes to each app.

ASP.NET app configuration

To set up the ASP.NET app to be able to receive requests from the ASP.NET Core app:

1. Install the nuget package Microsoft.AspNetCore.SystemWebAdapters.FrameworkServices
2. Call the `AddRemoteAppServer` extension method on the `ISystemWebAdapterBuilder`:

CSharp

```
SystemWebAdapterConfiguration.AddSystemWebAdapters(this)
    .AddRemoteAppServer(options =>
    {
        // ApiKey is a string representing a GUID
        options.ApiKey =
ConfigurationManager.AppSettings["RemoteAppApiKey"];
    });
```

In the options configuration method passed to the `AddRemoteAppServer` call, an API key must be specified. The API key is:

- Used to secure the endpoint so that only trusted callers can make requests to it.
- The same API key provided to the ASP.NET Core app when it is configured.
- A string and must be parsable as a GUID. Hyphens in the key are optional.

3. **Optional** : Add the `SystemWebAdapterModule` module to the `web.config` if it wasn't already added by NuGet. The `SystemWebAdapterModule` module is not added automatically when using SDK style projects for ASP.NET Core.

diff

```
  <system.webServer>
    <modules>
+       <remove name="SystemWebAdapterModule" />
+       <add name="SystemWebAdapterModule"
type="Microsoft.AspNetCore.SystemWebAdapters.SystemWebAdapterModule,
Microsoft.AspNetCore.SystemWebAdapters.FrameworkServices"
preCondition="managedHandler" />
    </modules>
</system.webServer>
```

ASP.NET Core app

To set up the ASP.NET Core app to be able to send requests to the ASP.NET app, you need to make a similar change, calling `AddRemoteApp` after registering System.Web adapter services with `AddSystemWebAdapters`.

CSharp

```
builder.Services.AddSystemWebAdapters()
    .AddRemoteAppClient(options =>
    {
        options.RemoteAppUrl =
new(builder.Configuration["ReverseProxy:Clusters:fallbackCluster:Destination
s:fallbackApp:Address"]);
        options.ApiKey = builder.Configuration["RemoteAppApiKey"];
    });
```

In the preceding code:

- The `AddRemoteApp` call is used to configure the remote app's URL and the shared secret API key.
- The `RemoteAppUrl` property specifies the URL of the ASP.NET Framework app that the ASP.NET Core app communicates with. In this example, the URL is read from an existing configuration setting used by the YARP proxy that proxies requests to the ASP.NET Framework app as part of the incremental migration's *strangler fig pattern*.

With both the ASP.NET and ASP.NET Core app updated, extension methods can now be used to set up remote app authentication or remote session, as needed.

Securing the remote app connection

Because remote app features involve serving requests on new endpoints from the ASP.NET app, it's important that communication to and from the ASP.NET app be secure.

First, make sure that the API key string used to authenticate the ASP.NET Core app with the ASP.NET app is unique and kept secret. It is a best practice to not store the API key in source control. Instead, load it at runtime from a secure source such as Azure Key Vault or other secure runtime configuration. In order to encourage secure API keys, remote app connections require that the keys be non-empty GUIDs (128-bit hex numbers).

Second, because it's important for the ASP.NET Core app to be able to trust that it is requesting information from the correct ASP.NET app, the ASP.NET app should use HTTPS in any production scenarios so that the ASP.NET Core app can know responses are being served by a trusted source.

Usage Guidance

Article • 08/30/2024

`Microsoft.AspNetCore.SystemWebAdapters` provides an emulation layer to mimic behavior from ASP.NET framework on ASP.NET Core. Below are some guidelines for some of the considerations when using them:

`HttpContext` lifetime

The adapters are backed by HttpContext which cannot be used past the lifetime of a request. Thus, HttpContext when run on ASP.NET Core cannot be used past a request as well, while on ASP.NET Framework it would work at times. An ObjectDisposedException will be thrown in cases where it is used past a request end.

Recommendation: Store the values needed into a POCO and hold onto that.

Conversion to HttpContext

There are two ways to convert an HttpContext to a HttpContext:

- Implicit casting
- Constructor usage

Recommendation: For the most cases, implicit casting should be preferred as this will cache the created instance and ensure only a single HttpContext per request.

CurrentCulture is not set by default

In ASP.NET Framework, CurrentCulture was set for a request, but this is not done automatically in ASP.NET Core. Instead, you must add the appropriate middleware to your pipeline.

Recommendation: See ASP.NET Core Localization for details on how to enable this.

Simplest way to enable this with similar behavior as ASP.NET Framework would be to add the following to your pipeline:

C#

```
app.UseRequestLocalization();
```

CurrentPrincipal

In ASP.NET Framework, CurrentPrincipal and Current would be set to the current user. This is not available on ASP.NET Core out of the box. Support for this is available with these adapters by adding the `ISetThreadCurrentPrincipal` to the endpoint (available to controllers via the `SetThreadCurrentPrincipalAttribute`). However, it should only be used if the code cannot be refactored to remove usage.

Recommendation: If possible, use the property User or User instead by passing it through to the call site. If not possible, enable setting the current user and also consider setting the request to be a logical single thread (see below for details).

Request thread does not exist in ASP.NET Core

In ASP.NET Framework, a request had thread-affinity and Current would only be available if on that thread. ASP.NET Core does not have this guarantee so Current will be available within the same async context, but no guarantees about threads are made.

Recommendation: If reading/writing to the HttpContext, you must ensure you are doing so in a single-threaded way. You can force a request to never run concurrently on any async context by setting the `ISingleThreadedRequestMetadata`. This will have performance implications and should only be used if you can't refactor usage to ensure non-concurrent access. There is an implementation available to add to controllers with `SingleThreadedRequestAttribute`:

C#

```
[SingleThreadedRequest]
public class SomeController : Controller
{
    ...
}
```

Request may need to be prebuffered

By default, the incoming request is not always seekable nor fully available. In order to get behavior seen in .NET Framework, you can opt into prebuffering the input stream. This will fully read the incoming stream and buffer it to memory or disk (depending on settings).

Recommendation: This can be enabled by applying endpoint metadata that implements the `IPreBufferRequestStreamMetadata` interface. This is available as an attribute

`PreBufferRequestStreamAttribute` that can be applied to controllers or methods.

To enable this on all MVC endpoints, there is an extension method that can be used as follows:

```cs
app.MapDefaultControllerRoute()
    .PreBufferRequestStream();
```

Response may require buffering

Some APIs on Response require that the output stream is buffered, such as Output, End(), Clear(), and SuppressContent.

Recommendation: In order to support behavior for Response that requires buffering the response before sending, endpoints must opt-into it with endpoint metadata implementing `IBufferResponseStreamMetadata`.

To enable this on all MVC endpoints, there is an extension method that can be used as follows:

```cs
app.MapDefaultControllerRoute()
    .BufferResponseStream();
```

Shared session state

In order to support Session, endpoints must opt-into it via metadata implementing `ISessionMetadata`.

Recommendation: To enable this on all MVC endpoints, there is an extension method that can be used as follows:

```cs
app.MapDefaultControllerRoute()
    .RequireSystemWebAdapterSession();
```

This also requires some implementation of a session store. For details of options here, see here.

Remote session exposes additional endpoint for application

The remote session support exposes an endpoint that allows the core app to retrieve session information. This may cause a potentially long-lived request to exist between the core app and the framework app, but will time out with the current request or the session timeout (by default is 20 minutes).

Recommendation: Ensure the API key used is a strong one and that the connection with the framework app is done over SSL.

Virtual directories must be identical for framework and core applications

The virtual directory setup is used for route generation, authorization, and other services within the system. At this point, no reliable method has been found to enable different virtual directories due to how ASP.NET Framework works.

Recommendation: Ensure your two applications are on different sites (hosts and/or ports) with the same application/virtual directory layout.

Wrapped ASP.NET Core session state

Article • 08/01/2023

This implementation wraps the session provided on ASP.NET Core so that it can be used with the adapters. The session will be using the same backing store as `Microsoft.AspNetCore.Http.ISession` but will provide strongly-typed access to its members.

Configuration for ASP.NET Core would look similar to the following:

C#

```
builder.Services.AddSystemWebAdapters()
    .AddJsonSessionSerializer(options =>
    {
        // Serialization/deserialization requires each session key to be
registered to a type
        options.RegisterKey<int>("test-value");
        options.RegisterKey<SessionDemoModel>("SampleSessionItem");
    })
    .WrapAspNetCoreSession();
```

The framework app would not need any changes to enable this behavior.

ASP.NET to ASP.NET Core incremental session state migration

Article • 08/01/2023

Session State

Session state in ASP.NET Framework provided a number of features that ASP.NET Core does not provide. In order to update from ASP.NET Framework to Core, the adapters provide mechanisms to enable populating session state with similar behavior as `System.Web` did. Some of the differences between framework and core are:

- ASP.NET Framework would lock session usage within a session, so subsequent requests in a session are handled in a serial fashion. This is different than ASP.NET Core that does not provide any of these guarantees.
- ASP.NET Framework would serialize and deserialize objects automatically (unless being done in-memory). ASP.NET Core provides a mechanism to store a `byte[]` given a key. Any object serialization/deserialization has to be done manually by the user.

The adapter infrastructure exposes two interfaces that can be used to implement any session storage system. These are:

- `Microsoft.AspNetCore.SystemWebAdapters.ISessionManager`: This has a single method that gets passed an HttpContext and the session metadata and expects an `ISessionState` object to be returned.
- `Microsoft.AspNetCore.SystemWebAdapters.ISessionState`: This describes the state of a session object. It is used as the backing of the HttpSessionState type.

Serialization

Since the adapters provide the ability to work with strongly-typed session state, we must be able to serialize and deserialize types. This is customized through the `Microsoft.AspNetCore.SystemWebAdapters.SessionState.Serialization.ISessionKeySerializer`.

A default JSON implementation is provided that is configured via the `JsonSessionSerializerOptions`:

- `RegisterKey<T>(string)` - Registers a session key to a known type. This is required in order to serialize/deserialize the session state correctly. If a key is found that there is no registration for, an error will be thrown and session will not be available.

C#

```
builder.Services.AddSystemWebAdapters()
    .AddJsonSessionSerializer(options =>
    {
        // Serialization/deserialization requires each session key to be
registered to a type
        options.RegisterKey<int>("test-value");
    });
```

Implementations

There are two available implementations of the session state object that currently ship, each with some trade offs of features. The best choice for an app may depend on which part of the migration it is in, and may change over time.

- Strongly typed: Provides the ability to access an object and can be cast to the expected type
- Locking: Ensures multiple requests within a single session are queued up and aren't accessing the session at the same time
- Standalone: Use when you're not sharing session between ASP.NET Framework and ASP.NET Core to avoid modifying code in class libraries that references SessionState

Below are the available implementations:

Expand table

Implementation	Strongly typed	Locking	Standalone
Remote app	✔	✔	⛔
Wrapped ASP.NET Core	✔	⛔	✔

ASP.NET to ASP.NET Core incremental IHttpModule migration

Article • 03/23/2024

Modules are types that implement IHttpModule and are used in ASP.NET Framework to hook into the request pipeline at various events. In an ASP.NET Core application, these should ideally be migrated to middleware. However, there are times when this cannot be done. In order to support migration scenarios in which modules are required and cannot be moved to middleware, System.Web adapters support adding them to ASP.NET Core.

IHttpModule Example

In order to support modules, an instance of HttpApplication must be available. If no custom HttpApplication is used, a default one will be used to add the modules to. Events declared in a custom application (including `Application_Start`) will be registered and run accordingly.

C#

```
using System.Web;
using Microsoft.AspNetCore.OutputCaching;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddSystemWebAdapters()
    .AddHttpApplication<MyApp>(options =>
    {
        // Size of pool for HttpApplication instances. Should be what the
expected concurrent requests will be
        options.PoolSize = 10;

        // Register a module (optionally) by name
        options.RegisterModule<MyModule>("MyModule");
    });

// Only available in .NET 7+
builder.Services.AddOutputCache(options =>
{
    options.AddHttpApplicationBasePolicy(_ => new[] { "browser" });
});

builder.Services.AddAuthentication();
builder.Services.AddAuthorization();

var app = builder.Build();
```

```
app.UseAuthentication();
app.UseAuthenticationEvents();

app.UseAuthorization();
app.UseAuthorizationEvents();

app.UseSystemWebAdapters();
app.UseOutputCache();

app.MapGet("/", () => "Hello World!")
    .CacheOutput();

app.Run();

class MyApp : HttpApplication
{
    protected void Application_Start()
    {
    }

    public override string? GetVaryByCustomString(System.Web.HttpContext
context, string custom)
    {
        // Any custom vary-by string needed

        return base.GetVaryByCustomString(context, custom);
    }
}

class MyModule : IHttpModule
{
    public void Init(HttpApplication application)
    {
        application.BeginRequest += (s, e) =>
        {
            // Handle events at the beginning of a request
        };

        application.AuthorizeRequest += (s, e) =>
        {
            // Handle events that need to be authorized
        };
    }

    public void Dispose()
    {
    }
}
```

Global.asax migration

This infrastructure can be used to migrate usage of `Global.asax` if needed. The source from `Global.asax` is a custom HttpApplication and the file can be included in an ASP.NET Core application. Since it is named `Global`, the following code can be used to register it:

```
C#

builder.Services.AddSystemWebAdapters()
    .AddHttpApplication<Global>();
```

As long as the logic within it is available in ASP.NET Core, this approach can be used to incrementally migrate reliance on `Global.asax` to ASP.NET Core.

Authentication/Authorization events

In order for the authentication and authorization events to run at the desired time, the following pattern should be used:

```
C#

app.UseAuthentication();
app.UseAuthenticationEvents();

app.UseAuthorization();
app.UseAuthorizationEvents();
```

If this is not done, the events will still run. However, it will be during the call of `.UseSystemWebAdapters()`.

HTTP Module pooling

Because modules and applications in ASP.NET Framework were assigned to a request, a new instance is needed for each request. However, since they can be expensive to create, they are pooled using ObjectPool<T>. In order to customize the actual lifetime of the HttpApplication instances, a custom pool can be used:

```
C#

builder.Services.TryAddSingleton<ObjectPool<HttpApplication>>(sp =>
{
    // Recommended to use the in-built policy as that will ensure everything
is initialized correctly and is not intended to be replaced
    var policy = sp.GetRequiredService<IPooledObjectPolicy<HttpApplication>>
();
```

```
    // Can use any provider needed
    var provider = new DefaultObjectPoolProvider();

    // Use the provider to create a custom pool that will then be used for
the application.
    return provider.Create(policy);
});
```

Remote app session state

Article • 08/01/2023

Remote app session state will enable communication between the ASP.NET Core and ASP.NET app to retrieve the session state. This is enabled by exposing an endpoint on the ASP.NET app that can be queried to retrieve and set the session state.

HttpSessionState serialization

The HttpSessionState object must be serialized for remote app session state to be enabled. This is accomplished through implementation of the type `Microsoft.AspNetCore.SystemWebAdapters.SessionState.Serialization.ISessionSerializer`, of which a default binary writer implementation is provided. This is added by the following code:

C#

```
builder.Services.AddSystemWebAdapters()
    .AddSessionSerializer(options =>
    {
        // Customize session serialization here
    });
```

Configuration

First, follow the remote app setup instructions to connect the ASP.NET Core and ASP.NET apps. Then, there are just a couple extra extension methods to call to enable remote app session state.

Configuration for ASP.NET Core involves calling `AddRemoteAppSession` and `AddJsonSessionSerializer` to register known session item types. The code should look similar to the following:

C#

```
builder.Services.AddSystemWebAdapters()
    .AddJsonSessionSerializer(options =>
    {
        // Serialization/deserialization requires each session key to be
registered to a type
        options.RegisterKey<int>("test-value");
        options.RegisterKey<SessionDemoModel>("SampleSessionItem");
```

```
    })
    .AddRemoteAppClient(options =>
    {
        // Provide the URL for the remote app that has enabled session
querying
        options.RemoteAppUrl =
new(builder.Configuration["ReverseProxy:Clusters:fallbackCluster:Destination
s:fallbackApp:Address"]);

        // Provide a strong API key that will be used to authenticate the
request on the remote app for querying the session
        options.ApiKey = builder.Configuration["RemoteAppApiKey"];
    })
    .AddSessionClient();
```

Session support requires additional work for the ASP.NET Core pipeline, and is not turned on by default. It can be configured on a per-route basis via ASP.NET Core metadata.

For example, session support requires either to annotate a controller:

C#

```
[Session]
public class SomeController : Controller
{
}
```

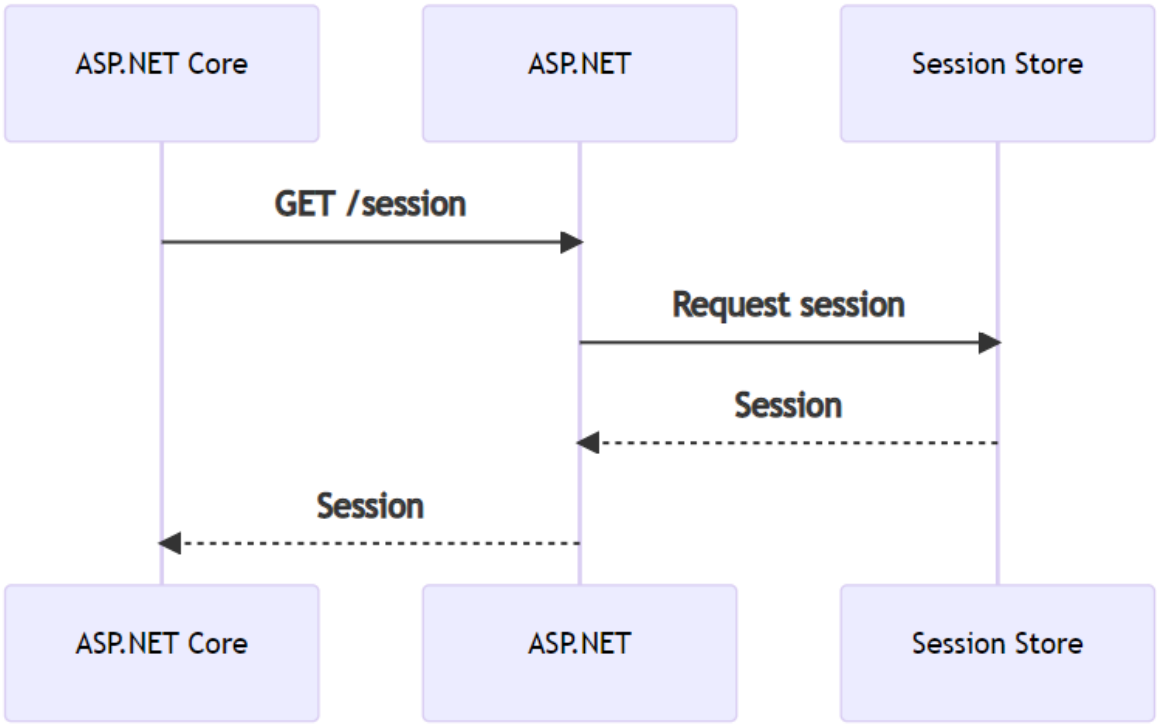
or to enable for all endpoints by default:

C#

```
app.MapDefaultControllerRoute()
    .RequireSystemWebAdapterSession();
```

The framework equivalent would look like the following change in `Global.asax.cs`:

C#

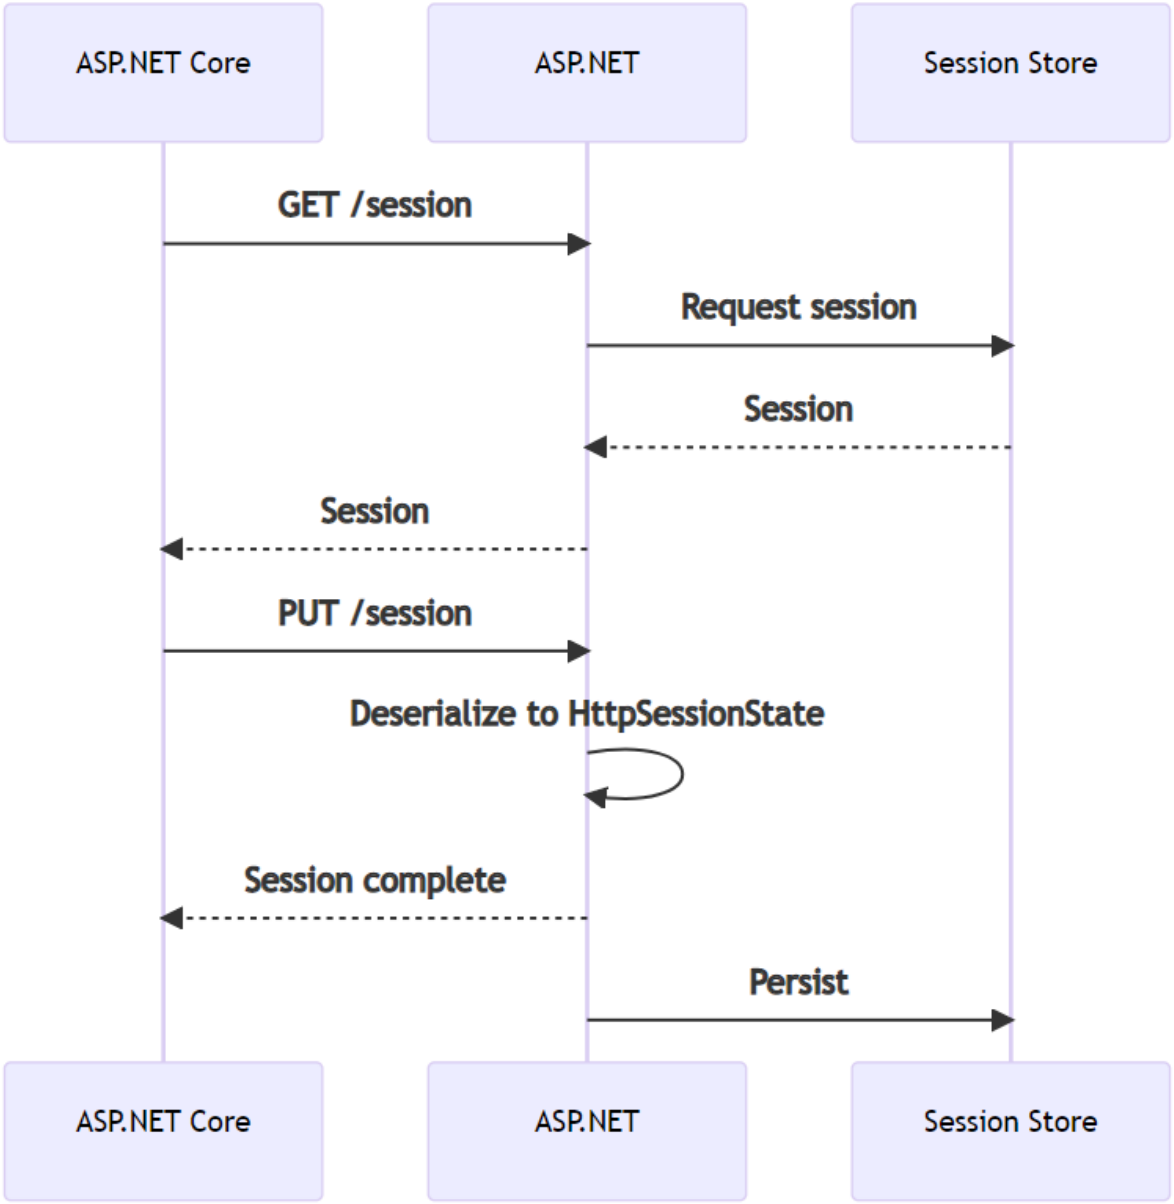


```
SystemWebAdapterConfiguration.AddSystemWebAdapters(this)
    .AddJsonSessionSerializer(options =>
    {
        // Serialization/deserialization requires each session key to be
registered to a type
        options.RegisterKey<int>("test-value");
        options.RegisterKey<SessionDemoModel>("SampleSessionItem");
    })
    // Provide a strong API key that will be used to authenticate the
request on the remote app for querying the session
```

```
    // ApiKey is a string representing a GUID
    .AddRemoteAppServer(options => options.ApiKey =
ConfigurationManager.AppSettings["RemoteAppApiKey"])
    .AddSessionServer();
```

Protocol

Readonly



Readonly session will retrieve the session state from the framework app without any sort of locking. This consists of a single `GET` request that will return a session state and can be closed immediately.

Writeable

Writeable session state protocol starts with the same as the readonly, but differs in the following:

- Requires an additional `PUT` request to update the state
- The initial `GET` request must be kept open until the session is done; if closed, the session will not be able to be updated

Remote Authentication

Article • 08/05/2023

The System.Web adapters' remote authentication feature allows an ASP.NET Core app to determine a user's identity (authenticate an HTTP request) by deferring to an ASP.NET app. Enabling the feature adds an endpoint to the ASP.NET app that returns a serialized ClaimsPrincipal representing the authenticated user for any requests made to the endpoint. The ASP.NET Core app, then, registers a custom authentication handler that will (for endpoints with remote authentication enabled) determine a user's identity by calling that endpoint on the ASP.NET app and passing selected headers and cookies from the original request received by the ASP.NET Core app.

Configuration

There are just a few small code changes needed to enable remote authentication in a solution that's already set up according to the Getting Started.

First, follow the remote app setup instructions to connect the ASP.NET Core and ASP.NET apps. Then, there are just a couple extra extension methods to call to enable remote app authentication.

ASP.NET app configuration

The ASP.NET app needs to be configured to add the authentication endpoint. Adding the authentication endpoint is done by calling the `AddAuthenticationServer` extension method to set up the HTTP module that watches for requests to the authentication endpoint. Note that remote authentication scenarios typically want to add proxy support as well, so that any authentication related redirects correctly route to the ASP.NET Core app rather than the ASP.NET one.

C#

```
SystemWebAdapterConfiguration.AddSystemWebAdapters(this)
    .AddProxySupport(options => options.UseForwardedHeaders = true)
    .AddRemoteAppServer(options =>
    {
        options.ApiKey =
ConfigurationManager.AppSettings["RemoteAppApiKey"];
    })
    .AddAuthenticationServer();
```

ASP.NET Core app configuration

Next, the ASP.NET Core app needs to be configured to enable the authentication handler that will authenticate users by making an HTTP request to the ASP.NET app. Again, this is done by calling `AddAuthenticationClient` when registering System.Web adapters services:

C#

```
builder.Services.AddSystemWebAdapters()
    .AddRemoteAppClient(options =>
    {
        options.RemoteAppUrl = new Uri(builder.Configuration

["ReverseProxy:Clusters:fallbackCluster:Destinations:fallbackApp:Address"]);
        options.ApiKey = builder.Configuration["RemoteAppApiKey"];
    })
    .AddAuthenticationClient(true);
```

The boolean that is passed to the `AddAuthenticationClient` call specifies whether remote app authentication should be the default authentication scheme. Passing `true` will cause the user to be authenticated via remote app authentication for all requests, whereas passing `false` means that the user will only be authenticated with remote app authentication if the remote app scheme is specifically requested (with `[Authorize(AuthenticationSchemes = RemoteAppAuthenticationDefaults.AuthenticationScheme)]` on a controller or action method, for example). Passing false for this parameter has the advantage of only making HTTP requests to the original ASP.NET app for authentication for endpoints that require remote app authentication but has the disadvantage of requiring annotating all such endpoints to indicate that they will use remote app auth.

In addition to the require boolean, an optional callback may be passed to `AddAuthenticationClient` to modify some other aspects of the remote authentication process's behavior:

- `RequestHeadersToForward`: This property contains headers that should be forwarded from a request when calling the authenticate API. By default, the only headers forwarded are `Authorization` and `Cookie`. Additional headers can be forwarded by adding them to this list. Alternatively, if the list is cleared (so that no headers are specified), then all headers will be forwarded.
- `ResponseHeadersToForward`: This property lists response headers that should be propagated back from the authenticate request to the original call that prompted

authentication in scenarios where identity is challenged. By default, this includes `Location`, `Set-Cookie`, and `WWW-Authenticate` headers.

- `AuthenticationEndpointPath`: The endpoint on the ASP.NET app where authenticate requests should be made. This defaults to `/systemweb-adapters/authenticate` and must match the endpoint specified in the ASP.NET authentication endpoint configuration.

Finally, if the ASP.NET Core app didn't previously include authentication middleware, that will need to be enabled (after routing middleware, but before authorization middleware):

```
C#

app.UseAuthentication();
```

Design

1. When requests are processed by the ASP.NET Core app, if remote app authentication is the default scheme or specified by the request's endpoint, the `RemoteAuthenticationAuthHandler` will attempt to authenticate the user.
   a. The handler will make an HTTP request to the ASP.NET app's authenticate endpoint. It will copy configured headers from the current request onto this new one in order to forward auth-relevant data. As mentioned above, default behavior is to copy the `Authorize` and `Cookie` headers. The API key header is also added for security purposes.
2. The ASP.NET app will serve requests sent to the authenticate endpoint. As long as the API keys match, the ASP.NET app will return either the current user's ClaimsPrincipal serialized into the response body or it will return an HTTP status code (like 401 or 302) and response headers indicating failure.
3. When the ASP.NET Core app's `RemoteAuthenticationAuthHandler` receives the response from the ASP.NET app:
   a. If a ClaimsPrincipal was successfully returned, the auth handler will deserialize it and use it as the current user's identity.
   b. If a ClaimsPrincipal was not successfully returned, the handler will store the result and if authentication is challenged (because the user is accessing a protected resource, for example), the request's response will be updated with the status code and selected response headers from the response from the authenticate endpoint. This enables challenge responses (like redirects to a login page) to be propagated to end users.

i. Because results from the ASP.NET app's authenticate endpoint may include data specific to that endpoint, users can register `IRemoteAuthenticationResultProcessor` implementations with the ASP.NET Core app which will run on any authentication results before they are used. As an example, the one built-in `IRemoteAuthenticationResultProcessor` is `RedirectUrlProcessor` which looks for `Location` response headers returned from the authenticate endpoint and ensures that they redirect back to the host of the ASP.NET Core app and not the ASP.NET app directly.

Known limitations

This remote authentication approach has a couple known limitations:

1. Because Windows authentication depends on a handle to a Windows identity, Windows authentication is not supported by this feature. Future work is planned to explore how shared Windows authentication might work. See dotnet/systemweb-adapters#246 for more information.
2. This feature allows the ASP.NET Core app to make use of an identity authenticated by the ASP.NET app, but all actions related to users (logging on, logging off, etc.) still need to be routed through the ASP.NET app.

Alternatives

If authentication in the ASP.NET app is done using `Microsoft.Owin` Cookie Authentication Middleware, an alternative solution to sharing identity is to configure the ASP.NET and ASP.NET Core apps so that they are able to share an authentication cookie. Sharing an authentication cookie enables:

- Both apps to determine the user identity from the same cookie.
- Signing in or out of one app signs the user in or out of the other app.

Note that because signing in typically depends on a specific database, not all authentication functionality will work in both apps:

- Users should sign in through only one of the apps, either the ASP.NET or ASP.NET Core app, whichever the database is setup to work with.
- Both apps are able to see the users' identity and claims.
- Both apps are able to sign the user out.

Details on how to configure sharing auth cookies between ASP.NET and ASP.NET Core apps are available in cookie sharing documentation. The following samples in the

System.Web adapters GitHub repo demonstrates remote app authentication with shared cookie configuration enabling both apps to sign users in and out :

- ASP.NET app
- ASP.NET Core app

Sharing authentication is a good option if both the following are true:

- The ASP.NET app is already using `Microsoft.Owin` cookie authentication.
- It's possible to update the ASP.NET app and ASP.NET Core apps to use matching data protection settings. Matching shared data protection settings includes a shared file path, Redis cache, or Azure Blob Storage for storing data protection keys.

For other scenarios, the remote authentication approach described previously in this doc is more flexible and is probably a better fit.

Unit Testing

Article • 10/04/2023

In most cases, there's no need to set up additional components for running tests. But if the component being tested uses HttpRuntime, it might be necessary to start up the `SystemWebAdapters` service, as shown in the following example:

C#

```
namespace TestProject1;

/// <summary>
/// This demonstrates an xUnit feature that ensures all tests
/// in classes marked with this collection are run sequentially.
/// </summary>
[CollectionDefinition(nameof(SystemWebAdaptersHostedTests),
    DisableParallelization = true)]
public class SystemWebAdaptersHostedTests
{
}
[Collection(nameof(SystemWebAdaptersHostedTests))]
public class RuntimeTests
{
    /// <summary>
    /// This method starts up a host in the background that
    /// makes it possible to initialize <see cref="HttpRuntime"/>
    /// and <see cref="HostingEnvironment"/> with values needed
    /// for testing with the <paramref name="configure"/> option.
    /// </summary>
    /// <param name="configure">
    /// Configuration for the hosting and runtime options.
    /// </param>
    public static async Task<IDisposable> EnableRuntimeAsync(
        Action<SystemWebAdaptersOptions>? configure = null,
        CancellationToken token = default)
        => await new HostBuilder()
           .ConfigureWebHost(webBuilder =>
           {
               webBuilder
                   .UseTestServer()
                   .ConfigureServices(services =>
                   {
                       services.AddSystemWebAdapters();
                       if (configure is not null)
                       {
                           services.AddOptions
                               <SystemWebAdaptersOptions>()
                               .Configure(configure);
                       }
                   })
                   .Configure(app =>
```

```
                    {
                        // No need to configure pipeline for tests
                    });
            })
            .StartAsync(token);
    [Fact]
    public async Task RuntimeEnabled()
    {
        using (await EnableRuntimeAsync(options =>
            options.AppDomainAppPath = "path"))
        {
            Assert.True(HostingEnvironment.IsHosted);
            Assert.Equal("path", HttpRuntime.AppDomainAppPath);
        }
        Assert.False(HostingEnvironment.IsHosted);
    }
}
```

The tests must be executed in sequence, not in parallel. The preceding example illustrates how to achieve this by setting XUnit's DisableParallelization option to `true`. This setting disables parallel execution for a specific test collection, ensuring that the tests within that collection run one after the other, without concurrency.

A/B Testing endpoints during migration

Article • 03/04/2023

During incremental migration, new endpoints are brought over to a YARP enabled ASP.NET Core app. With the default setup, these endpoints are automatically served for all requests once deployed. In order to test these endpoints, or be able to turn them off if needed, additional setup is needed.

This document describes how to setup a conditional endpoint selection system to enable A/B testing during incremental migration. It assumes a setup as described in incremental migration overview as a starting point.

Conditional endpoint selection

To enable conditional endpoint selection, a few services need to be defined:

1. Metadata that can be added to an endpoint to turn on any conditional related logic. Endpoints include controllers, minimal APIs, Razor Page, etc. If this metadata isn't added to an endpoint, no conditional checks are performed for it.

   CSharp

   ```
   [AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
   public sealed class ConditionalRouteAttribute : Attribute
   {
       public bool IsConditional { get; set; } = true;
   }
   ```

   The property `IsConditional` is useful to set it `true` at a global level, and then allow lower levels, such as controllers or routes, to turn off the conditional checks.

2. The API we want to implement to make a decision per request and endpoint selection:

   CSharp

   ```
   public interface IConditionalEndpointSelector
   {
       ValueTask<bool> IsEnabledAsync(HttpContext context, Endpoint
   candidate);
   }
   ```

3. A `MatcherPolicy` that is used to hook into routing and call the custom selector:

CSharp

```
public static class ConditionalEndpointExtensions
{
    /// <summary>
    /// Registers a <see cref="IConditionalEndpointSelector"/> that is
called when selecting
    /// an endpoint that has been marked as conditional by <see
cref="WithConditionalRoute{TBuilder}(TBuilder)"/>.
    /// </summary>
    /// <typeparam name="T">Type of selector</typeparam>
    /// <param name="services">Service collection to add to.</param>
    public static void AddConditionalEndpoints<T>(this
IServiceCollection services)
        where T : class, IConditionalEndpointSelector
    {
        services.AddTransient<IConditionalEndpointSelector, T>();

services.TryAddEnumerable(ServiceDescriptor.Singleton<MatcherPolicy,
ConditionalEndpointMatcherPolicy>());
    }

    /// <summary>
    /// Enable conditional behavior for supplied endpoints. An
implementation of <see cref="IConditionalEndpointSelector"/> must be
registered as a service for this to be enabled at runtime.
    /// </summary>
    /// <param name="builder">The endpoint convention builder</param>
    /// <returns>The original convention builder.</returns>
    public static TBuilder WithConditionalRoute<TBuilder>(this TBuilder
builder)
        where TBuilder : IEndpointConventionBuilder
    {
        ArgumentNullException.ThrowIfNull(builder);

        return builder.WithMetadata(new ConditionalRouteAttribute());
    }

    private sealed class ConditionalEndpointMatcherPolicy :
MatcherPolicy, IEndpointSelectorPolicy
    {
        private readonly IConditionalEndpointSelector _selector;

        public
ConditionalEndpointMatcherPolicy(IConditionalEndpointSelector selector)
        {
            _selector = selector;
        }

        public override int Order => 0;

        public bool AppliesToEndpoints(IReadOnlyList<Endpoint>
endpoints)
            => endpoints.Any(e =>
```

```
e.Metadata.GetMetadata<ConditionalRouteAttribute>() is { IsConditional:
true });

        public async Task ApplyAsync(HttpContext httpContext,
CandidateSet candidates)
        {
            for (int i = 0; i < candidates.Count; i++)
            {
                var endpoint = candidates[i].Endpoint;

                if
(endpoint.Metadata.GetMetadata<ConditionalRouteAttribute>() is {
IsConditional: true })
                {
                    if (await _selector.IsEnabledAsync(httpContext,
endpoint) == false)
                    {
                        candidates.SetValidity(i, false);
                    }
                }
            }
        }
    }
}
```

4. Implement a custom selector. As an example, this defines a check for the presence of a query parameter (`IgnoreLocal`) that turns off the local endpoint and uses the YARP endpoint instead.

CSharp

```
public class QueryConditionalSelector : IConditionalEndpointSelector
{
    public ValueTask<bool> IsEnabledAsync(HttpContext context, Endpoint
candidate)
    {
        var result = context.Request.Query.TryGetValue("IgnoreLocal",
out var values) &&
            values is { Count: 1 } &&
            bool.TryParse(values[0], out var skip)
            && skip;

        return ValueTask.FromResult(result);
    }
```

5. Register the services in the program startup and mark the controllers for conditional selection. This marking can also be done using attribute marking on controllers or routes if needed.

diff

```
using Microsoft.AspNetCore.SystemWebAdapters;

var builder = WebApplication.CreateBuilder();
builder.Services.AddReverseProxy().LoadFromConfig(builder.Configuration
.GetSection("ReverseProxy"));

// Add services to the container.
builder.Services.AddControllersWithViews();
builder.Services.AddSystemWebAdapters();
+ builder.Services.AddConditionalEndpoint<QueryConditionalSelector>();

var app = builder.Build();

app.UseSystemWebAdapters();

- app.MapDefaultControllerRoute();
+ app.MapDefaultControllerRoute().WithConditionalRoute();
app.MapReverseProxy();

app.Run();
```

Upgrade from ASP.NET MVC and Web API to ASP.NET Core MVC

Article • 07/18/2023

This article shows how to upgrade an ASP.NET Framework MVC or Web API app to ASP.NET Core MVC using the Visual Studio .NET Upgrade Assistant and the incremental update approach.

Upgrade using the .NET Upgrade Assistant

If your .NET Framework project has supporting libraries in the solution that are required, they should be upgraded to .NET Standard 2.0, if possible. For more information, see Upgrade supporting libraries.

1. Install the .NET Upgrade Assistant Visual Studio extension.
2. Open the ASP.NET MVC or Web API solution in Visual Studio.
3. In **Solution Explorer**, right click on the project to upgrade and select **Upgrade**. Select **Side-by-side incremental project upgrade**, which is the only upgrade option.
4. For the upgrade target, select **New project**.
5. Name the project and select the template. If the project you're migrating is a API project, select **ASP.NET Core Web API**. If it's an MVC project or MVC and Web API, select **ASP.NET Core MVC**.
6. Select **Next**
7. Select the target framework version and then select **Next**. For more information, see .NET and .NET Core Support Policy.
8. Review the **Summary of changes**, then select **Finish**.
9. The **Summary** step displays `<Framework Project>` **is now connected to** `<Framework ProjectCore>` **via Yarp proxy.** and a pie chart showing the migrated endpoints. Select **Upgrade Controller** and then select a controller to upgrade.
10. Select the component to upgrade, then select **Upgrade selection**.

Incremental update

Follow the steps in Get started with incremental ASP.NET to ASP.NET Core migration to continue the update process.

Upgrade an ASP.NET Framework Web Forms app to ASP.NET Core MVC

Article • 05/23/2023

This article shows how to upgrade an ASP.NET Framework Web Forms to ASP.NET Core MVC using the Visual Studio .NET Upgrade Assistant and the incremental update approach.

If your .NET Framework project has supporting libraries in its solution that are required, they should be upgraded to .NET Standard 2.0, if possible. For more information, see Upgrade supporting libraries.

1. Install the .NET Upgrade Assistant Visual Studio extension.
2. Open the ASP.NET Web Forms solution in Visual Studio.
3. In **Solution Explorer**, right click on the project to upgrade and select **Upgrade**. Select **Side-by-side incremental project upgrade**, which is the only upgrade option.
4. For the upgrade target, select **New project**.
5. Name the project and select the **ASP.NET Core** template and then select **Next**
6. Select the target framework version and then select **Next**. For more information, see .NET and .NET Core Support Policy.
7. Select **Done**, then select **Finish**.
8. The **Summary** step displays **`<Framework Project>` is now connected to `<Framework ProjectCore>` via Yarp proxy.**.
9. Select the component to upgrade, then select **Upgrade selection**.

Incremental update

Follow the steps in Get started with incremental ASP.NET to ASP.NET Core migration to continue the update process.

Migrate from ASP.NET Web API to ASP.NET Core

Article • 06/18/2024

ASP.NET Core combines ASP.NET 4.x's MVC and Web API app models into a single programming model known as ASP.NET Core MVC.

This article shows how to migrate the Products controller created in Getting Started with ASP.NET Web API 2 to ASP.NET Core.

Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.
- .NET 6.0 SDK

Create the new ASP.NET Core Web API project

Visual Studio

1. From the **File** menu, select **New** > **Project**.
2. Enter *Web API* in the search box.
3. Select the **ASP.NET Core Web API** template and select **Next**.
4. In the **Configure your new project** dialog, name the project *ProductsCore* and select **Next**.
5. In the **Additional information** dialog:
   a. Confirm the **Framework** is **.NET 6.0 (Long-term support)**.
   b. Confirm the checkbox for **Use controllers(uncheck to use minimal APIs)** is checked.
   c. Uncheck **Enable OpenAPI support**.
   d. Select **Create**.

Remove the *WeatherForecast* template files

1. Remove the `WeatherForecast.cs` and `Controllers/WeatherForecastController.cs` example files from the new *ProductsCore* project.
2. Open *Properties\launchSettings.json*.
3. Change `launchUrl` properties from `weatherforcast` to `productscore`.

The configuration for ASP.NET Core Web API

ASP.NET Core doesn't use the *App_Start* folder or the *Global.asax* file. The *web.config* file is added at publish time. For more information, see web.config file.

The `Program.cs` file:

- Replaces *Global.asax*.
- Handles all app startup tasks.

For more information, see App startup in ASP.NET Core.

The following shows the application startup code in the ASP.NET Core `Program.cs` file:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.

builder.Services.AddControllers();

var app = builder.Build();

// Configure the HTTP request pipeline.

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

Copy the *Product* model

Visual Studio

1. In **Solution Explorer**, right-click the project. Select **Add** > **New Folder**. Name the folder *Models*.

2. Right-click the **Models** folder. Select **Add** > **Class**. Name the class *Product* and select **Add**.
3. Replace the template model code with the following:

C#

```
namespace ProductsCore.Models
{
    public class Product
    {
        public int Id { get; set; }
        public string? Name { get; set; }
        public string? Category { get; set; }
        public decimal Price { get; set; }
    }
}
```

The preceding highlighted code changes the following:

- The `?` annotation has been added to declare the `Name` and `Category` properties as nullable reference types.

By utilizing the Nullable feature introduced in C# 8, ASP.NET Core can provide additional code flow analysis and compile-time safety in the handling of reference types. For example, protecting against `null` reference exceptions.

In this case, the intent is that the `Name` and `Category` can be nullable types.

ASP.NET Core 6.0 projects enable nullable reference types by default. For more information, see Nullable reference types.

Copy the *ProductsController*

Visual Studio

1. Right-click the **Controllers** folder.
2. Select **Add** > **Controller...**.
3. In **Add New Scaffolded Item** dialog, select **Mvc Controller - Empty** then select **Add**.
4. Name the controller *ProductsController* and select **Add**.
5. Replace the template controller code with the following:

C#

```
using Microsoft.AspNetCore.Mvc;
using ProductsCore.Models;

namespace ProductsCore.Controllers;

[Route("api/[controller]")]
[ApiController]
public class ProductsController : ControllerBase
{
    Product[] products = new Product[]
    {
            new Product
            {
                Id = 1, Name = "Tomato Soup", Category = "Groceries", Price
= 1
            },
            new Product
            {
                Id = 2, Name = "Yo-yo", Category = "Toys", Price = 3.75M
            },
            new Product
            {
                Id = 3, Name = "Hammer", Category = "Hardware", Price =
16.99M
            }
    };

    [HttpGet]
    public IEnumerable<Product> GetAllProducts()
    {
        return products;
    }

    [HttpGet("{id}")]
    public ActionResult<Product> GetProduct(int id)
    {
        var product = products.FirstOrDefault((p) => p.Id == id);
        if (product == null)
        {
            return NotFound();
        }
        return product;
    }
}
```

The preceding highlighted code changes the following, to migrate to ASP.NET Core:

- Removes using statements for the following ASP.NET 4.x components that don't exist in ASP.NET Core:
  - `ApiController` class

    - `System.Web.Http` namespace
    - `IHttpActionResult` interface
- Changes the `using ProductsApp.Models;` statement to `using ProductsCore.Models;`.
- Sets the root namespace to `ProductsCore`.
- Changes `ApiController` to ControllerBase.
- Adds `using Microsoft.AspNetCore.Mvc;` to resolve the `ControllerBase` reference.
- Changes the `GetProduct` action's return type from `IHttpActionResult` to `ActionResult<Product>`. For more info, see Controller action return types.
- Simplifies the `GetProduct` action's `return` statement to the following statement:

```
C#

return product;
```

- Adds the following attributes which are explained in the next sections:
    - `[Route("api/[controller]")]`
    - `[ApiController]`
    - `[HttpGet]`
    - `[HttpGet("{id}")]`

Routing

ASP.NET Core provides a minimal hosting model in which the endpoint routing middleware wraps the entire middleware pipeline, therefore routes can be added directly to the WebApplication without an explicit call to UseEndpoints or UseRouting to register routes.

`UseRouting` can still be used to specify where route matching happens, but `UseRouting` doesn't need to be explicitly called if routes should be matched at the beginning of the middleware pipeline.

```
C#

var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
```

```
builder.Services.AddControllers();

var app = builder.Build();

// Configure the HTTP request pipeline.

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

Note: Routes added directly to the WebApplication execute at the ***end*** of the pipeline.

Routing in the migrated `ProductsController`

The migrated `ProductsController` contains the following highlighted attributes:

C#

```
using Microsoft.AspNetCore.Mvc;
using ProductsCore.Models;

namespace ProductsCore.Controllers;

[Route("api/[controller]")]
[ApiController]
public class ProductsController : ControllerBase
{
    Product[] products = new Product[]
    {
            new Product
            {
                Id = 1, Name = "Tomato Soup", Category = "Groceries", Price
= 1
            },
            new Product
            {
                Id = 2, Name = "Yo-yo", Category = "Toys", Price = 3.75M
            },
            new Product
            {
                Id = 3, Name = "Hammer", Category = "Hardware", Price =
16.99M
            }
    };

    [HttpGet]
    public IEnumerable<Product> GetAllProducts()
```

```
    {
        return products;
    }

    [HttpGet("{id}")]
    public ActionResult<Product> GetProduct(int id)
    {
        var product = products.FirstOrDefault((p) => p.Id == id);
        if (product == null)
        {
            return NotFound();
        }
        return product;
    }
}
```

- The [Route] attribute configures the controller's attribute routing pattern.
- The [ApiController] attribute makes attribute routing a requirement for all actions in this controller.
- Attribute routing supports tokens, such as `[controller]` and `[action]`. At runtime, each token is replaced with the name of the controller or action, respectively, to which the attribute has been applied. The tokens:
  - Reduces or eliminates the need to use hard coded strings for the route.
  - Ensure routes remain synchronized with the corresponding controllers and actions when automatic rename refactorings are applied.
- HTTP Get requests are enabled for `ProductController` actions with the following attributes:
  - [HttpGet] attribute applied to the `GetAllProducts` action.
  - `[HttpGet("{id}")]` attribute applied to the `GetProduct` action.

Run the migrated project, and browse to `/api/products`. For example: https://localhost:`<port>`/api/products. A full list of three products appears. Browse to `/api/products/1`. The first product appears.

Migrate configuration to ASP.NET Core

Article • 10/04/2024

In the previous article, we began to migrate an ASP.NET MVC project to ASP.NET Core MVC. In this article, we migrate configuration.

View or download sample code (how to download)

Setup configuration

ASP.NET Core no longer uses the *Global.asax* and *web.config* files that previous versions of ASP.NET utilized. In the earlier versions of ASP.NET, application startup logic was placed in an `Application_StartUp` method within *Global.asax*. Later, in ASP.NET MVC, a `Startup.cs` file was included in the root of the project; and, it was called when the application started. ASP.NET Core has adopted this approach completely by placing all startup logic in the `Startup.cs` file.

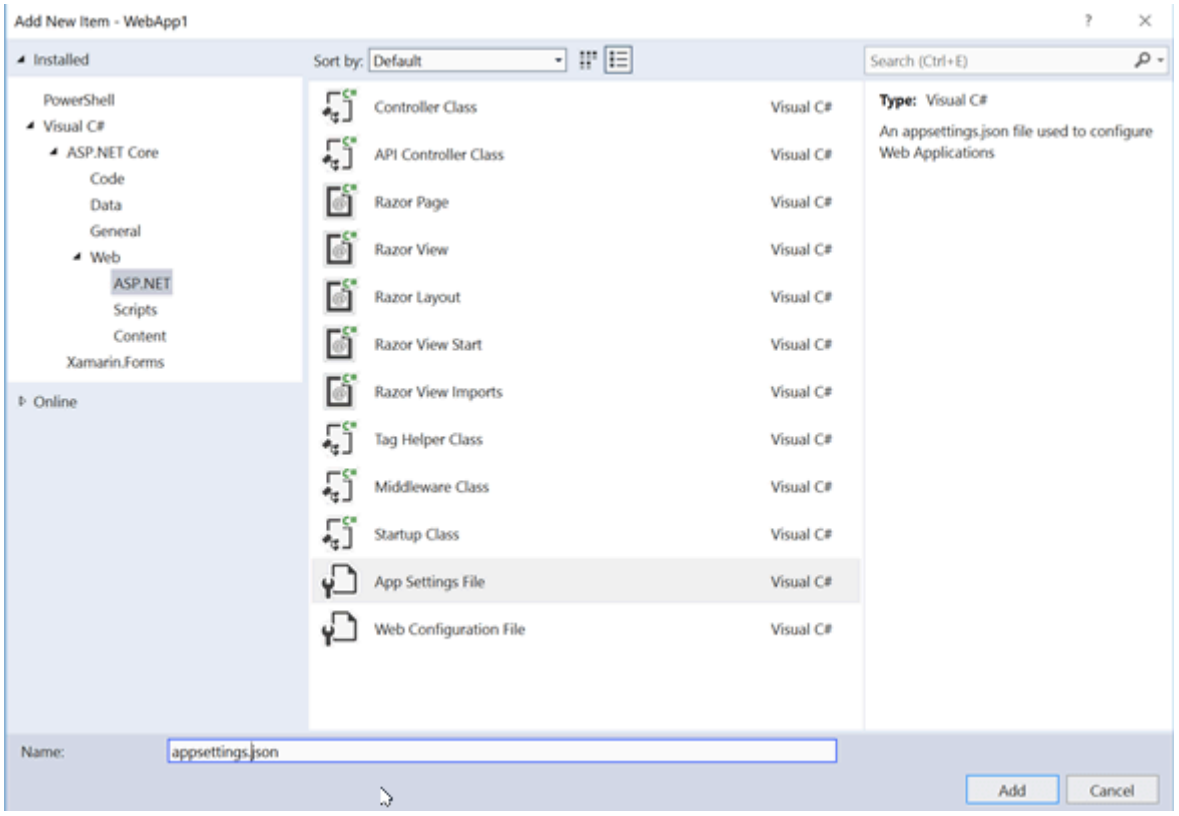
The *web.config* file has also been replaced in ASP.NET Core. Configuration itself can now be configured, as part of the application startup procedure described in `Startup.cs`. Configuration can still utilize XML files, but typically ASP.NET Core projects will place configuration values in a JSON-formatted file, such as `appsettings.json`. ASP.NET Core's configuration system can also easily access environment variables, which can provide a more secure and robust location for environment-specific values. This is especially true for secrets like connection strings and API keys that shouldn't be checked into source control. See Configuration to learn more about configuration in ASP.NET Core.

> ⚠ **Warning**
>
> This article uses a local database that doesn't require the user to be authenticated. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production apps, see Secure authentication flows.

For this article, we are starting with the partially migrated ASP.NET Core project from the previous article. To setup configuration, add the following constructor and property to the `Startup.cs` file located in the root of the project:

```
C#
```

```
public Startup(IConfiguration configuration)
{
    Configuration = configuration;
}



public IConfiguration Configuration { get; }
```

Note that at this point, the `Startup.cs` file won't compile, as we still need to add the following `using` statement:

C#

```
using Microsoft.Extensions.Configuration;
```

Add an `appsettings.json` file to the root of the project using the appropriate item template:

Migrate configuration settings from web.config

Our ASP.NET MVC project included the required database connection string in *web.config*, in the `<connectionStrings>` element. In our ASP.NET Core project, we are going to store this information in the `appsettings.json` file. Open `appsettings.json`, and note that it already includes the following:

```
```

JSON

```
{
    "Data": {
        "DefaultConnection": {
            "ConnectionString": "Server=
(localdb)\\MSSQLLocalDB;Database=_CHANGE_ME;Trusted_Connection=True;"
        }
    }
}
```

In the highlighted line depicted above, change the name of the database from **_CHANGE_ME** to the name of your database.

Summary

ASP.NET Core places all startup logic for the application in a single file, in which the necessary services and dependencies can be defined and configured. It replaces the *web.config* file with a flexible configuration feature that can leverage a variety of file formats, such as JSON, as well as environment variables.

Migrate Authentication and Identity to ASP.NET Core

Article • 10/30/2024

By Steve Smith

In the previous article, we migrated configuration from an ASP.NET MVC project to ASP.NET Core MVC. In this article, we migrate the registration, login, and user management features.

Configure Identity and Membership

In ASP.NET MVC, authentication and identity features are configured using ASP.NET Identity in `Startup.Auth.cs` and `IdentityConfig.cs`, located in the *App_Start* folder. In ASP.NET Core MVC, these features are configured in `Startup.cs`.

Install the following NuGet packages:

- `Microsoft.AspNetCore.Identity.EntityFrameworkCore`
- `Microsoft.AspNetCore.Authentication.Cookies`
- `Microsoft.EntityFrameworkCore.SqlServer`

> ⚠ **Warning**
>
> This article shows the use of connection strings. With a local database the user doesn't have to be authenticated, but in production, connection strings sometimes include a password to authenticate. A resource owner password credential (ROPC) is a security risk that should be avoided in production databases. Production apps should use the most secure authentication flow available. For more information on authentication for apps deployed to test or production environments, see Secure authentication flows.

In `Startup.cs`, update the `Startup.ConfigureServices` method to use Entity Framework and Identity services:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    // Add EF services to the services container.
```

```
    services.AddDbContext<ApplicationDbContext>(options =>

options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection"))
);

    services.AddIdentity<ApplicationUser, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

     services.AddMvc();
}
```

At this point, there are two types referenced in the above code that we haven't yet migrated from the ASP.NET MVC project: `ApplicationDbContext` and `ApplicationUser`. Create a new *Models* folder in the ASP.NET Core project, and add two classes to it corresponding to these types. You will find the ASP.NET MVC versions of these classes in `/Models/IdentityModels.cs`, but we will use one file per class in the migrated project since that's more clear.

`ApplicationUser.cs`:

C#

```
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;

namespace NewMvcProject.Models
{
    public class ApplicationUser : IdentityUser
    {
    }
}
```

`ApplicationDbContext.cs`:

C#

```
using Microsoft.AspNetCore.Identity.EntityFrameworkCore;
using Microsoft.Data.Entity;

namespace NewMvcProject.Models
{
    public class ApplicationDbContext : IdentityDbContext<ApplicationUser>
    {
        public ApplicationDbContext(DbContextOptions<ApplicationDbContext>
options)
            : base(options)
        {
        }
```

```
        protected override void OnModelCreating(ModelBuilder builder)
        {
            base.OnModelCreating(builder);
            // Customize the ASP.NET Core Identity model and override the
defaults if needed.
            // For example, you can rename the ASP.NET Core Identity table
names and more.
            // Add your customizations after calling
base.OnModelCreating(builder);
        }
    }
}
```

The ASP.NET Core MVC Starter Web project doesn't include much customization of users, or the `ApplicationDbContext`. When migrating a real app, you also need to migrate all of the custom properties and methods of your app's user and `DbContext` classes, as well as any other Model classes your app utilizes. For example, if your `DbContext` has a `DbSet<Album>`, you need to migrate the `Album` class.

With these files in place, the `Startup.cs` file can be made to compile by updating its `using` statements:

C#

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Hosting;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
```

Our app is now ready to support authentication and Identity services. It just needs to have these features exposed to users.

Migrate registration and login logic

With Identity services configured for the app and data access configured using Entity Framework and SQL Server, we're ready to add support for registration and login to the app. Recall that earlier in the migration process we commented out a reference to *_LoginPartial* in `_Layout.cshtml`. Now it's time to return to that code, uncomment it, and add in the necessary controllers and views to support login functionality.

Uncomment the `@Html.Partial` line in `_Layout.cshtml`:

CSHTML

```
      <li>@Html.ActionLink("Contact", "Contact", "Home")</li>
    </ul>
    @*@Html.Partial("_LoginPartial")*@
  </div>
</div>
```

Now, add a new Razor view called *_LoginPartial* to the *Views/Shared* folder:

Update `_LoginPartial.cshtml` with the following code (replace all of its contents):

CSHTML

```
@inject SignInManager<ApplicationUser> SignInManager
@inject UserManager<ApplicationUser> UserManager

@if (SignInManager.IsSignedIn(User))
{
    <form asp-area="" asp-controller="Account" asp-action="Logout"
method="post" id="logoutForm" class="navbar-right">
        <ul class="nav navbar-nav navbar-right">
            <li>
                <a asp-area="" asp-controller="Manage" asp-action="Index"
title="Manage">Hello @UserManager.GetUserName(User)!</a>
            </li>
            <li>
                <button type="submit" class="btn btn-link navbar-btn navbar-
link">Log out</button>
            </li>
        </ul>
    </form>
}
else
{
    <ul class="nav navbar-nav navbar-right">
        <li><a asp-area="" asp-controller="Account" asp-
action="Register">Register</a></li>
        <li><a asp-area="" asp-controller="Account" asp-action="Login">Log
in</a></li>
    </ul>
}
```

At this point, you should be able to refresh the site in your browser.

Summary

ASP.NET Core introduces changes to the ASP.NET Identity features. In this article, you have seen how to migrate the authentication and user management features of ASP.NET Identity to ASP.NET Core.

Migrate from ClaimsPrincipal.Current

Article • 06/18/2024

In ASP.NET 4.x projects, it was common to use ClaimsPrincipal.Current to retrieve the current authenticated user's identity and claims. In ASP.NET Core, this property is no longer set. Code that was depending on it needs to be updated to get the current authenticated user's identity through a different means.

Context-specific state instead of static state

When using ASP.NET Core, the values of both `ClaimsPrincipal.Current` and `Thread.CurrentPrincipal` aren't set. These properties both represent static state, which ASP.NET Core generally avoids. Instead, ASP.NET Core uses dependency injection (DI) to provide dependencies such as the current user's identity. Getting the current user's identity from DI is more testable, too, since test identities can be easily injected.

Retrieve the current user in an ASP.NET Core app

There are several options for retrieving the current authenticated user's `ClaimsPrincipal` in ASP.NET Core in place of `ClaimsPrincipal.Current`:

- **ControllerBase.User**. MVC controllers can access the current authenticated user with their User property.
- **HttpContext.User**. Components with access to the current `HttpContext` (middleware, for example) can get the current user's `ClaimsPrincipal` from HttpContext.User.
- **Passed in from caller**. Libraries without access to the current `HttpContext` are often called from controllers or middleware components and can have the current user's identity passed as an argument.
- **IHttpContextAccessor**. The project being migrated to ASP.NET Core may be too large to easily pass the current user's identity to all necessary locations. In such cases, IHttpContextAccessor can be used as a workaround. `IHttpContextAccessor` is able to access the current `HttpContext` (if one exists). If DI is being used, see Access HttpContext in ASP.NET Core. A short-term solution to getting the current

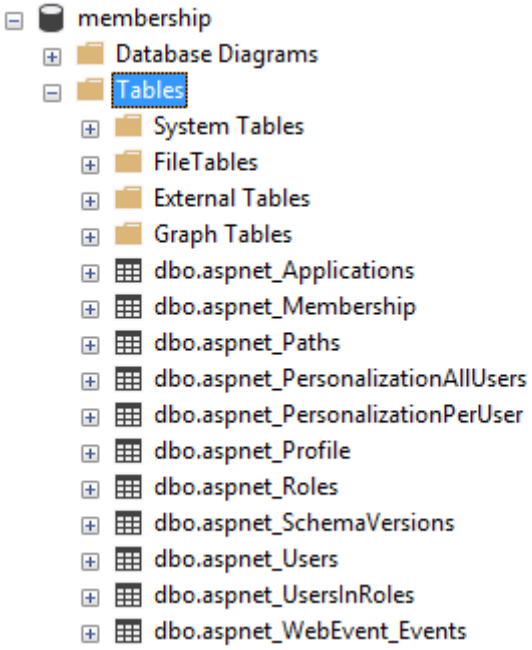
user's identity in code that hasn't yet been updated to work with ASP.NET Core's DI-driven architecture would be:

- Make `IHttpContextAccessor` available in the DI container by calling AddHttpContextAccessor in `Startup.ConfigureServices`.
- Get an instance of `IHttpContextAccessor` during startup and store it in a static variable. The instance is made available to code that was previously retrieving the current user from a static property.
- Retrieve the current user's `ClaimsPrincipal` using `HttpContextAccessor.HttpContext?.User`. If this code is used outside of the context of an HTTP request, the `HttpContext` is null.

The final option, using an `IHttpContextAccessor` instance stored in a static variable, is contrary to the ASP.NET Core principle of preferring injected dependencies to static dependencies. Plan to eventually retrieve `IHttpContextAccessor` instances from DI instead. A static helper can be a useful bridge, though, when migrating large existing ASP.NET apps that use `ClaimsPrincipal.Current`.

Migrate from ASP.NET Membership authentication to ASP.NET Core 2.0 Identity

Article • 10/29/2024



By Isaac Levin

This article demonstrates migrating the database schema for ASP.NET apps using Membership authentication to ASP.NET Core 2.0 Identity.

> **Note**
>
> This document provides the steps needed to migrate the database schema for ASP.NET Membership-based apps to the database schema used for ASP.NET Core Identity. For more information about migrating from ASP.NET Membership-based authentication to ASP.NET Identity, see Migrate an existing app from SQL Membership to ASP.NET Identity. For more information about ASP.NET Core Identity, see Introduction to Identity on ASP.NET Core.

Review of Membership schema

Prior to ASP.NET 2.0, developers were tasked with creating the entire authentication and authorization process for their apps. With ASP.NET 2.0, Membership was introduced, providing a boilerplate solution to handling security within ASP.NET apps. Developers were now able to bootstrap a schema into a SQL Server database with the ASP.NET SQL Server Registration Tool (`Aspnet_regsql.exe`) (no longer supported). After running this command, the following tables were created in the database.

To migrate existing apps to ASP.NET Core 2.0 Identity, the data in these tables needs to be migrated to the tables used by the new Identity schema.

ASP.NET Core Identity 2.0 schema

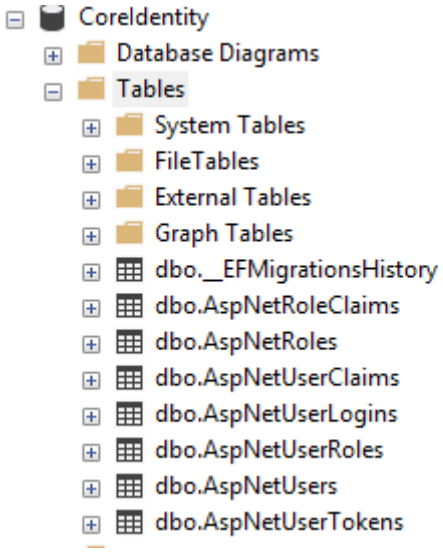
ASP.NET Core 2.0 follows the Identity principle introduced in ASP.NET 4.5. Though the principle is shared, the implementation between the frameworks is different, even between versions of ASP.NET Core (see Migrate authentication and Identity to ASP.NET Core 2.0).

The fastest way to view the schema for ASP.NET Core 2.0 Identity is to create a new ASP.NET Core 2.0 app. Follow these steps in Visual Studio 2017:

1. Select **File** > **New** > **Project**.
2. Create a new **ASP.NET Core Web Application** project named *CoreIdentitySample*.
3. Select **ASP.NET Core 2.0** in the dropdown and then select **Web Application**. This template produces a Razor Pages app. Before clicking **OK**, click **Change Authentication**.
4. Choose **Individual User Accounts** for the Identity templates. Finally, click **OK**, then **OK**. Visual Studio creates a project using the ASP.NET Core Identity template.
5. Select **Tools** > **NuGet Package Manager** > **Package Manager Console** to open the **Package Manager Console** (PMC) window.
6. Navigate to the project root in PMC, and run the Entity Framework (EF) Core `Update-Database` command.

ASP.NET Core 2.0 Identity uses EF Core to interact with the database storing the authentication data. In order for the newly created app to work, there needs to be a database to store this data. After creating a new app, the fastest way to inspect the schema in a database environment is to create the database using EF Core Migrations. This process creates a database, either locally or elsewhere, which mimics that schema. Review the preceding documentation for more information.

EF Core commands use the connection string for the database specified in `appsettings.json`. The following connection string targets a database on *localhost* named *asp-net-core-identity*. In this setting, EF Core is configured to use the `DefaultConnection` connection string.



JSON

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=localhost;Database=aspnet-core-
identity;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

> ⚠ **Warning**
>
> This article shows the use of connection strings. With a local database the user doesn't have to be authenticated, but in production, connection strings sometimes include a password to authenticate. A resource owner password credential (ROPC) is a security risk that should be avoided in production databases. Production apps should use the most secure authentication flow available. For more information on authentication for apps deployed to test or production environments, see Secure authentication flows.

1. Select **View** > **SQL Server Object Explorer**. Expand the node corresponding to the database name specified in the `ConnectionStrings:DefaultConnection` property of `appsettings.json`.

   The `Update-Database` command created the database specified with the schema and any data needed for app initialization. The following image depicts the table structure that's created with the preceding steps.

Migrate the schema

There are subtle differences in the table structures and fields for both Membership and ASP.NET Core Identity. The pattern has changed substantially for authentication/authorization with ASP.NET and ASP.NET Core apps. The key objects that are still used with Identity are *Users* and *Roles*. Here are mapping tables for *Users*, *Roles*, and *UserRoles*.

Users

Expand table

Identity (`dbo.AspNetUsers`) column	**Type**	**Membership (`dbo.aspnet_Users` / `dbo.aspnet_Membership`) column**	**Type**
`Id`	`string`	`aspnet_Users.UserId`	`string`
`UserName`	`string`	`aspnet_Users.UserName`	`string`
`Email`	`string`	`aspnet_Membership.Email`	`string`
`NormalizedUserName`	`string`	`aspnet_Users.LoweredUserName`	`string`
`NormalizedEmail`	`string`	`aspnet_Membership.LoweredEmail`	`string`
`PhoneNumber`	`string`	`aspnet_Users.MobileAlias`	`string`
`LockoutEnabled`	`bit`	`aspnet_Membership.IsLockedOut`	`bit`

`IsLockedOut` doesn't map to `LockoutEnabled`. `IsLockedOut` is set if a user had too many failed logins and is locked out for a set time. `LockoutEnabled` enables locking out a user

with too many failed sign in attempts. When the user has too many failed sign in attempts, `LockoutEnd` is set to a date in the future, and the user can't sign in until that date. If `LockoutEnabled` is false then a user is never locked out for too many failed sign in attempts. Per OWASP, *Temporary account lockout after several failed attempts is too simple of a target for DoS attacks against legitimate users*.

For more information on lock out, see OWASP Testing for Weak Lock Out Mechanism.

Apps migrating to Identity that wish to enable failed login lockout should set `LockoutEnabled` to true as part of the migration.

> **Note**
>
> Not all the field mappings resemble one-to-one relationships from Membership to ASP.NET Core Identity. The preceding table takes the default Membership User schema and maps it to the ASP.NET Core Identity schema. Any other custom fields that were used for Membership need to be mapped manually. In this mapping, there's no map for passwords, as both password criteria and password salts don't migrate between the two. **It's recommended to leave the password as null and to ask users to reset their passwords.** In ASP.NET Core Identity, `LockoutEnd` should be set to some date in the future if the user is locked out. This is shown in the migration script.

Roles

Expand table

Identity (`dbo.AspNetRoles`) column	Type	Membership (`dbo.aspnet_Roles`) column	Type
`Id`	`string`	`RoleId`	`string`
`Name`	`string`	`RoleName`	`string`
`NormalizedName`	`string`	`LoweredRoleName`	`string`

User Roles

Expand table

Identity (`dbo.AspNetUserRoles`) column	Type	Membership (`dbo.aspnet_UsersInRoles`) column	Type
`RoleId`	`string`	`RoleId`	`string`
`UserId`	`string`	`UserId`	`string`

Reference the preceding mapping tables when creating a migration script for *Users* and *Roles*. The following example assumes you have two databases on a database server. One database contains the existing ASP.NET Membership schema and data. The other *CoreIdentitySample* database was created using steps described earlier. Comments are included inline for more details.

SQL

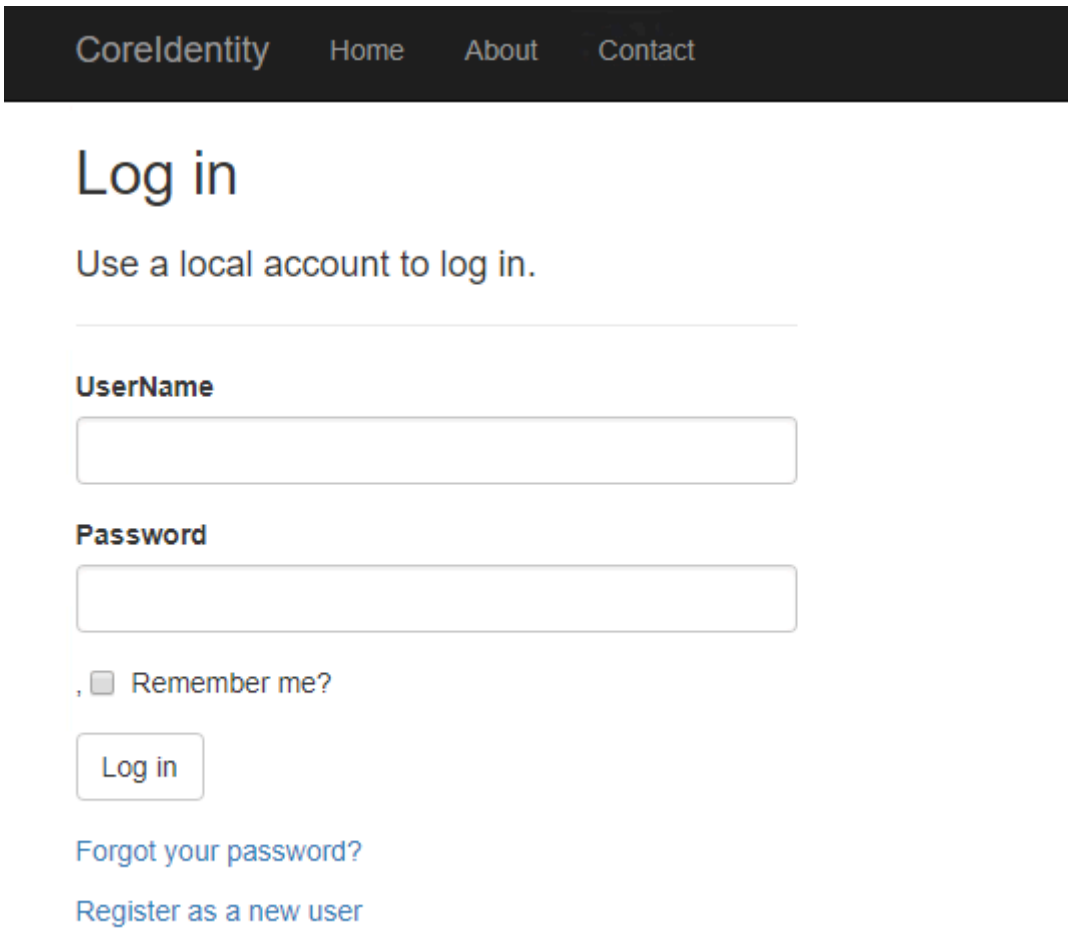
```
-- THIS SCRIPT NEEDS TO RUN FROM THE CONTEXT OF THE MEMBERSHIP DB
BEGIN TRANSACTION MigrateUsersAndRoles
USE aspnetdb

-- INSERT USERS
INSERT INTO CoreIdentitySample.dbo.AspNetUsers
            (Id,
             UserName,
             NormalizedUserName,
             PasswordHash,
             SecurityStamp,
             EmailConfirmed,
             PhoneNumber,
             PhoneNumberConfirmed,
             TwoFactorEnabled,
             LockoutEnd,
             LockoutEnabled,
             AccessFailedCount,
             Email,
             NormalizedEmail)
SELECT aspnet_Users.UserId,
       aspnet_Users.UserName,
       -- The NormalizedUserName value is upper case in ASP.NET Core
Identity
       UPPER(aspnet_Users.UserName),
       -- Creates an empty password since passwords don't map between the 2
schemas
       '',
       /*
        The SecurityStamp token is used to verify the state of an account
and
        is subject to change at any time. It should be initialized as a new
ID.
       */
       NewID(),
       /*
        EmailConfirmed is set when a new user is created and confirmed via
```

```
email.
        Users must have this set during migration to reset passwords.
       */
       1,
       aspnet_Users.MobileAlias,
       CASE
         WHEN aspnet_Users.MobileAlias IS NULL THEN 0
         ELSE 1
       END,
       -- 2FA likely wasn't setup in Membership for users, so setting as
false.
       0,
       CASE
         -- Setting lockout date to time in the future (1,000 years)
         WHEN aspnet_Membership.IsLockedOut = 1 THEN Dateadd(year, 1000,
                                                     Sysutcdatetime())
         ELSE NULL
       END,
       aspnet_Membership.IsLockedOut,
       /*
        AccessFailedAccount is used to track failed logins. This is stored
in
        Membership in multiple columns. Setting to 0 arbitrarily.
       */
       0,
       aspnet_Membership.Email,
       -- The NormalizedEmail value is upper case in ASP.NET Core Identity
       UPPER(aspnet_Membership.Email)
FROM   aspnet_Users
       LEFT OUTER JOIN aspnet_Membership
                    ON aspnet_Membership.ApplicationId =
                       aspnet_Users.ApplicationId
                       AND aspnet_Users.UserId = aspnet_Membership.UserId
       LEFT OUTER JOIN CoreIdentitySample.dbo.AspNetUsers
                    ON aspnet_Membership.UserId = AspNetUsers.Id
WHERE  AspNetUsers.Id IS NULL

-- INSERT ROLES
INSERT INTO CoreIdentitySample.dbo.AspNetRoles(Id, Name)
SELECT RoleId, RoleName
FROM aspnet_Roles;

-- INSERT USER ROLES
INSERT INTO CoreIdentitySample.dbo.AspNetUserRoles(UserId, RoleId)
SELECT UserId, RoleId
FROM aspnet_UsersInRoles;



IF @@ERROR <> 0
  BEGIN
    ROLLBACK TRANSACTION MigrateUsersAndRoles
    RETURN
  END

COMMIT TRANSACTION MigrateUsersAndRoles
```

After completion of the preceding script, the ASP.NET Core Identity app created earlier is populated with Membership users. Users need to change their passwords before logging in.

> **Note**
>
> If the Membership system had users with user names that didn't match their email address, changes are required to the app created earlier to accommodate this. The default template expects `UserName` and `Email` to be the same. For situations in which they're different, the login process needs to be modified to use `UserName` instead of `Email`.

In the `PageModel` of the Login Page, located at , remove the `[EmailAddress]` attribute from the *Email* property. Rename it to *UserName*. This requires a change wherever `EmailAddress` is mentioned, in the *View* and *PageModel*. The result looks like the following:

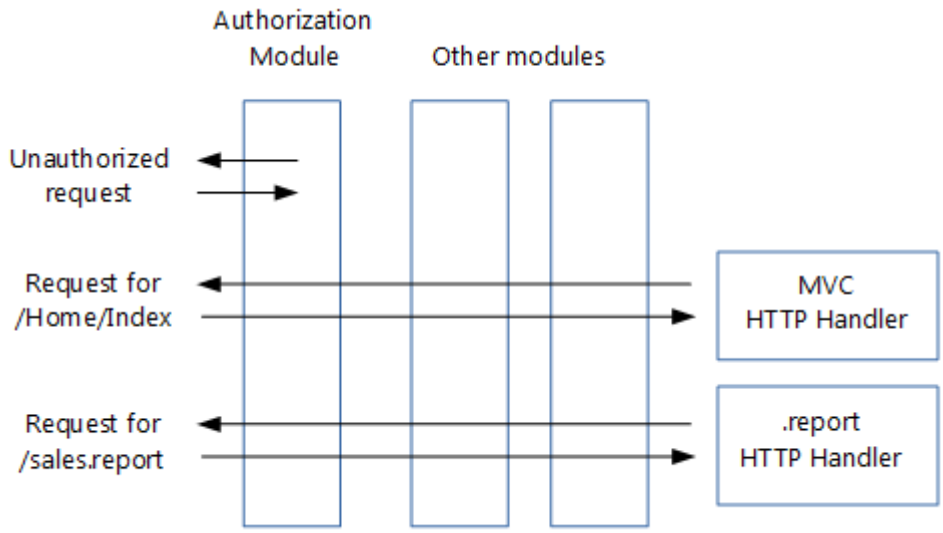
In this tutorial, you learned how to port users from SQL membership to ASP.NET Core 2.0 Identity. For more information regarding ASP.NET Core Identity, see Introduction to Identity.



Migrate HTTP handlers and modules to ASP.NET Core middleware

Article • 03/22/2024

This article shows how to migrate existing ASP.NET HTTP modules and handlers from system.webserver to ASP.NET Core middleware.

Modules and handlers revisited

Before proceeding to ASP.NET Core middleware, let's first recap how HTTP modules and handlers work:

Handlers are:

- Classes that implement IHttpHandler
- Used to handle requests with a given file name or extension, such as *.report*
- Configured in *Web.config*

Modules are:

- Classes that implement IHttpModule
- Invoked for every request
- Able to short-circuit (stop further processing of a request)
- Able to add to the HTTP response, or create their own

- Configured in *Web.config*

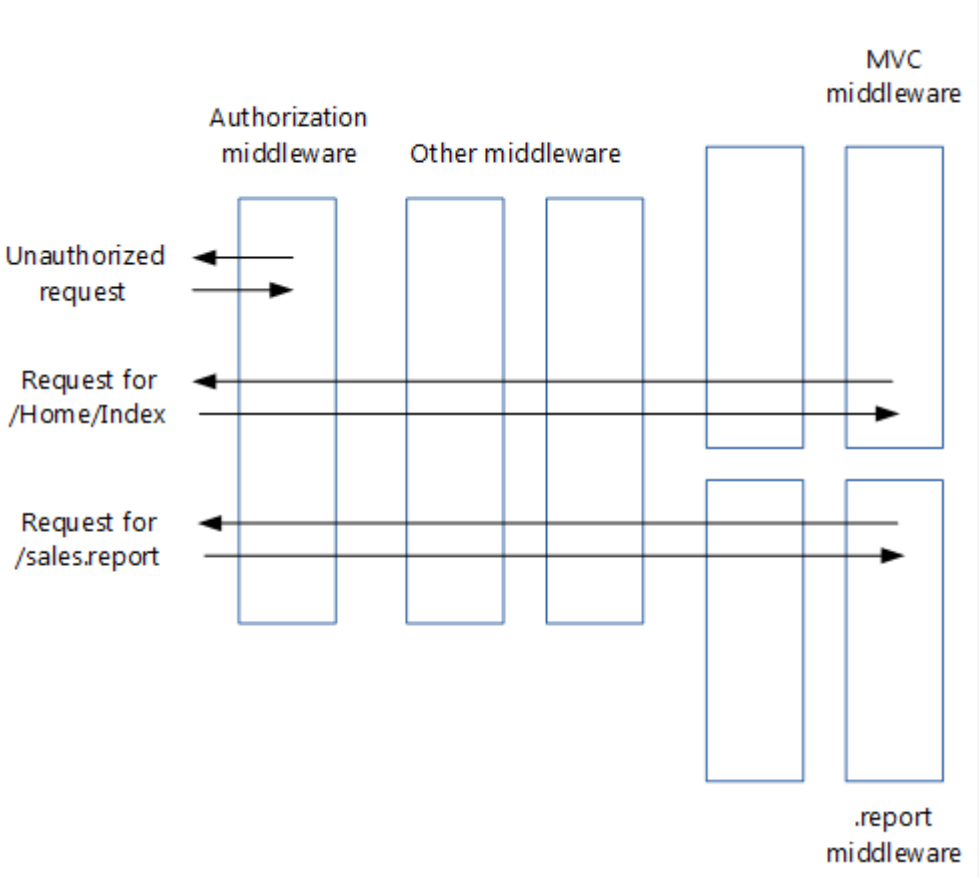
The order in which modules process incoming requests is determined by:

1. A series events fired by ASP.NET, such as BeginRequest and AuthenticateRequest. For a complete list, see System.Web.HttpApplication. Each module can create a handler for one or more events.
2. For the same event, the order in which they're configured in *Web.config*.

In addition to modules, you can add handlers for the life cycle events to your `Global.asax.cs` file. These handlers run after the handlers in the configured modules.

From handlers and modules to middleware

Middleware are simpler than HTTP modules and handlers:



- Modules, handlers, `Global.asax.cs`, *Web.config* (except for IIS configuration) and the application life cycle are gone
- The roles of both modules and handlers have been taken over by middleware
- Middleware are configured using code rather than in *Web.config*
- Pipeline branching lets you send requests to specific middleware, based on not only the URL but also on request headers, query strings, etc.

Middleware are very similar to modules:

- Invoked in principle for every request
- Able to short-circuit a request, by not passing the request to the next middleware
- Able to create their own HTTP response

Middleware and modules are processed in a different order:

- Order of middleware is based on the order in which they're inserted into the request pipeline, while order of modules is mainly based on System.Web.HttpApplication events.
- Order of middleware for responses is the reverse from that for requests, while order of modules is the same for requests and responses
- See Create a middleware pipeline with IApplicationBuilder

Note how in the image above, the authentication middleware short-circuited the request.

Migrating module code to middleware

An existing HTTP module will look similar to this:

C#

```
// ASP.NET 4 module

using System;
using System.Web;

namespace MyApp.Modules
{
    public class MyModule : IHttpModule
    {
        public void Dispose()
        {
        }

        public void Init(HttpApplication application)
        {
            application.BeginRequest += (new
EventHandler(this.Application_BeginRequest));
            application.EndRequest += (new
EventHandler(this.Application_EndRequest));
```

```
        }

        private void Application_BeginRequest(Object source, EventArgs e)
        {
            HttpContext context = ((HttpApplication)source).Context;

            // Do something with context near the beginning of request
processing.
        }

        private void Application_EndRequest(Object source, EventArgs e)
        {
            HttpContext context = ((HttpApplication)source).Context;

            // Do something with context near the end of request processing.
        }
    }
}
```

As shown in the Middleware page, an ASP.NET Core middleware is a class that exposes an `Invoke` method taking an `HttpContext` and returning a `Task`. Your new middleware will look like this:

C#

```
// ASP.NET Core middleware

using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Http;
using System.Threading.Tasks;

namespace MyApp.Middleware
{
    public class MyMiddleware
    {
        private readonly RequestDelegate _next;

        public MyMiddleware(RequestDelegate next)
        {
            _next = next;
        }

        public async Task Invoke(HttpContext context)
        {
            // Do something with context near the beginning of request
processing.

            await _next.Invoke(context);

            // Clean up.
        }
    }
```

```
    public static class MyMiddlewareExtensions
    {
        public static IApplicationBuilder UseMyMiddleware(this
IApplicationBuilder builder)
        {
            return builder.UseMiddleware<MyMiddleware>();
        }
    }
}
```

The preceding middleware template was taken from the section on writing middleware.

The *MyMiddlewareExtensions* helper class makes it easier to configure your middleware in your `Startup` class. The `UseMyMiddleware` method adds your middleware class to the request pipeline. Services required by the middleware get injected in the middleware's constructor.

Your module might terminate a request, for example if the user isn't authorized:

C#

```
// ASP.NET 4 module that may terminate the request

private void Application_BeginRequest(Object source, EventArgs e)
{
    HttpContext context = ((HttpApplication)source).Context;

    // Do something with context near the beginning of request processing.

    if (TerminateRequest())
    {
        context.Response.End();
        return;
    }
}
```

A middleware handles this by not calling `Invoke` on the next middleware in the pipeline. Keep in mind that this doesn't fully terminate the request, because previous middlewares will still be invoked when the response makes its way back through the pipeline.

C#

```
// ASP.NET Core middleware that may terminate the request

public async Task Invoke(HttpContext context)
{
    // Do something with context near the beginning of request processing.
```

```
    if (!TerminateRequest())
        await _next.Invoke(context);

    // Clean up.
}
```

When you migrate your module's functionality to your new middleware, you may find that your code doesn't compile because the `HttpContext` class has significantly changed in ASP.NET Core. Later on, you'll see how to migrate to the new ASP.NET Core HttpContext.

Migrating module insertion into the request pipeline

HTTP modules are typically added to the request pipeline using *Web.config*:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<!--ASP.NET 4 web.config-->
<configuration>
  <system.webServer>
    <modules>
      <add name="MyModule" type="MyApp.Modules.MyModule"/>
    </modules>
  </system.webServer>
</configuration>
```

Convert this by adding your new middleware to the request pipeline in your `Startup` class:

C#

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env,
ILoggerFactory loggerFactory)
{
    loggerFactory.AddConsole(Configuration.GetSection("Logging"));
    loggerFactory.AddDebug();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseBrowserLink();
    }
    else
    {
```

```
            app.UseExceptionHandler("/Home/Error");
        }

        app.UseMyMiddleware();

        app.UseMyMiddlewareWithParams();

        var myMiddlewareOptions =
Configuration.GetSection("MyMiddlewareOptionsSection").Get<MyMiddlewareOptio
ns>();
        var myMiddlewareOptions2 =
Configuration.GetSection("MyMiddlewareOptionsSection2").Get<MyMiddlewareOpti
ons>();
        app.UseMyMiddlewareWithParams(myMiddlewareOptions);
        app.UseMyMiddlewareWithParams(myMiddlewareOptions2);

        app.UseMyTerminatingMiddleware();

        // Create branch to the MyHandlerMiddleware.
        // All requests ending in .report will follow this branch.
        app.MapWhen(
            context => context.Request.Path.ToString().EndsWith(".report"),
            appBranch => {
                // ... optionally add more middleware to this branch
                appBranch.UseMyHandler();
            });

        app.MapWhen(
            context => context.Request.Path.ToString().EndsWith(".context"),
            appBranch => {
                appBranch.UseHttpContextDemoMiddleware();
            });

        app.UseStaticFiles();

        app.UseMvc(routes =>
        {
            routes.MapRoute(
                name: "default",
                template: "{controller=Home}/{action=Index}/{id?}");
        });
    }
```

The exact spot in the pipeline where you insert your new middleware depends on the event that it handled as a module (`BeginRequest`, `EndRequest`, etc.) and its order in your list of modules in *Web.config*.

As previously stated, there's no application life cycle in ASP.NET Core and the order in which responses are processed by middleware differs from the order used by modules. This could make your ordering decision more challenging.

If ordering becomes a problem, you could split your module into multiple middleware components that can be ordered independently.

Migrating handler code to middleware

An HTTP handler looks something like this:

C#

```
// ASP.NET 4 handler

using System.Web;

namespace MyApp.HttpHandlers
{
    public class MyHandler : IHttpHandler
    {
        public bool IsReusable { get { return true; } }

        public void ProcessRequest(HttpContext context)
        {
            string response = GenerateResponse(context);

            context.Response.ContentType = GetContentType();
            context.Response.Output.Write(response);
        }

        // ...

        private string GenerateResponse(HttpContext context)
        {
            string title = context.Request.QueryString["title"];
            return string.Format("Title of the report: {0}", title);
        }

        private string GetContentType()
        {
            return "text/plain";
        }
    }
}
```

In your ASP.NET Core project, you would translate this to a middleware similar to this:

C#

```
// ASP.NET Core middleware migrated from a handler

using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Http;
```

```
using System.Threading.Tasks;

namespace MyApp.Middleware
{
    public class MyHandlerMiddleware
    {

        // Must have constructor with this signature, otherwise exception at
run time
        public MyHandlerMiddleware(RequestDelegate next)
        {
            // This is an HTTP Handler, so no need to store next
        }

        public async Task Invoke(HttpContext context)
        {
            string response = GenerateResponse(context);

            context.Response.ContentType = GetContentType();
            await context.Response.WriteAsync(response);
        }

        // ...

        private string GenerateResponse(HttpContext context)
        {
            string title = context.Request.Query["title"];
            return string.Format("Title of the report: {0}", title);
        }

        private string GetContentType()
        {
            return "text/plain";
        }
    }

    public static class MyHandlerExtensions
    {
        public static IApplicationBuilder UseMyHandler(this
IApplicationBuilder builder)
        {
            return builder.UseMiddleware<MyHandlerMiddleware>();
        }
    }
}
```

This middleware is very similar to the middleware corresponding to modules. The only real difference is that here there's no call to `_next.Invoke(context)`. That makes sense, because the handler is at the end of the request pipeline, so there will be no next middleware to invoke.

Migrating handler insertion into the request pipeline

Configuring an HTTP handler is done in *Web.config* and looks something like this:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<!--ASP.NET 4 web.config-->
<configuration>
  <system.webServer>
    <handlers>
      <add name="MyHandler" verb="*" path="*.report"
type="MyApp.HttpHandlers.MyHandler" resourceType="Unspecified"
preCondition="integratedMode"/>
    </handlers>
  </system.webServer>
</configuration>
```

You could convert this by adding your new handler middleware to the request pipeline in your `Startup` class, similar to middleware converted from modules. The problem with that approach is that it would send all requests to your new handler middleware. However, you only want requests with a given extension to reach your middleware. That would give you the same functionality you had with your HTTP handler.

One solution is to branch the pipeline for requests with a given extension, using the `MapWhen` extension method. You do this in the same `Configure` method where you add the other middleware:

C#

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env,
ILoggerFactory loggerFactory)
{
    loggerFactory.AddConsole(Configuration.GetSection("Logging"));
    loggerFactory.AddDebug();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseBrowserLink();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
    }

    app.UseMyMiddleware();
```

```
    app.UseMyMiddlewareWithParams();

    var myMiddlewareOptions =
Configuration.GetSection("MyMiddlewareOptionsSection").Get<MyMiddlewareOptio
ns>();
    var myMiddlewareOptions2 =
Configuration.GetSection("MyMiddlewareOptionsSection2").Get<MyMiddlewareOpti
ons>();
    app.UseMyMiddlewareWithParams(myMiddlewareOptions);
    app.UseMyMiddlewareWithParams(myMiddlewareOptions2);

    app.UseMyTerminatingMiddleware();

    // Create branch to the MyHandlerMiddleware.
    // All requests ending in .report will follow this branch.
    app.MapWhen(
        context => context.Request.Path.ToString().EndsWith(".report"),
        appBranch => {
            // ... optionally add more middleware to this branch
            appBranch.UseMyHandler();
        });

    app.MapWhen(
        context => context.Request.Path.ToString().EndsWith(".context"),
        appBranch => {
            appBranch.UseHttpContextDemoMiddleware();
        });

    app.UseStaticFiles();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

`MapWhen` takes these parameters:

1. A lambda that takes the `HttpContext` and returns `true` if the request should go down the branch. This means you can branch requests not just based on their extension, but also on request headers, query string parameters, etc.
2. A lambda that takes an `IApplicationBuilder` and adds all the middleware for the branch. This means you can add additional middleware to the branch in front of your handler middleware.

Middleware added to the pipeline before the branch will be invoked on all requests; the branch will have no impact on them.

Loading middleware options using the options pattern

Some modules and handlers have configuration options that are stored in *Web.config*. However, in ASP.NET Core a new configuration model is used in place of *Web.config*.

The new configuration system gives you these options to solve this:

- Directly inject the options into the middleware, as shown in the next section.
- Use the options pattern:

1. Create a class to hold your middleware options, for example:

   C#

   ```
   public class MyMiddlewareOptions
   {
       public string Param1 { get; set; }
       public string Param2 { get; set; }
   }
   ```

2. Store the option values

   The configuration system allows you to store option values anywhere you want. However, most sites use `appsettings.json`, so we'll take that approach:

   JSON

   ```
   {
     "MyMiddlewareOptionsSection": {
       "Param1": "Param1Value",
       "Param2": "Param2Value"
     }
   }
   ```

   MyMiddlewareOptionsSection here is a section name. It doesn't have to be the same as the name of your options class.

3. Associate the option values with the options class

   The options pattern uses ASP.NET Core's dependency injection framework to associate the options type (such as `MyMiddlewareOptions`) with a `MyMiddlewareOptions` object that has the actual options.

   Update your `Startup` class:

a. If you're using `appsettings.json`, add it to the configuration builder in the `Startup` constructor:

```
C#

public Startup(IHostingEnvironment env)
{
    var builder = new ConfigurationBuilder()
        .SetBasePath(env.ContentRootPath)
        .AddJsonFile("appsettings.json", optional: true,
reloadOnChange: true)
        .AddJsonFile($"appsettings.{env.EnvironmentName}.json",
optional: true)
        .AddEnvironmentVariables();
    Configuration = builder.Build();
}
```

b. Configure the options service:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    // Setup options service
    services.AddOptions();

    // Load options from section "MyMiddlewareOptionsSection"
    services.Configure<MyMiddlewareOptions>(
        Configuration.GetSection("MyMiddlewareOptionsSection"));

    // Add framework services.
    services.AddMvc();
}
```

c. Associate your options with your options class:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    // Setup options service
    services.AddOptions();

    // Load options from section "MyMiddlewareOptionsSection"
    services.Configure<MyMiddlewareOptions>(
        Configuration.GetSection("MyMiddlewareOptionsSection"));

    // Add framework services.
```

```
        services.AddMvc();
    }
```

4. Inject the options into your middleware constructor. This is similar to injecting options into a controller.

```
C#

public class MyMiddlewareWithParams
{
    private readonly RequestDelegate _next;
    private readonly MyMiddlewareOptions _myMiddlewareOptions;

    public MyMiddlewareWithParams(RequestDelegate next,
        IOptions<MyMiddlewareOptions> optionsAccessor)
    {
        _next = next;
        _myMiddlewareOptions = optionsAccessor.Value;
    }

    public async Task Invoke(HttpContext context)
    {
        // Do something with context near the beginning of request
processing
        // using configuration in _myMiddlewareOptions

        await _next.Invoke(context);

        // Do something with context near the end of request processing
        // using configuration in _myMiddlewareOptions
    }
}
```

The UseMiddleware extension method that adds your middleware to the `IApplicationBuilder` takes care of dependency injection.

This isn't limited to `IOptions` objects. Any other object that your middleware requires can be injected this way.

Loading middleware options through direct injection

The options pattern has the advantage that it creates loose coupling between options values and their consumers. Once you've associated an options class with the actual options values, any other class can get access to the options through the dependency injection framework. There's no need to pass around options values.

This breaks down though if you want to use the same middleware twice, with different options. For example an authorization middleware used in different branches allowing different roles. You can't associate two different options objects with the one options class.

The solution is to get the options objects with the actual options values in your `Startup` class and pass those directly to each instance of your middleware.

1. Add a second key to `appsettings.json`

   To add a second set of options to the `appsettings.json` file, use a new key to uniquely identify it:

   JSON

   ```
   {
     "MyMiddlewareOptionsSection2": {
       "Param1": "Param1Value2",
       "Param2": "Param2Value2"
     },
     "MyMiddlewareOptionsSection": {
       "Param1": "Param1Value",
       "Param2": "Param2Value"
     }
   }
   ```

2. Retrieve options values and pass them to middleware. The `Use...` extension method (which adds your middleware to the pipeline) is a logical place to pass in the option values:

   C#

   ```
   public void Configure(IApplicationBuilder app, IHostingEnvironment env,
   ILoggerFactory loggerFactory)
   {
       loggerFactory.AddConsole(Configuration.GetSection("Logging"));
       loggerFactory.AddDebug();

       if (env.IsDevelopment())
       {
           app.UseDeveloperExceptionPage();
           app.UseBrowserLink();
       }
       else
       {
           app.UseExceptionHandler("/Home/Error");
       }

       app.UseMyMiddleware();
   ```

```
    app.UseMyMiddlewareWithParams();

    var myMiddlewareOptions =
Configuration.GetSection("MyMiddlewareOptionsSection").Get<MyMiddleware
Options>();
    var myMiddlewareOptions2 =
Configuration.GetSection("MyMiddlewareOptionsSection2").Get<MyMiddlewar
eOptions>();
    app.UseMyMiddlewareWithParams(myMiddlewareOptions);
    app.UseMyMiddlewareWithParams(myMiddlewareOptions2);

    app.UseMyTerminatingMiddleware();

    // Create branch to the MyHandlerMiddleware.
    // All requests ending in .report will follow this branch.
    app.MapWhen(
        context => context.Request.Path.ToString().EndsWith(".report"),
        appBranch => {
            // ... optionally add more middleware to this branch
            appBranch.UseMyHandler();
        });

    app.MapWhen(
        context =>
context.Request.Path.ToString().EndsWith(".context"),
        appBranch => {
            appBranch.UseHttpContextDemoMiddleware();
        });

    app.UseStaticFiles();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

3. Enable middleware to take an options parameter. Provide an overload of the `Use...` extension method (that takes the options parameter and passes it to `UseMiddleware`). When `UseMiddleware` is called with parameters, it passes the parameters to your middleware constructor when it instantiates the middleware object.

```
C#

public static class MyMiddlewareWithParamsExtensions
{
    public static IApplicationBuilder UseMyMiddlewareWithParams(
        this IApplicationBuilder builder)
```

```
    {
        return builder.UseMiddleware<MyMiddlewareWithParams>();
    }

    public static IApplicationBuilder UseMyMiddlewareWithParams(
        this IApplicationBuilder builder, MyMiddlewareOptions
myMiddlewareOptions)
    {
        return builder.UseMiddleware<MyMiddlewareWithParams>(
            new OptionsWrapper<MyMiddlewareOptions>
(myMiddlewareOptions));
    }
}
```

Note how this wraps the options object in an `OptionsWrapper` object. This implements `IOptions`, as expected by the middleware constructor.

Migrating to the new HttpContext

You saw earlier that the `Invoke` method in your middleware takes a parameter of type `HttpContext`:

C#

```
public async Task Invoke(HttpContext context)
```

`HttpContext` has significantly changed in ASP.NET Core. This section shows how to translate the most commonly used properties of System.Web.HttpContext to the new `Microsoft.AspNetCore.Http.HttpContext`.

HttpContext

HttpContext.Items translates to:

C#

```
IDictionary<object, object> items = httpContext.Items;
```

Unique request ID (no System.Web.HttpContext counterpart)

Gives you a unique id for each request. Very useful to include in your logs.

C#

```
string requestId = httpContext.TraceIdentifier;
```

HttpContext.Request

HttpContext.Request.HttpMethod translates to:

C#

```
string httpMethod = httpContext.Request.Method;
```

HttpContext.Request.QueryString translates to:

C#

```
IQueryCollection queryParameters = httpContext.Request.Query;

// If no query parameter "key" used, values will have 0 items
// If single value used for a key (...?key=v1), values will have 1 item
("v1")
// If key has multiple values (...?key=v1&key=v2), values will have 2 items
("v1" and "v2")
IList<string> values = queryParameters["key"];

// If no query parameter "key" used, value will be ""
// If single value used for a key (...?key=v1), value will be "v1"
// If key has multiple values (...?key=v1&key=v2), value will be "v1,v2"
string value = queryParameters["key"].ToString();
```

HttpContext.Request.Url and **HttpContext.Request.RawUrl** translate to:

C#

```
// using Microsoft.AspNetCore.Http.Extensions;
var url = httpContext.Request.GetDisplayUrl();
```

HttpContext.Request.IsSecureConnection translates to:

C#

```
var isSecureConnection = httpContext.Request.IsHttps;
```

HttpContext.Request.UserHostAddress translates to:

C#

```
var userHostAddress = httpContext.Connection.RemoteIpAddress?.ToString();
```

HttpContext.Request.Cookies translates to:

C#

```
IRequestCookieCollection cookies = httpContext.Request.Cookies;
string unknownCookieValue = cookies["unknownCookie"]; // will be null (no
exception)
string knownCookieValue = cookies["cookie1name"];     // will be actual
value
```

HttpContext.Request.RequestContext.RouteData translates to:

C#

```
var routeValue = httpContext.GetRouteValue("key");
```

HttpContext.Request.Headers translates to:

C#

```
// using Microsoft.AspNetCore.Http.Headers;
// using Microsoft.Net.Http.Headers;

IHeaderDictionary headersDictionary = httpContext.Request.Headers;

// GetTypedHeaders extension method provides strongly typed access to many
headers
var requestHeaders = httpContext.Request.GetTypedHeaders();
CacheControlHeaderValue cacheControlHeaderValue =
requestHeaders.CacheControl;

// For unknown header, unknownheaderValues has zero items and
unknownheaderValue is ""
IList<string> unknownheaderValues = headersDictionary["unknownheader"];
string unknownheaderValue = headersDictionary["unknownheader"].ToString();

// For known header, knownheaderValues has 1 item and knownheaderValue is
the value
IList<string> knownheaderValues =
headersDictionary[HeaderNames.AcceptLanguage];
string knownheaderValue =
headersDictionary[HeaderNames.AcceptLanguage].ToString();
```

HttpContext.Request.UserAgent translates to:

C#

```
string userAgent = headersDictionary[HeaderNames.UserAgent].ToString();
```

HttpContext.Request.UrlReferrer translates to:

C#

```
string urlReferrer = headersDictionary[HeaderNames.Referer].ToString();
```

HttpContext.Request.ContentType translates to:

C#

```
// using Microsoft.Net.Http.Headers;

MediaTypeHeaderValue mediaHeaderValue = requestHeaders.ContentType;
string contentType = mediaHeaderValue?.MediaType.ToString();   // ex.
application/x-www-form-urlencoded
string contentMainType = mediaHeaderValue?.Type.ToString();    // ex.
application
string contentSubType = mediaHeaderValue?.SubType.ToString();  // ex. x-www-
form-urlencoded

System.Text.Encoding requestEncoding = mediaHeaderValue?.Encoding;
```

HttpContext.Request.Form translates to:

C#

```
if (httpContext.Request.HasFormContentType)
{
    IFormCollection form;

    form = httpContext.Request.Form; // sync
    // Or
    form = await httpContext.Request.ReadFormAsync(); // async

    string firstName = form["firstname"];
    string lastName = form["lastname"];
}
```

> ⚠ **Warning**
>
> Read form values only if the content sub type is *x-www-form-urlencoded* or *form-data*.

HttpContext.Request.InputStream translates to:

C#

```
string inputBody;
using (var reader = new System.IO.StreamReader(
    httpContext.Request.Body, System.Text.Encoding.UTF8))
{
    inputBody = reader.ReadToEnd();
}
```

> ⚠ **Warning**
>
> Use this code only in a handler type middleware, at the end of a pipeline.
>
> You can read the raw body as shown above only once per request. Middleware trying to read the body after the first read will read an empty body.
>
> This doesn't apply to reading a form as shown earlier, because that's done from a buffer.

HttpContext.Response

HttpContext.Response.Status and **HttpContext.Response.StatusDescription** translate to:

C#

```
// using Microsoft.AspNetCore.Http;
httpContext.Response.StatusCode = StatusCodes.Status200OK;
```

HttpContext.Response.ContentEncoding and **HttpContext.Response.ContentType** translate to:

C#

```
// using Microsoft.Net.Http.Headers;
var mediaType = new MediaTypeHeaderValue("application/json");
mediaType.Encoding = System.Text.Encoding.UTF8;
httpContext.Response.ContentType = mediaType.ToString();
```

HttpContext.Response.ContentType on its own also translates to:

C#

```
httpContext.Response.ContentType = "text/html";
```

HttpContext.Response.Output translates to:

```
C#

string responseContent = GetResponseContent();
await httpContext.Response.WriteAsync(responseContent);
```

HttpContext.Response.TransmitFile

Serving up a file is discussed in Request Features in ASP.NET Core.

HttpContext.Response.Headers

Sending response headers is complicated by the fact that if you set them after anything has been written to the response body, they will not be sent.

The solution is to set a callback method that will be called right before writing to the response starts. This is best done at the start of the `Invoke` method in your middleware. It's this callback method that sets your response headers.

The following code sets a callback method called `SetHeaders`:

```
C#

public async Task Invoke(HttpContext httpContext)
{
    // ...
    httpContext.Response.OnStarting(SetHeaders, state: httpContext);
```

The `SetHeaders` callback method would look like this:

```
C#

// using Microsoft.AspNet.Http.Headers;
// using Microsoft.Net.Http.Headers;

private Task SetHeaders(object context)
{
    var httpContext = (HttpContext)context;

    // Set header with single value
    httpContext.Response.Headers["ResponseHeaderName"] = "headerValue";

    // Set header with multiple values
    string[] responseHeaderValues = new string[] { "headerValue1",
```

```
"headerValue1" };
    httpContext.Response.Headers["ResponseHeaderName"] =
responseHeaderValues;

    // Translating ASP.NET 4's HttpContext.Response.RedirectLocation
    httpContext.Response.Headers[HeaderNames.Location] =
"http://www.example.com";
    // Or
    httpContext.Response.Redirect("http://www.example.com");

    // GetTypedHeaders extension method provides strongly typed access to
many headers
    var responseHeaders = httpContext.Response.GetTypedHeaders();

    // Translating ASP.NET 4's HttpContext.Response.CacheControl
    responseHeaders.CacheControl = new CacheControlHeaderValue
    {
        MaxAge = new System.TimeSpan(365, 0, 0, 0)
        // Many more properties available
    };

    // If you use .NET Framework 4.6+, Task.CompletedTask will be a bit
faster
    return Task.FromResult(0);
}
```

HttpContext.Response.Cookies

Cookies travel to the browser in a *Set-Cookie* response header. As a result, sending cookies requires the same callback as used for sending response headers:

C#

```
public async Task Invoke(HttpContext httpContext)
{
    // ...
    httpContext.Response.OnStarting(SetCookies, state: httpContext);
    httpContext.Response.OnStarting(SetHeaders, state: httpContext);
```

The `SetCookies` callback method would look like the following:

C#

```
private Task SetCookies(object context)
{
    var httpContext = (HttpContext)context;

    IResponseCookies responseCookies = httpContext.Response.Cookies;

    responseCookies.Append("cookie1name", "cookie1value");
    responseCookies.Append("cookie2name", "cookie2value",
```

```
        new CookieOptions { Expires = System.DateTime.Now.AddDays(5),
HttpOnly = true });

    // If you use .NET Framework 4.6+, Task.CompletedTask will be a bit
faster
    return Task.FromResult(0);
}
```
